8. In recurrent pancreatitis, family history is important, since hereditary pancreatitis has an inherent propensity to lead onto carcinoma of the pancreas.
9. Early enteral feeding is of great importance; children should not be kept fasting for prolonged periods and nasogastric aspiration should be avoided.

Chapter 35.15

Practical Approach to Malabsorption

VS Sankaranarayanan

Maldigestion often occurs due to defect in the luminal phase of digestion of ingested food (defective hydrolysis of nutrients) secondary to insufficiency of exocrine pancreatic enzymes such as pancreatic amylase, lipase and bile salts, pancreatic trypsin and chymotrypsin, and small intestinal bacterial overgrowth (SIBO) due to surgical causes resulting in failure of mixed micelle formation for fat digestion.

Malabsorption occurs most often due to defective mucosal absorption like celiac disease, cow's milk protein allergy (CMPA), tropical sprue, etc. It is characterized by relatively less fat in stool (absence of grease/oil) and presence of abdominal bloating/flatulence, anemia and hypoalbuminemia. A good history and physical examination of the patient will give clue to the etiology and clinical diagnosis of malabsorption.

HISTORY

Consanguinity Abetalipoproteinemia, cystic fibrosis, congenital intestinal defects.

Age of onset Diseases causing malabsorption can present insidiously at different age groups (e.g., congenital disorders like cystic fibrosis, primary lactase deficiency at birth, acrodermatitis enteropathica and celiac disease by weaning age). Family history of similar illness has a role in cystic fibrosis, Crohn's disease, abetalipoproteinemia and food allergy.

Stool history Duration of chronic diarrhea, character, frequency, volume, consistency of stools, presence or absence of blood, mucus [inflammatory bowel disease (IBD)], oily or greasy, soft, bulky, pale and rancid stools (exocrine pancreatic insufficiency, biliary disease) or explosive with sore bottom (lactose malabsorption); diarrhea after gluten containing diet (celiac disease) or cow's milk (CMPA); associated symptoms like abdominal pain (Crohn's disease, pancreatic or biliary disease) failure to thrive and (fat, protein or carbohydrate malabsorption) nutrient deficiency like pallor and anemia (iron deficiency) glossitis and cheilitis (vitamin B complex especially, folic and B₁₂ deficiency) angular stomatitis and cheilitis (riboflavin deficiency), edema (protein deficiency), stunting of growth with bony abnormalities (rickets), bleeding gums (vitamin C deficiency) epistaxis and petechiae (vitamin K deficiency) perioral and perianogenital ulcerations with alopecia (zinc deficiency—acrodermatitis enteropathica).

Abdominal surgery will suggest small bowel bacterial overgrowth or short gut syndrome or adhesive obstruction.

Immune deficiency History of contact with human immunodeficiency virus (HIV), or history of organ transplantation, chronic recurrent infections (tuberculosis, congenital immune deficiency) and drugs causing malabsorption (anticonvulsants).

Dietetic history Early introduction of cow's milk in CMPA, cereals in weaning food—wheat, rye, barley, oats in celiac disease. Appetite is often increased in exocrine pancreatic insufficiency and decreased in celiac disease.

PHYSICAL EXAMINATION

Physical examination includes a systematic general examination and systemic examination with assessment and recording of growth of the child. Any drop in growth centiles clinically will manifest as malnutrition and growth stunting (an indicator of chronic malabsorption). The attending physician is expected to look for hydration status; nutritional status [grade of protein energy malnutrition (PEM), stunting, vitamin, trace elements and mineral deficiencies]; presence/absence of peripheral edema (protein deficiency); constitutional symptoms such as fever (infection or inflammation); extra gut manifestations in eyes like Bitot spots; skin (infection, dermatosis, rash, edema, surgical scar, joint swelling in autoimmune diseases, and oral cavity (stomatoglossitis); perianal area for excoriation, fistulae, fissures (Crohn's disease); persistent thrush in HIV; and abdominal examination for distension, scar, masses, organomegaly and ascites.

In summary, the physician at this stage should approach any child with malabsorption with high degree of clinical suspicion and try to answer the following questions: whether the patient is having chronic diarrhea of small bowel or large bowel; if small bowel, whether secretory or osmotic or mixed; if large bowel, whether it is inflammatory or infective or infiltrative; whether the child has maldigestion or malabsorption. What are the consequences of the disorder and how serious? And also determine the attitude of the caretaker and affordability for battery of laboratory diagnostic investigations to assess the specific cause. Only then a long-term management, counseling, and follow-up can be planned in an effective manner.

INVESTIGATIONS

Confirmation of malabsorption is based on the relevant laboratory tests (**Table 1**). Various laboratory investigations intended for chronic diarrhea hold good for malabsorption with chronic diarrhea also. These will be discussed in detail in the next section on diarrheal disorders.

The cause for malabsorption can be determined by the following tests: endoscopy (scalloping for atopy, white plaques in lymphagiectasia, eosinophilic abscesses, duplication cysts, aphthoid ulcers in Crohn's disease); small intestinal biopsy for villi/crypt study, parasites, eosinophil count (> 15/HPF); colonoscopy and biopsy (for tuberculosis, IBD, CMPA) and CT scan. The specific diagnostic tests for etiology of malabsorption include celiac serology [endomysial antibody, immunoglobulin A (IgA) tissue transglutaminase]; sweat chloride test and mutation analysis (cystic fibrosis); cow's milk specific IgE antibody (IgE specific CMPA), among others. Upper gastrointestinal endoscopy and duodenal biopsy are the mainstay of confirmatory diagnosis of malabsorption (**Table 2**).

If pancreatic disease with secretory insufficiency is suspected, consider tests for secretory function, e.g., elastase or chymotrypsin in stool; and CT/MRI of pancreatic duct-systems or ERCP. The gold standard still is the secretin-pancreozymin test; this test is

Table 1 Clinical and laboratory findings in malabsorption

<i>Signs and symptoms</i>	<i>Laboratory findings</i>	<i>Malabsorbed nutrient</i>
Diarrhea	Stool weight ↑, serum potassium ↓	Water, electrolytes
Steatorrhea	Fecal fat ↑, serum cholesterol ↓	Dietary lipids, bile acids
Weight loss	Fecal fat ↑, fecal chymotrypsin or elastase ↓, xylose test ↓	Fat, carbohydrates, protein
Anemia	Serum iron ↓, hypochromic, microcytic, RDW ↑	Iron
Pernicious anemia, glossitis, Knuckle pigmentation	Macrocytic blood picture, megaloblastic marrow, Schilling's test abnormal	Vitamin B ₁₂ , folic acid
Pain in limbs and bones, pathologic bone fractures, Chvostek sign	Serum calcium ↓, alkaline phosphatase ↑	Potassium, magnesium, calcium, vitamin D ₃ , protein, amino acids
Signs of bleeding, easy bruising, petechial hemorrhage	Prothrombin time ↑	Vitamin K, vitamin C
Edema	Total protein ↓, serum albumin ↓, fecal α1-antitrypsin clearance ↑	Protein
Abdominal distension, gas	Abdominal X-ray, sonography, glucose H ₂ -breath test	Carbohydrates
Lactose intolerance (explosive diarrhea)	Lactose H ₂ -breath test ↑ intestinal mucosal lactase ↓	Lactose
Peripheral neuropathy		Vitamins B ₁ , B ₆ , B ₁₂
Hyperkeratosis, parakeratosis, acrodermatitis	Retinol, zinc serum levels ↓	Vitamin A, zinc
Night blindness	Serum retinol ↓	Vitamin A
Malabsorption-clinical	Lymphocytopenia	Lymphangiectasia
Younger age, chronic diarrhea, Abetalipoproteinemia	Acanthocytes in blood smear	Calorie deficiency, deficiency of essential nutrients
Suspected Crohn's disease, tuberculosis	ESR ↑	Essential nutrients, calorie deficiency

Abbreviations: RDW, red cell distribution width; ESR, erythrocyte sedimentation rate.

Table 2 Diagnostic significance of small bowel mucosal biopsy for malabsorption

<i>Always positive</i>	<i>Diagnostic and patchy</i>	<i>Diagnostic but nonspecific (abnormal villus atrophy)</i>
<ul style="list-style-type: none"> Abetalipoproteinemia (intraepithelial fat) Whipple disease (acid fast organism) Agammaglobulinemia (absent plasma cells in LP) 	<ul style="list-style-type: none"> Lymphangiectasia (dilated lacteals in LP) Giardiasis Strongyloidiasis Lymphoma Eosinophilic gastroenteritis (> 15 eosinophils/hpf) Crohn's disease (noncaseating granuloma), etc. 	<ul style="list-style-type: none"> Celiac disease Tropical sprue Cow's milk protein allergy Severe PEM Prolonged iron and folate deficiency

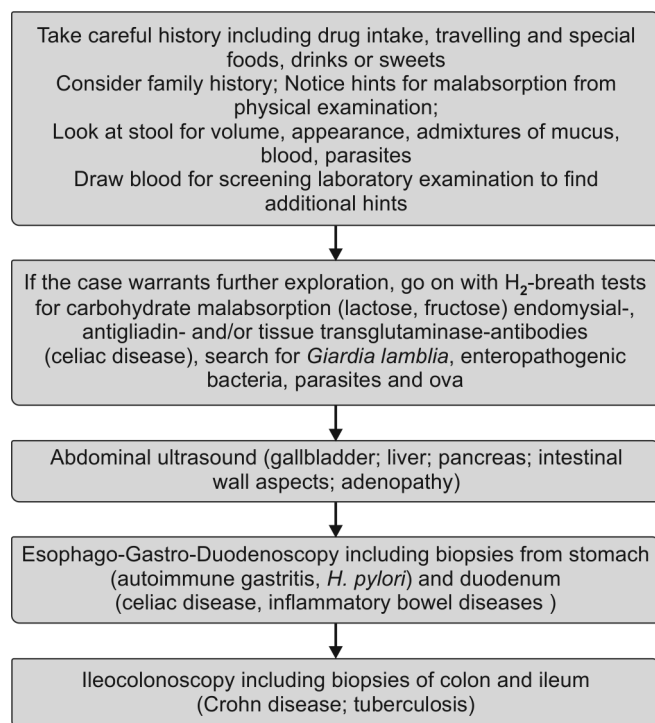

Abbreviations: LP, lamina propria; PEM, protein energy malnutrition.

not really necessary for routine examination but may be helpful in individual cases; likewise the quantitative determination of 72 hour fecal fat excretion is cumbersome and not done now. When in doubt a therapeutic trial with pancreatic enzyme supplementation may be considered. If small bowel disease is still within the differential diagnostic scope, consider: Schilling-test (Vitamin B₁₂ malabsorption), Glucose-H₂ breath test (bacterial overgrowth), α1-antitrypsin clearance (protein losing enteropathy), small bowel X-ray (fistulae, diverticula, blind loops, short bowel, etc.), and angiography of celiac and mesenteric arteries (ischemic bowel damage).

Flow chart 1 presents an algorithm for diagnosis of malabsorption syndrome.

IN A NUTSHELL

1. Maldigestion and malabsorption describe insufficient nutrient uptake and utilization by the gastrointestinal tract.
2. The etiology is varied with wide spectrum of clinical signs, symptoms and biochemical findings including vitamin and nutrient deficiency syndromes.
3. Chronic diarrhea and failure to thrive are the most common presenting symptom, yet there are several other presentations.
4. It is emphasized that the attending physician should focus on the underlying disease entity to provide appropriate counseling and treatment after making the diagnosis of a malabsorption syndrome.

Chapter 35.16

Specific Malabsorption Syndromes

Srinivas S

Malabsorption syndromes refer to disorders in the intestinal processes of digestion and/or transport one or more nutrients—*carbohydrate, fat, protein or micronutrients* across the intestinal mucosa into the systemic circulation. This could be either due to a congenital disorder or a secondarily acquired disorder. **Table 1** enlists the common causes of malabsorption syndrome in India. In this chapter we will discuss some causes of malabsorption which are not discussed elsewhere in this book. Readers are also advised to refer to the chapters on chronic diarrhea, celiac disease, inflammatory bowel diseases (IBD), cystic fibrosis and alpha-1-antitrypsin deficiency.

SHORT BOWEL SYNDROME

Most patients with short bowel syndrome (SBS) have undergone bowel resection for one of the following:

- A congenital anomaly such as an omphalocele, gastroschisis, or intestinal atresia
- Necrotizing enterocolitis associated with prematurity
- Intestinal ischemia from malrotation and volvulus
- Crohn's disease (infrequent with current treatment)
- Total colonic aganglionosis.

Pathogenesis In general, virtually all digestion and absorption are completed within the first 100–150 cm of jejunum in a healthy individual. In the absence of an intact colon, the minimum length of healthy bowel necessary to avoid parenteral nutrition is approximately 100 cm. Patients who have less than 100 cm of jejunum exhibit significant malabsorption.

Table 1 Etiology of malabsorption in India

Pathology	Specific diseases
• Short gut syndrome	<i>Due to surgical intestinal resection for bowel gangrene as in</i> <ul style="list-style-type: none"> • Neonatal necrotizing enterocolitis • Intussusception • Malrotation and volvulus
• Damage to mucosal villi	<ul style="list-style-type: none"> • Celiac disease • Rotaviral diarrhea • Food protein enterocolitis, e.g., CMPA • Persistent diarrhea • Crohn's disease • Tuberculosis • Immunodeficiency state—with recurrent infections including giardiasis/strongyloidiasis • Radiation/chemotherapy/GVHD
• Pancreatic insufficiency	<ul style="list-style-type: none"> • Chronic pancreatitis • Cystic fibrosis
• Reduced intraduodenal bile causing fat malabsorption	<ul style="list-style-type: none"> • Cholestatic liver disorders

Abbreviations: CMPA, Cows' milk protein allergy; GVHD, graft-versus-host disease.

Clinical features Children with SBS may present with various medical issues, depending on the extent of their bowel resection, presence/absence of ileocecal valve and the level of medical complexity like total parenteral nutrition (TPN) dependency. These may include failure to thrive (FTT), nutritional deficiencies, malabsorptive diarrhea, recurrent dehydration, need for specialized enteral formula, catheter-related infections or sepsis.

Malabsorption of various nutrients also is likely to occur depending upon the area of bowel resected. For example, extensive jejunal resection leads to carbohydrate malabsorption. The undigested foods produce an osmotic diarrhea typical of most patients with SBS. The proximal small bowel is also important in the absorption of proteins, fat, and certain micronutrients, including copper. Semi-elemental or pre-digested formula is hence better tolerated than normal formula in short gut syndrome. Extensive terminal ileal resection would result in vitamin B₁₂ deficiency and bile salt malabsorption causing cholestatic diarrhea.

Management The management of SBS requires an aggressive multidisciplinary approach. Since loss of intestinal mucosal absorptive surface remains the major hurdle, the main issues during the initial months following resection would be loss of fluid and electrolytes causing dyselectrolytemia and dehydration. The institution of early and aggressive enteral therapy is the most important stimulus for intestinal adaptation and the eventual discontinuation of parenteral therapy. Aggressive resuscitation with fluids, parenteral nutrition, or both is often required in the 1st week after intestinal resection. The hypersecretion of HCl noted within the first 12 months postresection is usually treated with H₂ blockers or proton pump inhibitors. Cholestyramine has been used to bind bile salts in patients with cholestatic diarrhea.

Prognosis Over a period time (months to years) intestinal adaptation occurs and diarrhea is no longer a problem in children with SBS; though some children with extensive bowel resections remain partially/completely TPN dependent for life. The ileum has greater adaptive function as far as improving its absorptive function in the presence of SBS. Small-bowel transplantation is used only if absolutely necessary in patients with associated severe advanced liver disease and those with major vascular access problems.

LACTOSE INTOLERANCE

Lactose intolerance is a syndrome characterized by impaired digestion of a disaccharide-lactose. This could be a congenital (primary lactose intolerance) or acquired (secondary lactose intolerance). The congenital variety is extremely rare.

Primary lactose intolerance due to congenital lactase deficiency is an extremely rare condition which presents with diarrhea since birth. The diarrhea typically is profuse while breastfed and stops while the child is put on a nonlactose containing formula. This is a permanent deficiency of lactase enzyme and does not improve with time.

In contrast secondary lactose intolerance is much more common and is often transient. Virtually any condition which causes intestinal mucosal damage can cause secondary lactose intolerance. This is because the *lactase* is present in the tips of the intestinal villi and is often the first among the intestinal disaccharidases to be lost in the event of mucosal injury.

Etiology The most common cause of transient secondary lactose intolerance is a viral gastroenteritis—like rotaviral diarrhea. Other causes include celiac disease, CMPA, Crohn's disease, radiation enteritis, GVHD, etc. Secondary lactase deficiency due to intestinal mucosal injury can appear at any age. However, children below 2 years are more susceptible because of many factors, including a high sensitivity of the gut to infectious agents, low reserve because of the small intestinal surface area, and high reliance on milk-based products for nutrition. Adult-onset lactase deficiency is more of a

genetically determined condition. Asians are known to be more prone for lactase deficiency than Caucasians.

Clinical features Symptoms are more severe in infants and younger children because of many factors, including a high sensitivity of the gut to infectious agents, low reserve because of the small intestinal surface area, and high reliance on milk-based products for nutrition. These include abdominal distension, borborygmi and a profuse watery diarrhea following ingestion of milk often causing perianal excoriation in infants and young children. Stool pH less than 5.5 along with the presence of stool reducing substance greater than or equal to 2+ (yellow) aids in the diagnosis. It is important to test the liquid component of stool for reducing substance. The clinical features in older children are less severe and restricted to flatulence, abdominal discomfort/crampy pain and the occasional diarrhea. A lactose hydrogen breath test is used for the diagnosis of lactose intolerance in older children.

Management Lactose intolerance is easily managed by reducing or completely avoiding lactose containing foods. Alternative non-lactose milk formula like soymilk is well tolerated. The secondary lactose intolerance improves within a few weeks once the primary disease causing intestinal damage is treated adequately and the intestinal villi recover.

PANCREATIC EXOCRINE INSUFFICIENCY

This is infrequently seen in chronic pancreatitis and invariably seen in cystic fibrosis in children. The classical clinical manifestation is steatorrhea described as the passage of large volume, foul smelling and greasy stools. This is seldom confused with chronic diarrhea and almost never needs intravenous fluid rehydration. The classical history is that of a hungry child who eats a lot and still does not grow well due to passage of large volume stools—occasionally oily. Traditionally the confirmation of pancreatic exocrine insufficiency requires a 72 hours fecal fat estimation. This is very cumbersome and is not routinely used except in select laboratories in the world. Early pancreatic exocrine insufficiency may manifest only as failure to thrive and estimating fecal elastase is useful method to confirm the same. In general as the conventional Indian diet tends to be low in fat when compared to the Western diet, clinically apparent steatorrhea does not manifest until later.

Management of pancreatic steatorrhea includes supplementing the patient's diet with oral pancreatic lipase enzyme as capsules. Pancreatic lipase capsules have to be given along with every meal with higher doses being needed for fat rich meals. Doses as high as 2,500 lipase units/kg/day are used in infants with cystic fibrosis without any complications.

MALABSORPTION IN CHOLESTATIC DISORDERS

The classical example of this syndrome is a child with neonatal cholestasis syndrome presenting with an intracranial bleed secondary to late hemorrhagic disease of newborn, i.e., secondary to vitamin K malabsorption.

The fat soluble vitamins A, D, E and K depend on bile acids for their absorption. Hence, the lack of intraduodenal bile in neonatal cholestatic disorders predisposes to fat soluble vitamin deficiency. Malabsorption of fat soluble vitamins increases with severity of cholestasis. Infants with prolonged cholestasis of infancy like Watson Alagille syndrome or progressive familial intrahepatic cholestasis are likely to develop Bitot's spots unless given regular parenteral vitamin A supplements. Children with cholestatic disorders should be given vitamin K, A and D injections regularly.

Dietary fat is broken down by pancreatic lipase into predominantly long-chain fatty acids and they are dependent on bile acids for micelle formation and absorption. In cholestasis, due to the lack of intraduodenal bile acids, fat is malabsorbed and this

results in the passage of greasy/oily stools (steatorrhea). Unlike in pancreatic steatorrhea, exocrine pancreatic lipase enzyme supplementation will not improve the malabsorption. Substitution of medium-chain triglycerides (MCT) in the diet in place of long-chain fatty acids improves steatorrhea and weight gain as MCT does not require bile acids/micelle formation for its absorption. This forms the basis for prescribing a formula rich in median chain triglycerides for young infants with cholestasis. Coconut oil is a naturally rich source of MCT and should be used in their diet.

PROTEIN LOSING ENTEROPATHY: INTESTINAL LYMPHANGIECTASIA

Protein losing enteropathy is a general term used to describe all conditions that cause loss of proteins through the gastrointestinal tract. For practical purposes the diseases causing protein losing enteropathy can be grouped into the following categories:

- Bad mucosal disease with ulcerations and erosions causing loss of protein, e.g., IBD, intestinal tuberculosis, GVHD, CMPA or
- Conditions causing lymphatic block, e.g., primary intestinal lymphangiectasia (PIL), constrictive pericarditis, post-Fontan procedure.

Primary intestinal lymphangiectasia This is a unique condition manifesting as a protein losing enteropathy where the lymphatic channels in the intestines are congenitally and abnormally dilated (ectatic).

Pathophysiology These abnormally dilated lymph channels have some form of functional block to lymph flow. A fat rich meal is often the best stimulus for lymph flow as this causes the ectatic channels to swell up and burst open thus discharging/leaking lymph into the intestines. As lymph is a rich source of proteins and immunoglobulins, this results in protein losing enteropathy.

Clinical manifestations Patients with primary intestinal lymphangiectasia usually present in childhood with edema and diarrhea (malabsorption and steatorrhea). Edema may be unilateral or bilateral, depending on the site of the lesion. Edema in primary intestinal lymphangiectasia is usually bilateral, while the secondary type often manifests as unilateral edema and is caused by various neoplastic, infiltrative, and inflammatory lesions affecting one side of the body. Frequently, lymphocytopenia and hypogammaglobulinemia are present, though the absence of these does not exclude intestinal lymphangiectasia.

Upper gastrointestinal (GI) endoscopy may occasionally reveal a starry sky pattern of the duodenal mucosa due to dilated intestinal lacteals and biopsies may reveal dilated intestinal lacteals consistent with the diagnosis of PIL.

Complications Despite hypogammaglobulinemia, opportunistic infections rarely occur, although lymphocytopenia predisposes patients to abnormal cellular immunities, including homograft rejection and cutaneous anergy. In patients with early onset PIL, growth retardation is common. The risk of lymphoma is increased in PIL. Fibrotic entrapment of the small bowel is reported in patients with congenital intestinal lymphangiectasia. Oral manifestations include gingivitis caused by poor lymphocytic function and enamel defects caused by poor calcium absorption.

Management Dietary modifications include a low-fat diet and substitution of long-chain fatty acids with MCT. MCTs do not stimulate lymph flow and are directly absorbed into the circulation without micelle formation. This strategy thus reduces the lymph leak/protein loss into the intestines.

Clinical course and response are highly variable depending upon the extent and severity of intestinal lymphangiectasia and whether it is part of a syndrome involving abnormal lymphatics throughout the body; e.g., Hennekam syndrome carries a poor

prognosis. Medications are not usually useful in intestinal lymphangiectasia. Treatment of secondary causes of lymphangiectasia targets the underlying disease. Octreotide is found to be effective in refractory cases.

IN A NUTSHELL

1. Calcium, vitamin D, iron and folic acid are absorbed in proximal small intestine while bile acids and vitamin B₁₂ are absorbed in terminal ileum.
2. Virtually any disease process causing intestinal mucosal villi damage can cause a secondary lactose intolerance which improves with intestinal villi recovery.
3. Patients with a short bowel and an intact ileum and colon rarely need long-term enteral or parenteral nutrition.
4. Celiac disease needs to be treated with lifelong adherence to gluten-free diet.
5. Pancreatic steatorrhea can be effectively treated with exocrine pancreatic enzyme supplementation.
6. Children with neonatal cholestasis are prone for fat soluble vitamin deficiency—which if not treated in time can result in intracranial bleed/night blindness.
7. Intestinal lymphangiectasia is a congenital cause of protein losing enteropathy which is managed with diet rich in MCT.

Chapter 35.17

Inflammatory Bowel Disease

Rishi Bolia, Anshu Srivastava

The term *inflammatory bowel disease (IBD)* denotes a group of disorders characterized by chronic intestinal inflammation. It includes Crohn's disease (CD), ulcerative colitis (UC) and inflammatory bowel disease unclassified (IBDU).

Ulcerative colitis, the first to be described in 1859, is localized to the colon and spares the rest of the gastrointestinal (GI) tract. The disease begins in the rectum and extends proximally for a variable distance and is limited to the colonic mucosa. CD, which was first described as *regional ileitis* in 1932, can involve any region of the alimentary tract from the mouth to the anus and leads to transmural inflammation. Although there is an overlap between the two disorders, they differ significantly in their clinical course, management and outcome. Around 10% of patients with isolated colonic involvement have some features of both UC and CD, and are labeled as IBDU at diagnosis. These cases may show typical UC or CD features on follow-up. The term *indeterminate colitis* is used when the diagnosis of CD or UC cannot be made even on the histology of a colectomy sample.

EPIDEMIOLOGY

Inflammatory bowel disease has been most prevalent in North America, Northern Europe and the United Kingdom. The prevalence varies not only by the geographic location, but also by race and ethnicity. Pediatric IBD accounts for about 20–25% of all cases of IBD in the west and 7% of all cases in the available data from India. Overall, CD is more common than UC with a slightly higher prevalence in boys than girls. Most cases present between 10 years and 14 years of age. About 10% of all pediatric IBD occurs in children less than 6 years of age and 1% in infants. Children with UC have a more extensive colonic involvement at presentation and a higher propensity for extension of the disease compared to adults. In CD, children have more colonic and perianal disease and less of isolated small bowel involvement in comparison to adults.

The risk of IBD in family members of an affected person is around 7–30% and a child in whom both parents have IBD has a 33% chance of developing the disease. Although it is more common to have the same type (UC/CD) of IBD in family members, both CD and UC have been reported in the same family. A concordance rate of approximately 50% has been observed amongst monozygotic twins for all types of IBD.

ETIOPATHOGENESIS AND GENETICS

The etiopathogenesis of IBD is multifactorial. There is a complex interplay of genetic factors, environmental triggers and gut microflora which initiates an abnormal mucosal immune response and leads to intestinal inflammation. When the normal body mechanisms that keep *physiologic* inflammation in check fail, then pathologic inflammation ensues. But whether this represents an abnormal response to normal enteric antigens or a normal response to an as-yet-unidentified microbe is not known. Inflammatory mediators (cytokines, arachidonic acid metabolites, reactive oxygen metabolites and growth factors) are involved, with overproduction of proinflammatory cytokines and underproduction of anti-inflammatory or regulatory cytokines, leading to destruction of the tissue and remodeling with fibrosis.

Ulcerative colitis A number of environmental factors have been postulated to be important and may influence the development of

UC. Appendectomy, a diet low in refined sugars, breastfeeding and smoking are considered protective. Psychological stress and nonsteroidal anti-inflammatory drugs (NSAIDs) are potential triggers. The intestinal microbiome of IBD patients (both UC and CD) differs from that of healthy controls. Genome wide association study has shown that IBD is a complex disorder, with some shared and many unique predisposing genes between CD and UC. About 47 susceptibility loci/genes for UC alone and another 28 for both UC and CD are known. Linkage studies have shown that there are susceptibility genes for UC on chromosome 1, 2, 3, 5, 6, 7, 10, 12 and 17. The *IBD2* locus on chromosome 12 is the most common.

Crohn's disease A number of environmental factors such as gut microflora, *westernized* diet [rich in refined sugars and n-6 polyunsaturated fatty acids (PUFAs)], lack of breastfeeding and presence of infectious agents such as *measles* and *Mycobacterium paratuberculosis* have been implicated. Smoking and oral contraceptives appears to predispose to CD. Genome wide association study has shown 71 susceptibility loci/genes for CD. Mutations in *NOD2/CARD15* gene, located in pericentromeric region of chromosome 16, significantly increase the risk of CD and this is particularly associated with ileal location, younger age of disease onset and penetrating disease phenotype. Recently two new pathways have been implicated, which includes T-cell regulation by the IL-23 pathway and the process of autophagy which controls intracellular bacteria by the *ATG16L1* and *IRGM* gene. Mutations in IL-10 and IL-10R pathway have also been identified, especially in children with infantile onset of the disease. This subgroup of infantile IBD is characterized by severe disease, lack of response to the standard IBD therapy and poor outcome.

In CD, the main abnormality is in defective recognition and processing of intracellular bacteria whereas in UC it is of intestinal barrier integrity and function. However, it is important to remember that genetic factors provide no direct bearing on therapy.

CLINICAL PRESENTATION

Ulcerative colitis Passage of loose stools with blood and mucus accompanied by tenesmus and urgency is the most common presentation in children. In majority of cases, symptoms have a slow and insidious onset. Systemic symptoms such as anorexia, weight loss, fever and abdominal pain are present in those with extensive disease. The abdominal pain is crampy in nature and occurs before passage of stools. Fecal incontinence may be seen in patients with severe proctitis. A small percentage of children have an initial fulminant presentation with greater than five bloody stools/day, fever, tachycardia, anemia and abdominal tenderness and known as acute severe colitis. These children are at risk of developing the complication of toxic megacolon (presence of dilated colonic loop greater than 5.5 cm on abdominal X-ray) and perforation.

Crohn's disease The various sites of disease (small bowel, colon and gastroduodenal), discontinuous lesions and progression to involve other bowel segments with time lead to varied clinical manifestations in CD. This is also responsible for the delay in diagnosis of these subjects. Diarrhea, abdominal pain and weight loss are the classical triad of CD, but only 25% of affected children have this typical presentation. Abdominal pain is the most common presenting symptom (72%), followed by diarrhea (56%), weight loss (58%), lethargy (25%), anorexia (27%) and poor growth. Patients with predominant colonic disease present as diarrhea with blood and mucus, while those with small bowel involvement manifest as abdominal pain, watery diarrhea or with features of subacute intestinal obstruction. Some children may present with perianal disease in the form of fissures, fistulas and abscesses (**Fig. 1**). Growth failure in CD may precede the abdominal complaints by few months and is characterized by delayed skeletal maturation,

Figure 1 Perianal fistula (marked with black arrow) and fissure (short white arrow) along with rash in a child with Crohn's disease

reduced lean body mass and delayed puberty. Early satiety, nausea, vomiting and epigastric pain may be seen in patients with gastroduodenal CD. Esophageal involvement is very uncommon and leads to dysphagia and odynophagia.

Extraintestinal Manifestations

Extraintestinal manifestations (EIM) of IBD are present at diagnosis in 6–28% cases. Musculoskeletal (arthralgia, arthritis, and sacroiliitis) complaints are the most common EIM seen in 20–25% cases. Other EIM include aphthous stomatitis, pyoderma gangrenosum, erythema nodosum (EN), uveitis, scleritis, primary sclerosing cholangitis (PSC), fatty liver, autoimmune hepatitis and autoimmune hemolytic anemia. They may be present before, during or after the development of intestinal symptoms. EIM are more frequent in subjects with moderate to severe disease as compared to those with mild disease. Amongst the various EIM, PSC is more common in UC while ankylosing spondylitis (AS) and EN are more often seen in CD than UC cases.

Some EIMs, such as peripheral arthritis and EN correlate with disease activity whereas PSC, AS, and sacroiliitis do not. Arthritis in IBD is of two types: (1) peripheral arthritis involving primarily large joints, which may be further subclassified as pauciarticular (< five joints) or polyarticular (\geq five joints), and (2) axial arthropathy which includes AS and sacroiliitis.

Examination Complete physical examination with weight and height monitoring at each visit to detect growth faltering is essential in all children with IBD. Anemia, clubbing and pedal edema due to hypoalbuminemia may be present in patients with moderate to severe disease. Abdominal distension, loss of bowel sounds and rebound tenderness suggest presence of toxic megacolon. Patients with ileocolonic CD may have a mass palpable in right iliac fossa. Perianal examination may show presence of fleshy anal tags, deep fissures, abscesses and fistulae in children with CD. Presence of hepatosplenomegaly with or without jaundice points towards liver disease like sclerosing cholangitis.

DIAGNOSIS

As a result of its varied presentation, diagnosis of IBD is often delayed by 5–15 months, with UC being diagnosed earlier than CD due to the alarming symptom of blood in the stools. The IBD working group of the European Society of Pediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN), published *The Porto*

Criteria for the diagnosis of childhood IBD. These criteria require that diagnosis of IBD should be based on a combination of history, physical examination, laboratory evaluation, esophagogastroduodenoscopy (EGD) and ileocolonoscopy with histology and imaging of the small bowel.

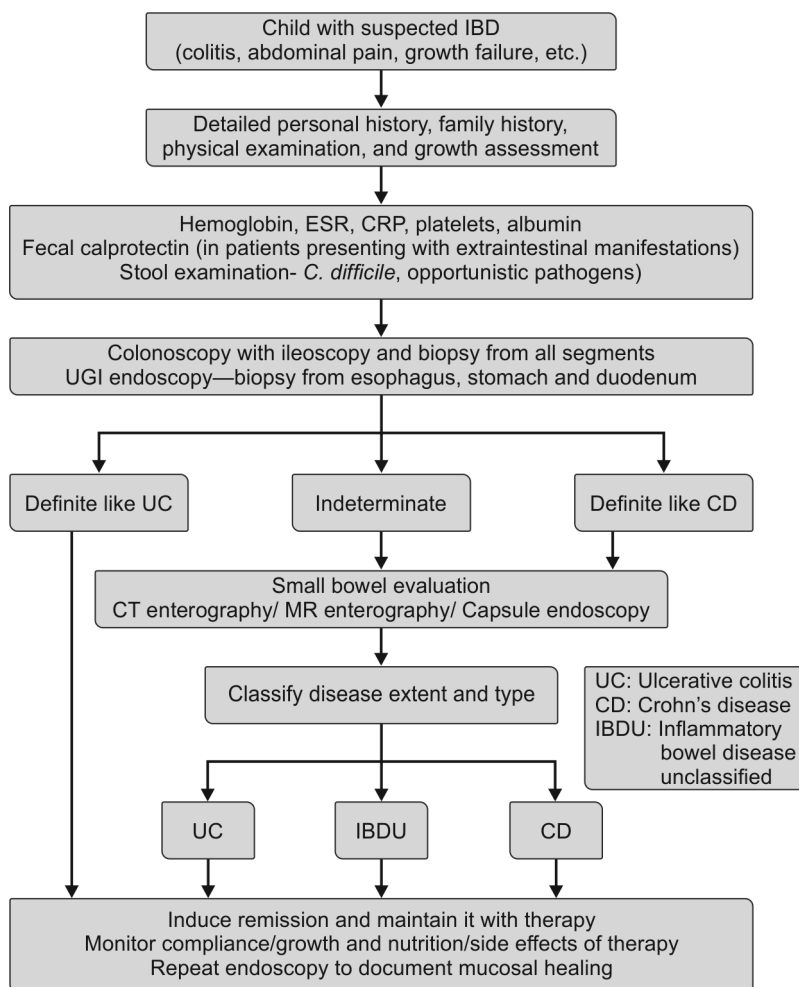

The stepwise evaluation of a child with suspected IBD is shown in **Flow chart 1**. Initial blood tests should include complete blood count, inflammatory markers such as erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP), serum albumin, transaminases and gamma-glutamyl transpeptidase (GGT). In a patient with active disease, there is anemia, hypoalbuminemia, thrombocytosis with raised ESR and CRP. However, normal values may be seen in patients with mild or inactive disease and thus do not exclude IBD.

Calprotectin is a protein, accounting for 30–40% of a neutrophil's cytosol. For the detection of intestinal inflammation fecal calprotectin (FC) is superior to any blood test. However, it is a nonspecific marker of inflammation and elevated FC levels cannot distinguish between the different causes of inflammation (e.g., IBD vs infection) or location of the disease (small vs large bowel). It is useful to discriminate between abdominal pain of functional origin and that due to inflammatory lesion of CD. Extraintestinal disease such as uveitis and PSC should be screened for by an ophthalmic examination and liver function tests (transaminases and GGT).

Various serological tests like antisaccharomyces cerevisiae antibody (ASCA) and perinuclear-antineutrophil antibody (p-ANCA) have been used for diagnosis and subtyping of IBD. ASCA is found more often in CD (50–70%) than in UC (10–15%) and p-ANCA is more common in UC (60–70%) than in CD (20–25%). However, they have a poor sensitivity and specificity and thus not very useful in clinical practice. Presence of ASCA also does not help in differentiating CD from colonic tuberculosis (TB).

Ileocolonoscopy and EGD should be done as the initial work-up for all children with suspected IBD. It is important that multiple biopsies are obtained from all areas of the visualized GI tract, even when macroscopic lesions are absent. The findings on endoscopy should be well documented. The typical macroscopic features of UC include erythema, granularity, friability, and superficial small ulcers which start from the rectum and extend proximally to various levels (**Fig. 2**). As per the Paris Classification, UC is labeled as proctitis (rectum only), left-sided (distal to splenic flexure), extensive (distal to hepatic flexure) and pancolitis, depending upon the extent of colonic involvement. Pancolitis is the most common type in children, seen in 43–90% cases of UC. At times, the distal 5–10 cm of the terminal ileum may show erythema and/or edema without any ulceration and stricture in patients with pancolitis and this is known as *backwash ileitis*. Colonic histology shows cryptitis and crypt abscess along with signs of chronicity, i.e., alteration of the crypt architecture (crypt loss, branching), basal plasmacytosis and paneth cell metaplasia (**Fig. 3**).

Crohn's disease is characterized by the presence of noncontiguous aphthous or linear deep ulcers involving single or multiple segments of the colon (**Fig. 4**). The terminal ileum may show aphthous or linear ulcers with or without luminal narrowing. Histologically the disease is characterized by chronic focal inflammation, signs of activity (crypt abscess/cryptitis) and noncaseating granulomas (**Fig. 5**). The Paris classification is used for defining the disease extent and nature. It gives an account of the age of onset, disease location (ileal alone, colonic, ileocolonic, isolated upper GI), behavior (stricturing/penetrating/inflammatory) and effect on growth at a glance. Ileocolonic disease is most commonly seen in children with CD. The differentiating features between CD and UC have been summed up in **Table 1**. In some cases, despite all efforts, it may not be possible to confidently diagnose patients as UC or CD so they are best labeled as IBDU.

Flow chart 1 Algorithm for diagnosis of pediatric inflammatory bowel disease (IBD)**Figure 2** Colonoscopy showing diffuse ulceration, erythema, loss of vascular pattern and edema in a patient with ulcerative colitis**Figure 3** Rectal biopsy section from a case of active ulcerative colitis shows crypt distortion, crypt loss, crypt branching and mucodepletion and dense mixed inflammatory cell infiltrate in lamina propria. (HE X 200 original magnification)

Figure 5 Sections from right-sided colectomy specimen shows granuloma in muscularis propria near adventitial adipose tissue from a case of Crohn's disease. (HE X 100 original magnification)

Table 1 Differences between Crohn's disease and ulcerative colitis

	<i>Crohn's disease</i>	<i>Ulcerative colitis</i>
Abdominal pain	+++	±
Bleed per rectum	++	++++
Growth failure	++	±
Weight loss	++	±
Perianal disease	+++	—
Rectal sparing	++	Rare
Small bowel disease	Common	None except backwash ileitis
Strictures	++	Rare
Fistulas	++	—
Colonoscopy	Aphthous, deep linear or serpiginous ulcers which are asymmetrical in distribution	Diffuse, small, superficial with erythema, edema, loss of vascular pattern and friability
Discontinuous (skip) lesions	Yes	No
Bowel involvement	Transmural	Mucosal
Granulomas on histology	Yes	No

Except when clinical, laboratory and endoscopic findings are suggestive of typical UC, an evaluation of the small bowel by imaging is mandatory at diagnosis. Magnetic resonance enterography (MRE) is the recommended imaging modality and is preferred over CT largely due to high diagnostic accuracy and lack of radiation exposure. It can help to define disease activity, distinguish between inflammatory, stricturing and penetrating disease and can demonstrate both mural and extramural complications. However, CT enterography may be used to delineate small bowel disease (**Fig. 6**) in places where MR facilities/expertise is not available.

To assess the severity of UC or CD, various scoring systems have been devised which take into consideration clinical (stool frequency, nocturnal stools, general activity, abdominal pain and presence of blood in stools) and laboratory (hemoglobin,

Figure 6 CT enterography showing thickening of ileum in a patient with Crohn's disease

albumin, ESR) parameters. The pediatric Crohn's disease activity index (PCDAI) is used for CD, while the pediatric ulcerative colitis activity index (PUCAI) is used for UC. They are useful for assessing response to therapy and comparing outcomes across studies.

DIFFERENTIAL DIAGNOSIS

Inflammatory bowel disease has to be differentiated from other causes of colitis like infective colitis, allergic colitis, pseudomembranous colitis, immunodeficiency and TB. The important points that help in differentiating between these conditions and IBD are as follows:

- *Infective colitis, i.e., dysentery*: The most common cause of colitis in children; seen at all ages; acute onset often with fever and occasionally with vomiting; short duration of illness of 5–7 days, rarely last for more than 2 weeks and good response to treatment with antibiotics.
- *Cow's milk protein allergy*: Onset less than 3 years of age; temporal association with introduction of bovine milk; features of eczema, wheezing; family history of atopy; definite response to milk withdrawal and reappearance with a challenge;

peripheral eosinophilia; and aphthous ulcers in rectum on proctosigmoidoscopy.

- **Pseudomembranous [*Clostridium difficile* (*C. difficile*)] colitis:** Seen at all ages; history of antibiotic intake; *C. difficile* toxin assay positive in stool; presence of pseudomembranes (yellowish gray plaques of 2–5 mm or larger) on colonoscopy are pathognomonic of *C. difficile* colitis. *C. difficile* colitis may occur in patients with IBD and should always be excluded in patients presenting with severe acute colitis.
- **Immunodeficiency:** Presents at an early age usually in infants or young children; family history of similar illness; history of infection at other sites, e.g., multiple episodes of respiratory or skin infections and liver abscesses. Chronic granulomatous disease may present with enterocolitis and perianal disease just like CD. Acquired immunodeficiency syndrome (AIDS) may present with colitis secondary to opportunistic infections like cytomegalovirus (CMV) colitis. Immunodeficiency work-up is required in few cases with immunoglobulin profile, test of phagocytic function and retrovirus serology.
- **Intestinal tuberculosis:** Intestinal TB often masquerades as CD in its clinical features. Colonic ulcers are circular in TB and longitudinal (along the long axis of colon) in CD. Cecum and ileocecal valve involvement is more common in TB. Ascites and necrotic abdominal lymph nodes are seen in TB. Granulomas are larger and show caseation in TB. Presence of acid fast bacilli on histology confirms the diagnosis of TB. It is essential to diagnose CD or TB correctly as the treatment for these two conditions is different and immunosuppression in a patient with intestinal TB may lead to disease flare and poor outcome.

TREATMENT

Medical Management

Inflammatory bowel disease is a disease of remissions and relapses. The goal of medical therapy is to induce and maintain remission (**Table 2**) and prevent disease complications with the

Table 2 Induction and maintenance therapy in patients with Crohn's disease and ulcerative colitis

Therapy	Crohn's disease	Ulcerative colitis
Induction	<p>Mild or moderate disease</p> <ul style="list-style-type: none"> • Oral prednisolone or • Exclusive enteral nutrition <p>Severe disease</p> <ul style="list-style-type: none"> • Intravenous steroids or • Infliximab <p>5-ASA may be effective in mild disease</p> <p>Antibiotics [metronidazole (7.5 mg/kg/dose TDS)/ciprofloxacin (5 mg/kg/dose BD)] in perianal disease</p>	<p>Mild disease</p> <ul style="list-style-type: none"> • Oral 5-ASA ± Topical mesalamine <p>Moderate or severe</p> <ul style="list-style-type: none"> • Oral prednisolone <p>Acute severe colitis</p> <ul style="list-style-type: none"> • Intravenous steroids (1st line) • Infliximab or IV cyclosporine (2nd line) • Surgery (failure of medical therapy)
Maintenance	<p>Immunomodulators (Azathioprine/6-MP/or methotrexate) or</p> <p>Infliximab and other biologicals (severe disease)</p>	<p>5-ASA preparation or</p> <p>Azathioprine/6-MP (in frequent relapsers)</p>

Abbreviations: ASA, aminosalicic acid; IV, intravenous; MP, mercaptopurine.

minimum possible medications. Apart from the control of disease activity, maintenance of nutrition and bone health and prevention of infections by appropriate immunization is important. The main drugs used for treatment of children with IBD are as follows (**Table 3**).

Steroids They have a central role as an induction agent in CD and moderate to severe UC. Prednisolone, in a dose of 2 mg/kg/day (maximum 40 mg/day) for 2–4 weeks followed by gradual tapering over 6–8 weeks achieves clinical remission in majority of cases. They are not used as maintenance therapy. The principles of steroid use in IBD are as follows—use an effective dose, do not overdose, do not treat for excessively short periods, do not treat for excessively long periods and anticipate side effects. Adequate dietary supplementation with calcium and vitamin D is essential to prevent bone disease.

5-aminosalicylic acid (ASA) agents They act by modifying neutrophil mediated tissue damage, by inhibition of leukotriene biosynthesis via the lipoxigenase pathway and scavenging of reactive oxygen species. Oral 5-ASA compound are recommended as first-line induction therapy for mild to moderately active UC and also for maintenance therapy in patients with UC. In CD its use is limited as an adjunctive role in isolated colonic CD as an induction agent. Combining oral 5-ASA with topical 5-ASA (enema, suppository) is more effective than oral alone. Sulfasalazine consists of 5-ASA in aza bond linkage with sulfapyridine. The sulfa moiety here acts as

Table 3 Dosage and side effects of medication used for treatment of inflammatory bowel disease (IBD)

Medication and dose	Side effects	Monitor
<p>Steroids</p> <ul style="list-style-type: none"> • Oral prednisolone (1–2 mg/kg/day) • IV methyl prednisolone (2 mg/kg/day) 	<p>Common: Acne, moon facies, hirsutism, cutaneous striae</p> <p>Uncommon: Steroid psychosis, hypertension proximal myopathy, growth impairment, osteoporosis, cataract and raised intraocular pressure</p>	<ul style="list-style-type: none"> • Blood pressure • Ophthalmic evaluation
<p>Aminosalicylate</p> <ul style="list-style-type: none"> • Mesalamine (50–100 mg/kg/day) • Sulfasalazine (40–60 mg/kg/day) 	<ul style="list-style-type: none"> • Vomiting, headache, diarrhea • Stevens-Johnson syndrome, pulmonary fibrosis, hepatotoxicity, agranulocytosis and mild hemolysis 	<ul style="list-style-type: none"> • CBC • LFT • Creatinine
<p>Immune modulator</p> <ul style="list-style-type: none"> • Azathioprine (2–2.5 mg/kg/day PO) • 6-mercaptopurine (1–1.25 mg/kg/day PO) • Methotrexate (15 mg/m²/week—PO/SC) 	<ul style="list-style-type: none"> • Bone marrow suppression, pancreatitis and increased risk of infections • Hepatotoxicity 	<ul style="list-style-type: none"> • CBC • Amylase • LFT
<p>Biologicals</p> <p>IV infliximab (5 mg/kg/dose at 0, 2 and 6 weeks and 4–8 weeks thereafter for maintenance)</p>	<p>Infusion reactions, flare of infections (TB, hepatitis B), demyelinating diseases, psoriatic rash</p>	<p>Screen for sepsis/TB before therapy</p>

a carrier delivering the pharmacological active ASA moiety to the colon.

Immunomodulators These include drugs like azathioprine, 6-mercaptopurine (6-MP) and methotrexate. Thiopurines (AZA, 6-MP) take about 3 months to be fully effective and therefore cannot be used to induce remission. They have a role in steroid refractory [defined as active disease despite an adequate dose (1–2 mg/kg or minimum 20 mg/day) and duration (2 weeks) of steroids] and steroid dependent [relapse when steroids are tapered to 10 mg/day/frequently relapsing (≥ 2 relapses/year)] cases as a steroid sparing agent. Some centers add azathioprine from the beginning in severe cases to prevent subsequent relapses and repeated use of steroid.

Biologicals These include various antitumor necrosis factor alpha (anti-TNF- α) agents like infliximab, adalimumab and anti- α -integrin agents like natalizumab. These are potent and expensive medications indicated for induction and maintenance of severe luminal or fistulizing CD or induction of severe active UC refractory to steroid treatment. Infliximab is administered as an infusion at a dose of 5 mg/kg/dose at weeks 0, 2 and 6 and thereafter at 8-week intervals for maintenance.

Exclusive enteral nutrition (EEN) Exclusive enteral nutrition, in which a specific liquid formula (elemental, semi-elemental, or polymeric) is given without any other food item for 6–8 weeks, has been used for inducing remission in pediatric CD. Postulated mechanisms of action have included elimination of dietary antigens, overall nutritional repletion, correction of intestinal permeability, diminution of intestinal synthesis of inflammatory mediators via reduction in dietary fat, and provision of important micronutrients. EEN is as effective as steroids in inducing remission in newly diagnosed and active CD. EEN promotes mucosal healing and has beneficial effect on linear growth. The disadvantages of EEN include the high cost of the formula and the fact that the child cannot eat anything else for 6–8 weeks.

Surgery

Ulcerative colitis Surgery with restorative proctocolectomy (ileoanal pouch anastomosis) is curative and the surgical procedure of choice. The indications for surgery in UC patients are: acute severe colitis refractory to medical therapy; toxic megacolon; colonic perforation; uncontrolled GI hemorrhage; chronic ongoing disease with steroid dependence and colonic dysplasia or carcinoma.

Crohn's disease In CD surgery is not curative and management is directed at minimizing the impact of disease. At least 30% of patients require surgery in the first 10 years of disease and approximately 70–80% will have surgery in their lifetime. Surgery is indicated for bowel obstruction, drainage of abscesses, nonhealing fistulae, perforation or GI bleeding. Surgery should be considered for those in whom medical treatment has failed. In view of the chronic disease, attempts should be made to minimize intestinal resection and prevent short gut.

A close collaboration between gastroenterologist and surgeon experienced in pediatric IBD is essential for a good outcome.

Supportive Therapy

Nutritional therapy Recognition and correction of malnutrition by provision of adequate calories and proteins is important. The details of growth, pubertal status, disease mapping (site, extent and resections) and drugs administered should be noted. Anemia is

seen commonly and is multifactorial due to iron deficiency (blood loss), vitamin B₁₂ deficiency (terminal ileal disease/resection), folate deficiency (use of methotrexate, sulfasalazine) and chronic disease. Recognition of the type of anemia and appropriate supplementation of iron, B₁₂ or folate should be done. *High-risk* children with IBD, i.e., those with growth failure, pubertal delay, vertebral fractures and prolonged steroid therapy should have a dual X-ray absorptiometry (DXA) scan for assessment of bone mineral density. Appropriate supplementation of vitamin D and calcium is essential.

Immunization Inflammatory bowel disease patients are treated with immunosuppressant medications which increase the risk of developing infections, several of which can be prevented by appropriate vaccination. A detailed history of prior immunization and illnesses suffered should be taken in all patients. Ideally, an effort should be made to immunize pediatric patients with IBD with age appropriate live viral vaccines [e.g., *varicella* and measles, mumps and rubella (MMR)] before starting immunosuppressive therapy. Treatment with high-dose systemic corticosteroids (≥ 2 mg/kg/day of prednisone or ≥ 20 mg/day of prednisone or its equivalent for ≥ 14 days), cyclosporine or tacrolimus, thiopurines, methotrexate or biological is defined as immunosuppressive therapy. It is recommended that patients wait at least 1 month after discontinuing corticosteroids before immunization with *varicella* vaccine. However, inactivated vaccines can be safely given even along with immunosuppressant therapy.

COMPLICATIONS AND PROGNOSIS

The disease course is characterized by remissions and exacerbations. The complications depend upon the disease extent and severity of IBD. Patients with severe disease are more likely to require prolonged immunosuppressive therapy and surgical interventions, which increases the risk of short bowel and adhesive intestinal obstruction. The risk of colon cancer is increased in patients with UC and CD (with colonic involvement) and they should undergo screening colonoscopy with surveillance biopsies every 1–2 years, beginning approximately 7–10 years after their initial diagnosis. Patients who require therapy with immunomodulators and biologicals also have an increased risk of non-Hodgkin lymphoma. Children with IBD are at increased risk of having depression, social isolation, poor self-esteem and poor scholastic achievement due to chronic illness and school absences. Appropriate screening and attention to these psychosocial issues can improve the clinical outcome and health-related quality of life of these children.

PREVENTION

Efforts towards prevention of IBD by manipulation of gut microflora, exposure to helminths in childhood and dietary alterations (e.g., intake of polyunsaturated fatty acids, curcumin) are still in experimental stages. Prevention in IBD is therefore largely limited to preventing side effects related to disease management. Children with IBD, specifically CD, are at risk of exposure to ionizing radiation secondary to repeated medical imaging. Radiation has increased risk of cancer in children and therefore it is important to limit radiation exposure by using appropriate imaging modalities like ultrasonography, MRI and endoscopy. The combination of immunosuppressive medications places children with IBD at increased risk of opportunistic infections. Population studies suggest that there is an increased risk of thromboembolism in children with IBD (UC more than CD)

compared to controls. Good control of disease activity and mucosal healing are paramount to achieve adequate growth, timely puberty and bone health. Meta-analysis of patients requiring surgery has shown that ileal pouch-anal anastomosis (IPAA) increases the risk of infertility compared to medical management alone and this should always be considered and discussed with the family.

IN A NUTSHELL

1. Inflammatory bowel disease includes Crohn's disease (CD), ulcerative colitis (UC) and inflammatory bowel disease unclassified (IBDU).
2. Nearly, 20–25% of all IBD has onset in childhood (< 18 years) with most children being diagnosed at 10–14 years of age.
3. The etiopathogenesis of IBD involves interplay between genetic factors, environmental triggers and gut microflora which initiates an abnormal mucosal immune response and leads to intestinal inflammation.
4. Crohn's disease can involve any part of the GI tract from mouth to rectum whereas UC is limited to the colon. Correct diagnosis of IBD and its subtype, i.e., UC or CD is essential as the management and outcome differs.
5. Loose stools with blood and mucus, i.e., features of colitis are the most common presentation. In addition, CD may present with abdominal pain, growth failure or small bowel type of diarrhea.
6. Extraintestinal manifestations (arthralgia, arthritis, EN, pyoderma gangrenosum, sclerosing cholangitis, uveitis, etc.) are seen in 6–28% children with IBD.
7. Diagnosis of IBD should be based on a combination of history, physical examination, laboratory evaluation, EGD with biopsy, ileo-colonoscopy with biopsy and small bowel imaging.
8. Treatment comprises of an induction phase (5-ASA, steroids, enteral nutrition, biological), followed by a maintenance phase (5-ASA, immunomodulators and biological).
9. Surgery is reserved for patients refractory to medical therapy or those with complications like toxic megacolon, perforation or hemorrhage.
10. Achieving optimal growth, timely puberty and prevention of bone disease is a very important aspect of management of children with IBD.

Chapter 35.18

Celiac Disease

Lalit Bharadia

Celiac disease (CD) is an immune-mediated systemic disorder elicited by gluten and related prolamines in genetically susceptible individuals. It is characterized by the presence of a variable combination of gluten-dependent clinical manifestations, CD-specific antibodies, human leukocyte antigen (*HLA*)-*DQ2* or *HLA-DQ8* haplotypes, and enteropathy. CD has a prevalence of 0.8–2.67% in the Western world. In one of the large population studies in Northern India, the prevalence was 15.44% by serology and 1.04% by histology. In India the disease is not only underdiagnosed because of varied and nonspecific clinical symptoms, but also delayed due to lack of awareness.

The prevalence of CD, as well as other autoimmune disorders like type 1 diabetes, has greatly increased in recent years, for reasons that are currently unclear but are likely related to environmental changes. Samuel Gee, in 1888, published the first complete modern description of the clinical picture of CD and stressed the importance of diet in its control. By 1952, Willem Dicke recognized that the disease is caused by the ingestion of wheat proteins, and not carbohydrates.

PATHOGENESIS

Celiac disease is a disease of genes and grains. *HLA* class II genes play an important role in the disease pathogenesis. Most patients with CD carry a variant of *HLA-DQ2* (DQ2.5; DQA1*05/DQB1*02), whereas the remaining patients carry *HLA-DQ8* (DQA1*03/DQB1*0302). The *HLA* genes present gluten peptide to T-cells which function as central effector cells of inflammation by releasing different cytokines, notably, interferon (IFN) γ , a key marker of the inflammatory Th1 response. The release of these cytokines precipitates a cascade of immune, mesenchymal, and epithelial cell activation in the small intestine, resulting in the hallmark lesions of crypt hyperplasia, villus atrophy and increased intraepithelial lymphocytes (IELs) (**Fig. 1**).

In addition to genetics, grains play an important role in the pathogenesis of CD. Gluten is the most significant identified factor. Dietary gluten contains several distinct T-cell epitopes rich in proline and glutamine residues. The high-proline content of dietary gluten leads to peptides that are not easily degraded by gastrointestinal (GI) proteases, leading to an elevated concentration of potentially immunogenic epitopes in the small intestine. IgA-transglutaminase 2 (TG2), a ubiquitous intracellular and facultative extracellular enzyme that can associate with the extracellular

Figure 1 Normal histology (left) and total villus atrophy (right) in celiac disease

matrix, plays a central role in CD. TG2 targets certain glutamine residues found in dietary gluten and deamidates them to negatively charged glutamic acid residues. The negatively charged gluten peptides are able to bind with greater affinity to *HLA-DQ2* or *HLA-DQ8*, leading to enhanced gluten-specific CD41 Th1 cell activation.

CLINICAL FEATURES

There are four different clinical presentations of CD as shown in **Table 1**. On the basis of clinical presentation, symptomatic CD is broadly divided into typical and atypical CD. Because of its varied manifestations, atypical CD runs the risk of delayed diagnosis. With the use of serologic markers, the spectrum of CD has further widened to include potential and latent CD. **Box 1** shows the common extraintestinal manifestations of CD. In a recent study from North America, up to 55% children with CD did not have chronic diarrhea. A similar Indian study reported a figure of 36%.

Recent Oslo definitions have discouraged use of the terms typical, atypical, silent and latent celiac and suggested the use of classical, nonclassical, asymptomatic and latent CD respectively. Those asymptomatic patients who improve after gluten-free diet (GLD) in any manner (e.g., improvement in fatigue) are labeled as subclinical CD. Groups that are at risk of having silent CD are listed in **Table 2**. National Institute for Health and Clinical Excellence (NICE) Clinical Guidelines 2009 on CD recommend offering serological test to those mentioned in **Table 3** and considering offering the same to those in **Table 4**.

DIAGNOSIS OF CELIAC DISEASE

European Society for Pediatric Gastroenterology, Hepatology, and Nutrition (ESPGHAN) Guidelines of 2012 for are the current standard for management of CD. This guideline describes two algorithms—one for symptomatic and another for high-risk asymptomatic groups.

Table 1 Presentations of celiac disease

Type	Presentation
Typical	<ul style="list-style-type: none"> • Predominant gastrointestinal signs/symptoms • Vomiting • Anorexia • Constipation • Diarrhea • Failure to thrive • Recurrent abdominal pain
Atypical or extraintestinal	Gastrointestinal signs/symptoms are minimal or absent. Most common extraintestinal manifestations described in Box 1 .
Silent	No signs/symptoms. Gluten dependent duodenal mucosa are typical of celiac disease
Latent	Signs, symptoms may or may not be present. Duodenal mucosa normal. Gluten dependent changes with or without symptoms appear later in time

BOX 1 Extraintestinal manifestation of celiac disease

- Dermatitis herpetiformis
- Permanent enamel hypoplasia
- Iron-deficient anemia resistant to oral iron supplements
- Short stature, delayed puberty
- Chronic hepatitis
- Arthritis
- Osteopenia/osteoporosis
- Epilepsy with occipital calcifications
- Primary ataxia, white matter-focal lesions
- Psychiatric disorders.

Table 2 Groups that are at risk of having silent celiac disease

Condition	Approximate prevalence of celiac disease (%)
Type 1 diabetes mellitus	8–10
Thyroiditis	3–5
Sjögren syndrome and other connective tissue disorder	3–4
Down syndrome	10–12
William syndrome	5
Turner syndrome	5
First degree relative of celiac patient	8–10

Table 3 Situations which warrant serologic testing for celiac disease (CD)

Signs and symptoms	Conditions
Chronic or intermittent diarrhea	Autoimmune thyroid disease
Failure to thrive	Dermatitis herpetiformis
Persistent or unexplained GI symptoms including nausea and vomiting	Irritable Bowel syndrome
Prolonged fatigue	Type 1 diabetes
Recurrent abdominal pain, cramping or abdominal distension	First degree relative with celiac disease
Sudden or unexpected weight loss	
Unexplained iron deficiency anemia or unspecified anemia	

Table 4 Consider offering serological testing to children and adults with any of the following

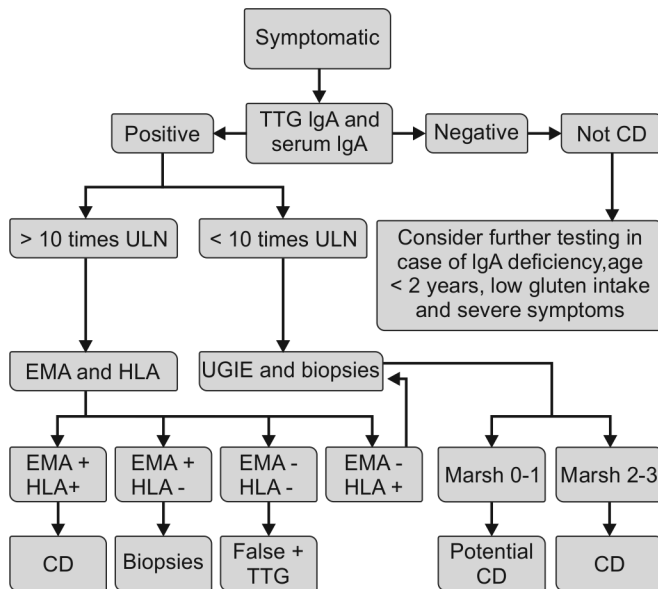

Addison disease	Microscopic colitis
Amenorrhea	Persistent or unexplained constipation
Aphthous stomatitis (mouth ulcers)	Persistently raised liver enzymes with no cause
Autoimmune liver disease	Polyneuropathy
Autoimmune myocarditis	Recurrent miscarriages
Chronic thrombocytopenic purpura	Reduced bone mineral density
Dental enamel defects	Sarcoidosis
Depression or bipolar disorder	Sjögren syndrome
Down syndrome	Turner syndrome
Epilepsy	Unexplained alopecia
Low trauma fracture	Unexplained subfertility
Lymphoma	
Metabolic bone disease	

The *symptomatic group* should first be offered serology (**Flow chart 1**), as against the previous guidelines which insisted on duodenal biopsies for the diagnosis of CD. If serology is more than 10 times the upper limit of normal, duodenal biopsies may be omitted, provided an additional serologic test and HLA are both positive. In all other children, a duodenal biopsy must be done to confirm CD. Symptomatic children who are negative for serology may require, further testing if they are less than 2 years of age, have immunoglobulin A (IgA) deficiency, have severe symptoms or have been on a low gluten diet at presentation.

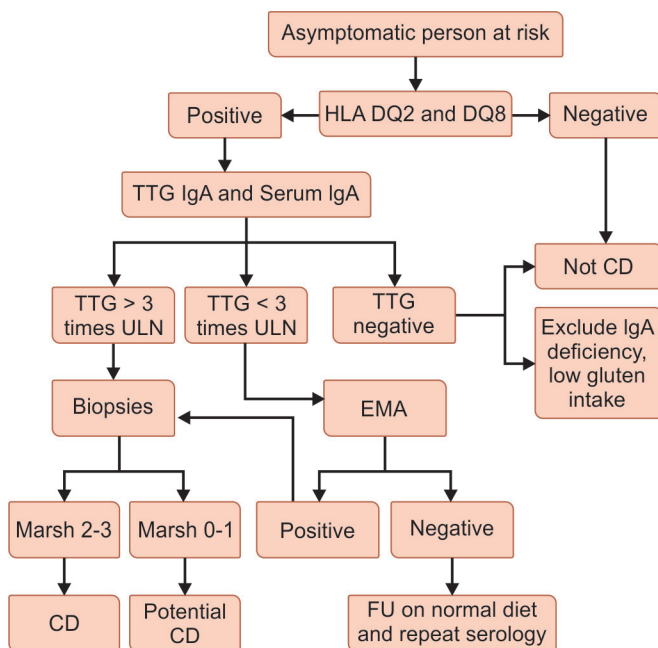

The *asymptomatic group* who are investigated because of their increased risk for the disease should first be offered HLA test (**Flow chart 2**). Those positive for *HLA-DQ2* or *-DQ8* should be tested for serology and offered duodenal biopsy if serology is more than three times upper limit normal. If serology is less than three times upper limit of normal, a repeat serology should be done after 3–6 months.

Which Serological Test

- Immunoglobulin A tissue transglutaminase (tTGA) is the first screening test.
- Immunoglobulin A endomysial antibodies (EMA) testing if the result of the tTGA test is equivocal.
- Check for IgA deficiency if the serology is negative.
- Immunoglobulin G tTGA and/or IgG EMA serological tests are for people with confirmed IgA deficiency.
- In children less than 2 years of age, deamidated gliadin peptide (DGP) IgG is better than other tests.

Flow chart 1 Guideline for diagnosis of symptomatic patient

Abbreviations: TTG, tissue transglutaminase; CD, celiac disease; EMA, endomysial antibodies; F/u, follow-up; GFD, gluten-free diet; HLA, human leukocyte antigen; IgA, immunoglobulin A; IgG, immunoglobulin G; UGIE, upper gastrointestinal endoscopy; ULN, upper limit of normal.

Flow chart 2 Diagnosis of celiac disease in asymptomatic patient

Abbreviations: TTG, tissue transglutaminase; CD, celiac disease; EMA, endomysial antibodies; F/u, follow-up; GFD, gluten-free diet; HLA, human leukocyte antigen; IgA, immunoglobulin A; IgG, immunoglobulin G; UGIE, upper gastrointestinal endoscopy; ULN, upper limit of normal.

Upper GI Endoscopy

While performing the upper GI endoscopy, biopsies should be taken preferably from the duodenal bulb (at least one biopsy) and from the second or third portion of duodenum (at least four biopsies). The various endoscopic duodenal appearances which suggest CD include mosaic pattern (in 100%), scalloped folds of

duodenum (70%) (**Figs 2A and B**), visible vasculature (15%) and reduced folds of duodenum (6%). The pathology report should include a description of the orientation, the presence or not of normal villi or degree of atrophy and crypt elongation, the villus-crypt ratio, the number of IELs, and grading according to the Marsh-Oberhuber classification.

The enteropathy in CD is of variable severity and may be patchy, with changes present only in the duodenal bulb in some patients. The histological appearance is not specific for CD and may be found in other enteropathies as well. The characteristic histological changes in CD are increased IELs (> 25/100 enterocytes), increased crypt length, partial to total villus atrophy, decreased villus crypt ratio and infiltration of plasma cells and lymphocytes in the lamina propria. The histological changes are graded according to modified Marsh criteria as follows:

- Grade 0—Normal
- Grade 1—Infiltrative (increased IEL)
- Grade 2—Hyperplastic (grade 1 + hyperplastic crypt)
- Grade 3a—Partial villus atrophy
 - 3b—Subtotal villus atrophy
 - 3c—Total villus atrophy (23)
- Grade 4—Hypoplastic (total villus atrophy + hypoplastic crypts).

Marsh 3 and 4 are characteristic of CD. Marsh 2 is compatible with CD but needs serological positivity for definite diagnosis while Marsh 1 is not specific for CD in children.

Human Leukocyte Antigen Testing

The principal determinants of genetic susceptibility for CD are the major histocompatibility class II *HLA* class II *DQA* and *DQB* genes coded by the major histocompatibility region in the short arm of chromosome 6. More than 95% of patients with CD share the *HLA-DQ2* heterodimer and most of the remaining have the *HLA-DQ8* heterodimer. CD is a multigenetic disorder, which means that the expression of these *HLA-DQ2* or *HLA-DQ8* molecules is necessary but not sufficient to cause disease. Approximately 30–40% of the white population holds the *HLA-DQ2* haplotype, while only 1% of them develop CD.

Human leukocyte antigen testing should be performed in patients with an uncertain diagnosis of CD, for example, in patients with negative CD-specific antibodies and mild infiltrative changes in proximal small intestinal biopsy specimens. HLA testing may be offered to asymptomatic individuals with CD-associated conditions (group 2) to select them for further CD-specific antibody testing.

TREATMENT

All children with proven CD must be started on GFD. An unequivocal response to GFD within few weeks to months confirms the diagnosis of CD. A strict GFD for life is the cornerstone of treatment. Patients need to be counseled in local language on the specific cereals to be avoided. In India, wheat and barley (*Jaun*)

Figures 2A and B (A) Normal endoscopic appearance of duodenum; (B) Characteristic scalloped folds of duodenum in celiac disease

are the most commonly used grains which contain gluten. *Rye* is another gluten containing cereal used to make breads in some parts of Europe, but is not available in India. In India, mustard (*Rai*, *Sarson*) is often wrongly excluded from diet, since it sounds similar to *Rye*. Sorghum (*Jowar*) is also wrongly excluded due to confusion with barley (*Jaun*). Pure oats (*Jae*) does not contain gluten, but often gets contaminated with gluten during milling and harvesting. If purity is ensured, oats can be allowed. Patients and families need to be educated about sources of accidental contamination of gluten (e.g., common grinding machine or common cooking place for gluten and gluten-free food) and also about reading the ingredients of any ready to eat food. While no mention of *wheat* or *barley* in the contents is reassuring, a reliable label of *gluten free* is ideal. Supportive nutritional care to prevent vitamin, iron and calcium deficiency is required.

Although a *zero tolerance* policy is recommended, it is known that sensitivity to ingested gluten varies greatly amongst patients. A recent meta-analysis estimated, that gluten in amounts less than 10 mg/day may be safe to consume, while more than 100 mg/day are likely to result in the majority of patients exhibiting some signs of immune reactivation and/or symptoms. A typical western diet contains an average of 156 g of wheat (i.e., 40 g of gluten) a day. On a strict GFD, GI symptoms resolve within a few weeks, followed by normalization of biochemical parameters and finally increase in weight and height. Treatment with GFD also reverses the decrease in bone mineralization as well as risk for fractures. There is also marked improvement in their sense of physical and psychological well-being, as documented by a recent quality of life study.

REFRACTORY CELIAC DISEASE

Refractory celiac sprue is defined as symptomatic severe enteritis that does not respond to a strict GFD even after 6 months, without any other causes of enteropathy or overt intestinal lymphoma. It is rare in children and usually seen in elderly patients with poor nutritional status because of chronic malabsorption and protein losing enteropathy. Such patients require treatment with corticosteroids and immunosuppressants, like azathioprine or cyclosporin as well as total parenteral nutrition.

FOLLOW-UP AND MONITORING

If the diagnosis of CD is made according to the diagnostic criteria mentioned above, the family should receive professional dietary counseling for a GFD. They should be followed up regularly for growth monitoring as well as for re-emphasizing the need for lifelong GFD. The CD specific antibody titers fall to below normal within 12 months after starting therapy. If there is no clinical response to a GFD in symptomatic patients, a careful dietary re-assessment should be done to exclude lack of compliance. If none is found, further investigations are required to look for coexisting food intolerances.

Gluten challenge is considered necessary in situations where there is doubt about the initial diagnosis. Gluten challenge should be preceded by HLA typing and assessment of mucosal histology and should be performed under medical supervision. Gluten

challenge should be discouraged in children below 5 years of age and during the pubertal growth spurt, unless the child is *HLA-DQ2* and *HLA-DQ8* negative or has been placed on a GFD without proper testing. The daily gluten intake during gluten challenge should contain at least the normal amount of gluten intake for children (approximately 15 g/day). IgA anti-TG2 antibody (IgG in low levels of serum IgA) should be measured during the challenge period. A patient should be considered to have relapsed (and hence the diagnosis of CD confirmed) if CD-specific antibodies become positive and a clinical and/or histological relapse is observed. In the absence of positive antibodies or clinical symptoms, the challenge should be considered completed after 2 years. However, additional biopsies on a normal diet are recommended because delayed relapse may occur later in life.

PROGNOSIS

Gluten-free diet usually results in clinical, serologic, and histologic remission. In the long-term, it not only reduces the risk of malignancies, but also protects against developing autoimmune diseases such as IDDM, hematologic disorders, and inflammatory bowel disease. In western countries, adherence to a GFD in the general population is reported to be less than 50%, but may be as high as 81% in children. Studies from the developing world have reported a GFD adherence of 45–100%. Those who start a GFD below 10 years of age are 1.3–2 times more compliant. Maintaining a strict long-term GFD is a challenge, especially in children and adolescents. Noncompliance is due to several factors including ignorance about the diet, social/peer pressure, nonavailability of commercially available GFD, dislike of the taste of alternative food, increased outdoor activities, increased risk-taking behavior, and conflicts with parents. Adherence to a GFD is lower in asymptomatic patients who are diagnosed through a mass screening program, than in those referred because of clinical suspicion. In addition, more than 30% of those who think that they are adhering to a GFD are consuming gluten-contaminated food daily. The benefits of adherence to a GFD have been well documented in even in developing countries. Demir and colleagues reported improvement in growth rate in Turkish children with CD adhering to a GFD. Moreover, diabetic children with CD adhering to a GFD have fewer hypoglycemic episodes and better diabetic control. Zamani and colleagues found that Iranian patients with CD with IDA who are on a GFD had spontaneous recovery of their anemia even without iron supplementation.

Problems with therapy Currently, the only available therapy for CD is strict lifelong adherence to a GFD. Although the GFD is a safe and effective therapy, there are practical problems in enforcing it. Guidelines for permissible gluten content in gluten free products vary across the globe and monitoring is lacking in most developing countries. GFD is expensive, not readily available in many countries, and may be lower in its nutritional value, which can significantly impact patient adherence and quality of life. In addition there are issues related to social stigma in communities where awareness about the disease is poor. Alternatives to GFD is desirable and future possible therapies are shown in **Table 5**.

Table 5 Newer therapies for celiac disease

Target	Approach
Gluten modification	Modified grain, pretreated flour, oral glutenase
Intraluminal therapies	Gluten sequestering polymers, gluten neutralizing antibodies
Immune modification	Gluten vaccination
Modification of intestinal permeability	Zonulin receptor antagonist
Immune cell targeted therapies	Immunosuppressant

IN A NUTSHELL

1. Celiac disease (CD) is prevalent in 1% of general population in north India.
2. Due to its varied presentation, it runs the risk of remaining undiagnosed and delayed diagnosis in significant number.
3. Except in a minority of symptomatic children with two serologies and HLA DQ2/DQ8 positive, all other need duodenal biopsies for confirmation of CD.
4. Lifelong strict gluten free diet remains the only treatment for CD currently.

Chapter 35.19

Abdominal Tuberculosis

Yogesh Waikar

Abdomen is a common site of extrapulmonary tuberculosis (TB) in children. It can involve the gastrointestinal (GI) tract, mesenteric lymph nodes or peritoneum. The diagnosis is difficult, since clinical features are varied as well as nonspecific. About 10% of all cases of abdominal TB occur under the age of 10 years.

PATHOGENESIS

The tubercle bacillus reaches the GI system by hematogenous spread from the primary lung focus, ingestion of bacilli from the sputum from an active pulmonary focus, direct spread from adjacent organs or through lymph channels from infected abdominal nodes. Ileocecal region is commonly involved. Mesenteric and peritoneal TB are seen in approximately one-third of patients. The initial infection is localized to the *Peyer's patches* leading to local ulcers followed by mesenteric lymphadenitis and peritonitis.

Intestinal TB is commonly classified as ulcerative, ulcerohyperplastic and hyperplastic forms. Liver and spleen also can get involved by the tubercle bacillus leading to formation of tuberculoma. Peritoneal TB can be wet type with ascites or loculated ascites or fibrotic/plastic type with abdominal masses and omental thickening.

Esophageal TB is rare. It occurs mainly by extension of disease from adjacent intrathoracic lymph nodes. Duodenal TB is also rare, presenting as stricture. Abdominal TB can also present as malabsorption. Involvement of colon, rectum and anal canal in TB is rare.

CLINICAL FEATURES

Childhood abdominal TB is commonly seen in age group 7–15 years old. Fever, abdominal pain and/or discomfort and weight loss are common presenting symptoms. One of the most common differential diagnoses is Crohn's disease. The features of hematochezia, intestinal obstruction, fistula, oral ulcers, longitudinal ulcers, cobblestone appearance and pseudopolyps are more common in Crohn's disease than in intestinal TB. Hepatic TB presents with hepatomegaly. Tuberculoma and tuberculous liver abscesses are uncommon manifestations of hepatic TB. In miliary TB tubercles are seen near the hepatic veins. In localized forms of hepatic TB the portal vein appears to be the route of spread. TB can also involve pancreas and can present as acute or chronic pancreatitis.

APPROACH TO DIAGNOSIS

The following points are important in history: contact with an open case of TB; past treatment for pulmonary or extrapulmonary TB and features suggestive of an immunocompromised state. The following should be looked for on examination: peripheral stigmata of TB like lupus vulgaris, TB verrucosa cutis, cold abscess in neck, multiple ear drum perforations, scrofuloderma, lymphadenopathy, phlyctenular conjunctivitis, or spinal swelling. Associated involvement of other organs leading to respective manifestations should be screened, e.g., soft neurological signs of neurotuberculoma. Also obtain detailed anthropometry to determine the nutritional status. Examination of the abdomen should focus on the right iliac fossa. Subtle

signs of subacute intestinal obstruction should not be missed. Peritoneal TB commonly present as ascites which should be carefully looked for.

DIAGNOSIS

Imaging studies Chest X-ray needs to be done to rule out associated pulmonary TB, which may be seen in about 25% of cases. X-ray of the abdomen may show evidence of intestinal obstruction or surgical complications of the disease. Small bowel contrast meal follow through imaging may reveal involvement of terminal ileum and ileocecal junction. The most common abnormality is short-segment strictures with symmetrical concentric mural thickening and homogeneous mural enhancement. Lymphadenopathy, ascites, enteroliths, peritoneal thickening, and enhancement can also be made out. *Barium enema* may reveal the following findings:

- *Fleischner or inverted umbrella sign* suggestive of early involvement of ileocecal valve.
- *Conical cecum*: Cecum pulled out of iliac fossa due to contraction or fibrosis of mesocolon.
- *Purse string stenosis*: Localized stenosis opposite the ileocecal valve with a rounded off smooth cecum and a dilated terminal ileum.
- *Stierlin's sign*: Narrowing of the terminal ileum with rapid emptying into a shortened, rigid or obliterated cecum.
- *String sign*: Persistent narrow stream of barium suggest stenosis.

Cross-sectional imaging is useful in detecting abdominal lymph nodes. Mesenteric and periportal lymph nodes are involved more often in patients with abdominal tuberculosis, while iliac and inguinal lymph nodes are more with lymphoma. While peripheral enhancement is seen more often in tuberculous lymphadenopathy, homogeneous enhancement suggests lymphoma. Ultrasonography of abdomen may reveal ascites, loculated ascites, interloop ascites, mesenteric lymph nodes, bowel thickening, or pseudokidney sign (pulled up cecum).

Endoscopy On colonoscopy, mucosal nodules of variable sizes and ulcers in a discrete segment of colon, ulcer between nodules, and deformed ileocecal valve, are characteristic. Biopsies should be taken from the edge of the ulcers. The characteristic caseous granulomas are seen only in about one-third of cases. While acid fast bacilli (AFB) staining has a variable yield, cultures are rarely positive. Balloon-assisted and spiral enteroscopy with biopsy can be used for evaluating the small bowel. Upper GI endoscopy has limited role.

Others Ascitic fluid analysis shows a predominance of mononuclear cells. Ascitic fluid ADA (adenosine deaminase) greater than 39 IU/L can be used as adjunct test in diagnosis. Serum ascites albumin gradient (SAAG) is less than 1.1 g/dL in peritoneal TB. Ascitic fluid mycobacterial culture (after centrifugation) is positive in only 50% of cases. Laparoscopy with histology and culture of peritoneal biopsies has better sensitivity. Gastric lavage for AFB and positive *Mantoux test* are useful supportive investigations. Serological tests and nucleic acid amplification [e.g., polymerase chain reaction (PCR)] are not useful.

DIFFERENTIATING TB FROM CROHN'S DISEASE

Increased erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) may be seen in both TB and inflammatory bowel disease. Anti-*Saccharomyces cerevisiae* antibody (ASCA) is not useful in differentiating between Crohn's disease and TB. In one-third of cases tubercle bacilli can be cultured from mucosal

biopsies. Ascites, transverse ulcers, patulous ileocecal valve and granulomas are more common in intestinal TB than in Crohn's disease. Granulomas exceeding 300 μm in maximal diameter, more than five granulomas per section, and confluent granulomas are more frequently identified in intestinal TB than in Crohn's disease. Demonstration of caseating granuloma in the biopsy specimen is definitive. Granulomas of TB and Crohn's disease can be differentiated by CD73. Mesenchymal cells surface marker expression CD73 is expressed around the granulomas of TB alone and is absent in the Crohn's disease.

The sensitivity, specificity, positive predictive value and negative predictive value of T-SPOT-TB (interferon- γ release assay) are around 80–90%. Quantiferon-TB Gold test has many limitations and therefore not very useful. PCR using *Mycobacterium tuberculosis* complex-specific primers for IS6110 to differentiate TB and Crohn's disease is not sensitive enough. Correlation between PCR positivity and histological lesions such as caseation and granulomas is yet to be established. Immunohistochemical staining of biopsy specimens with anti-VP-M660 has high specificity but low sensitivity in differentiation.

MANAGEMENT

Abdominal TB comes in category of extrapulmonary TB and should be treated as $2\text{H}_3\text{R}_3\text{Z}_3\text{E}_3$ in intensive phase followed by $4\text{H}_3\text{R}_3$ in continuation phase as per the updated Revised National Tuberculosis Control Program with the Indian Academy of Pediatrics (RNTCP-IAP) guidelines. Previously incompletely treated abdominal TB may be considered to have in intensive phase regimen as $2\text{S}_3\text{H}_3\text{R}_3\text{Z}_3\text{E}_3 + 1\text{H}_3\text{R}_3\text{Z}_3\text{E}_3$. Follow-up therapy is recommended with $5\text{H}_3\text{R}_3\text{E}_3$. Abdominal TB in immunosuppressed patients and those with multidrug resistant TB are challenges which require specialist help. Strict drug compliance needs to be ensured to avoid emergence of multidrug resistant strains. Role of corticosteroids is controversial. Complications of abdominal TB depend on the site of involvement. They include ulcer, perforation, adhesion, obstruction, bleeding, fistulae formation and stenosis.

IN A NUTSHELL

1. The risk factors for abdominal TB are household contact with a newly diagnosed smear-positive case, age less than 5 years, human immunodeficiency virus (HIV) infection and severe malnutrition.
2. In wet type, peritoneal TB calculation of SAAG and ADA helps in diagnosing peritoneal TB.
3. The diagnosis of abdominal TB is based on clinical features, imaging of the abdomen and histology of the affected tissue. There is no role of serology to diagnose abdominal TB.
4. Abdominal TB in immunosuppressed patients or multidrug resistant TB should be managed with the help of pediatric infectious disease specialist and clinical microbiologist.

Chapter 35.20

Ascites

Malathi Sathiyasekeran, R Ganesh

Ascites, defined as the pathologic accumulation of fluid (more than 25 mL in adults) within the peritoneal cavity. Ascites can occur at any age with varying etiological spectrum in the different groups.

INCIDENCE

In liver disease, the incidence of ascites depends on the underlying pathology. In cirrhosis, ascites is seen in 44%, in presinusoidal portal hypertension (PHT) in 10–12% and in more than 80% in postsinusoidal PHT. In acute liver failure and AVH it is seen in about 50% and 10% of patients, respectively.

ETIOPATHOGENESIS

The causes of ascites are shown in **Table 1**. Ascites can be broadly classified into cirrhotic and noncirrhotic ascites.

Noncirrhotic Ascites

Hepatic causes (a) *Acute viral hepatitis (AVH)*: Transient PHT due to sinusoidal collapse, spontaneous bacterial peritonitis (SBP) and hypoalbuminemia are possible explanations; (b) *Postsinusoidal PHT*: Ascites occurs when the hydrostatic and osmotic pressures within hepatic capillaries produce a shift of fluid from blood to the lymphatics at a rate which exceeds its drainage capacity; (c) *Presinusoidal PHT*: Ascites is uncommon in presinusoidal PHT but may occur following hemorrhage or surgery due to depressed hepatocellular function.

Pancreatic ascites Fluid initially accumulates due to leakage of pancreatic juice from a disrupted pancreatic duct or a pseudocyst. Further formation occurs secondary to *chemical burn* of the peritoneum.

Biliary ascites Bile may leak into the peritoneal cavity due to spontaneous or iatrogenic perforation of the bile duct.

Malignant ascites The malignant cells on the peritoneum produce fluid that is rich in protein which causes a rapid shift of fluid into the peritoneal cavity secondary to the osmotic drag.

Chylous ascites Rupture of obstructed or distorted abdominal lymphatics as occurs in congenital lymphangiectasia or other acquired conditions.

Tuberculous ascites Peritoneal tubercles secrete proteinaceous material causing an osmotic drag of fluid and present as either diffuse or loculated ascites.

Eosinophilic ascites In eosinophilic gastroenteritis (EGE), the eosinophils infiltrate the Peyer's patches and if the serosa is infiltrated it results in eosinophilic ascites.

Infections Transient ascites may occur in several febrile illnesses. Third spacing of fluid in dengue shock may cause ascites. In leptospirosis and typhoid fever the ascites is due to serositis.

Cirrhotic Ascites

Sinusoidal PHT is the initial mechanism that determines leakage of fluid into the peritoneal cavity. Sinusoidal PHT with increase in portal pressure is an essential component in the pathogenesis and ascites rarely develops unless the threshold pressure is more than 12 mm Hg. Hypoalbuminemia may predispose to fluid accumulation, but is not an essential component. Sodium and water retention causes increase in intravascular volume leading to ascites formation. The pathophysiology of cirrhotic ascites is shown in **Figure 1**.

A. Underfill theory: Portal hypertension results in decreased blood volume leading to decreased renal perfusion. This activates the plasma renin-aldosterone pathway and the sympathetic nervous system resulting in renal sodium and water retention and promotes ascites formation.

B. Overflow theory: An unknown hepatorenal reflex causes inappropriate sodium and water retention followed by increasing blood volume which together with PHT, leads to ascites.

C. Peripheral arterial vasodilation theory: The first step is vasodilation of the peripheral vessels leading to systemic hypotension and a decrease in cardiac output. This is followed by renal retention of sodium and water, plasma volume expansion and ascites. This theory has been modified and termed as *forward*

Table 1 Causes of ascites in children

Organ involved	Condition
Hepatic	<p><i>Chronic liver disease</i>: Portal hypertension(PHT)—Common</p> <p><i>Postsinusoidal PHT</i>: Hepatic venous outflow tract obstruction (HVOTO): Sinusoidal Obstruction syndrome, Budd-Chiari syndrome, IVC obstruction</p> <p><i>Sinusoidal PHT</i>: All causes of cirrhosis, e.g., HBV, HCV, Wilson's disease, tyrosinemia, autoimmune, biliary, malignancy</p> <p><i>Presinusoidal PHT</i>:</p> <ul style="list-style-type: none"> • <i>Intrahepatic presinusoidal</i>: Congenital hepatic fibrosis, noncirrhotic portal fibrosis (10%) • <i>Extrahepatic</i>: Extrahepatic portal venous obstruction (EHPVO): 5–10% <p><i>Acute liver disease</i>: Acute hepatitis, acute liver failure</p> <p><i>Traumatic</i>: Liver injury secondary to accidents, liver biopsy</p>
Biliary	Perforation of bile duct: Spontaneous, iatrogenic
Pancreas	Anterior disruption of pancreatic duct, rupture of pseudocyst
Luminal GI	Intestinal perforation, appendicitis, eosinophilic gastroenteritis (EGE)
Peritoneal	Tuberculosis
Renal	Nephrotic syndrome, peritoneal dialysis
Hematological	Hemolysis, tumors
Lymphatic	Primary intestinal lymphangiectasia, Hennekam syndrome
Cardiac	Complex cyanotic heart disease, CCF, arrhythmia
Vasculitis	Henoch-Schönlein purpura, connective tissue disorder, SLE
Infections	Dengue fever, salmonellosis, leptospirosis, scrub typhus
Malignancy	Wilms tumor, germ cell and ovarian tumors, metastasis
Pseudo ascites	Omental cyst, retroperitoneal lymphangioma

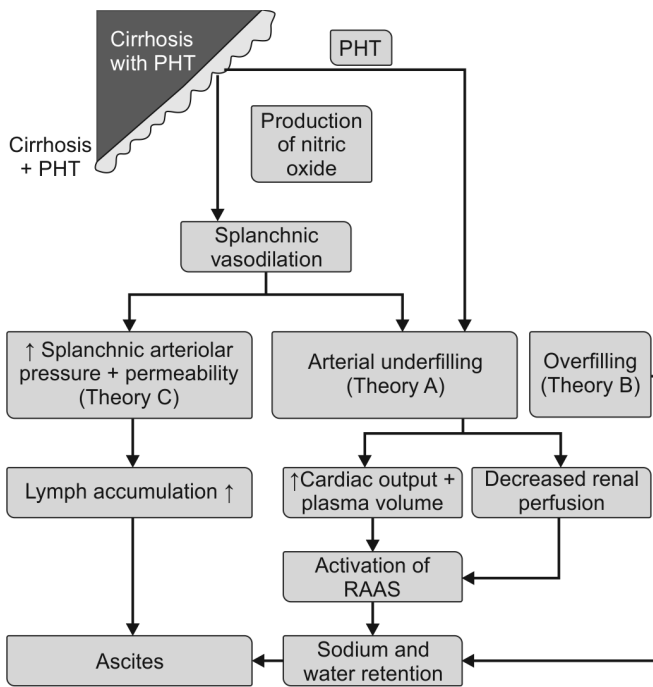

Figure 1 Pathophysiology of cirrhotic ascites

theory of ascites formation and combines arterial under-filling with a forward increase in splanchnic capillary pressure and filtration with increased lymph formation. In cirrhosis, several vasodilators such as the potent nitric oxide, calcitonin gene-related peptide, substance P, carbon monoxide and endogenous cannabinoids are produced which augment the ascites formation.

CLINICAL PRESENTATION

The child may be asymptomatic or have mild abdominal discomfort if the fluid is minimal. An increase in abdominal girth and weight gain may be early symptoms. Anorexia, nausea and growth failure are indicators of increasing ascites. When the ascites is massive and tense, the child presents with breathlessness and respiratory distress (Fig. 2). Pain is not present unless there is an infection such as spontaneous/secondary bacterial peritonitis or malignancy. Depending upon the etiology there may be additional features such as jaundice, gastrointestinal (GI) bleed and altered sensorium in cirrhotic ascites. Fever and contact with tuberculosis (TB) may be suggestive of TB ascites.

The physical findings are a protuberant abdomen, fullness of the flanks, formation of hernias (umbilical, inguinal or femoral) and smiling/inverted umbilicus. The presence of splenomegaly and prominent abdominal veins suggest sinusoidal PHT. Splenomegaly with minimal free fluid in the abdomen and absence of abdominal veins indicates presinusoidal PHT whereas massive ascites and back veins suggest postsinusoidal PHT. Tender hepatomegaly with distended jugular veins and elevated jugular venous pressure suggests cardiac ascites.

Complications

Mechanical Massive or tense ascites may cause respiratory distress, compression of great vessels, abdominal wall hernias (umbilical, inguinal or femoral), gastroesophageal reflux disease, delayed gastric emptying and obstructive sleep apnea syndrome. Pleural effusion or hepatic hydrothorax is a common finding in cirrhotic ascites.

Metabolic complications Dyselektrolytemia may occur secondary to diuretic use.

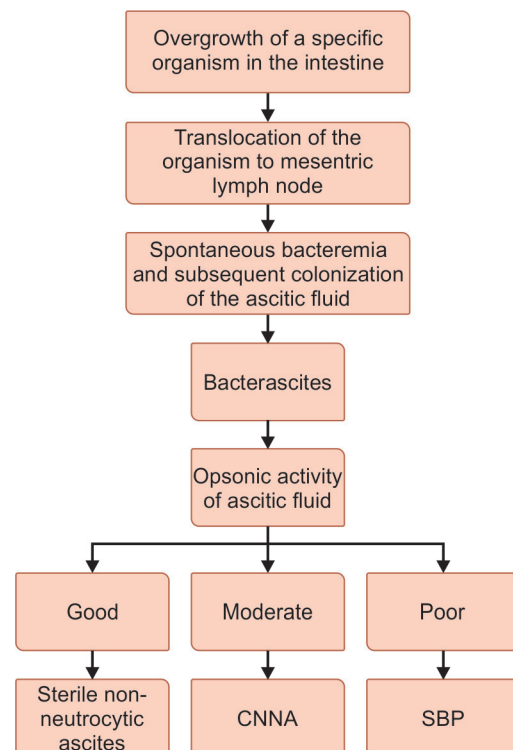

Figure 2 Child with tense ascites

Infection Spontaneous bacterial peritonitis (SBP) is an important complication of cirrhotic ascites seen in 10–30% of patients and is associated with a high mortality. SBP denotes infection of ascitic fluid without evidence of an abdominal source and is usually due to gram-negative bacilli (*E. coli*, *Klebsiella*) and gram-positive cocci (*Streptococcus pneumoniae*, enterococci). The pathogenesis of bacterial peritonitis is shown in Flow chart 1.

Hepatorenal syndrome (HRS) Hepatorenal syndrome is the functional renal failure that occurs in patients with decompensated liver disease, in the absence of an identifiable renal cause.

Differential diagnosis Pseudoascites caused by retroperitoneal lymphangioma, ovarian tumor, large mesenteric cyst can mimic true ascites.

Flow chart 1 Pathophysiology of spontaneous bacterial peritonitis

Abbreviations: CNNA, culture negative neutrocytic ascites; SBP, spontaneous bacterial peritonitis.

APPROACH TO A CHILD WITH ASCITES

Demonstration of Ascitic Fluid

Clinical Signs

Puddle or Lawson's sign This test detects a minimal amount (120 mL) of fluid and is beneficial in small children.

Shifting dullness This finding is based on the alteration of the percussion note in the flanks when the position is changed and the air filled loops are displaced by the fluid. In children at least greater than 500 mL is necessary for demonstration.

Fluid thrill Demonstration of a fluid wave indicates large amount greater than 1,000 mL of fluid in the peritoneal cavity. Ascites is graded according to the International club of ascites as Grade 0 if there is no demonstrable ascites, Grade 1 if mild ascites detected only by ultrasound, Grade 2 if moderate ascites without fluid thrill and Grade 3 if large/tense ascites with marked distension of abdomen and fluid thrill.

Imaging Studies

Plain abdomen skiagram reveals ground glass appearance, obliteration of the hepatic angle (Hellmer's sign), flank stripe sign and *mickey mouse sign*. On ultrasound (US) of the abdomen: Minimal peritoneal fluid (10–20 mL) has been detected in 7% of asymptomatic children. Limitations to ultrasound include obesity and complex, loculated ascites since fat and air are poor conductors of sonic waves. US also helps in the etiological diagnosis and guiding paracentesis. CT and MRI are as sensitive as US of abdomen in detecting fluid but cost is a limiting factor.

Diagnostic Abdominal Paracentesis

Diagnostic paracentesis is an essential part of the first evaluation. It is a simple, safe method for confirming diagnosis and identifying etiology. It is performed under local anesthesia following aseptic precautions and using the standard technique. Prophylactic platelet or fresh frozen plasma is not recommended prior to paracentesis.

Color The fluid may be watery or transparent in cirrhosis with hypoproteinemia, straw colored in TB and cirrhosis, bloody or hemorrhagic in pancreatic ascites and malignancy, deep yellow or dark brown in biliary ascites, milky or chylous in TB, cirrhosis and intestinal lymphangiectasia (**Fig. 3**).

Cell count Normally the total leukocyte count is less than 500 cells/mm³ with less than 250 polymorphs/mm³. A polymorphonuclear (PMN) count greater than 250 cells/mm³ is suggestive of bacterial peritonitis.

Gram stain and acid-fast bacillus (AFB) stain In SBP, Gram's stain is not routinely required since the infection is paucibacillary with a yield rate of only 10%. However, in secondary bacterial peritonitis, neutrophils and multiple organisms are seen. AFB staining for TB rarely yields positive results.

Culture 10 mL of ascitic fluid directly inoculated into the blood culture bottles increases the positive yield of neutrocytic ascites to 80%. Polymicrobial infection is seen in secondary bacterial peritonitis while mono-microbial infection denotes SBP. There are five subtypes of bacterial ascites of which SBP, Mono-microbial non-neutrocytic bacterascites (MNB) and culture negative neutrocytic ascites (CNNA) are spontaneous bacterial infections. Secondary bacterial peritonitis and polymicrobial bacterascites occur due to an underlying pathological or procedural cause.

Serum ascites albumin gradient (SAAG) This gradient is calculated by subtracting the value of ascitic fluid albumin from the serum albumin estimated concurrently. SAAG is classified as high gradient ascites (> 1.1) and low gradient ascites (< 1.1). High gradient ascites is seen in PHT with a diagnostic accuracy of 97%. Other conditions

Figure 3 Color of ascitic fluid: straw, hemorrhagic, watery, xanthochromic and milky (from Left to right)

where high SAAG is seen are Budd-Chiari syndrome, portal vein thrombosis, acute liver failure and hypothyroidism. Low-gradient ascites is seen in TB peritonitis, pancreatic ascites, biliary ascites, nephrotic syndrome and serositis. SAAG may be falsely high in chylous ascites since lipid interferes with albumin estimation.

Special additional tests High amylase in ascitic fluid [(AF)/serum ratio > 0.4] indicates pancreatic ascites, urea and creatinine in AF more than the serum indicates uroascites, AF bilirubin greater than 6 mg/dL indicates biliary ascites and AF triglyceride greater than 200 mg/dL indicates chylous ascites. GeneXpert MTB/RIF test is a new molecular test for TB that detects the DNA in TB bacteria.

Complications Paracentesis is generally considered a safe procedure when performed cautiously. Complications are uncommon though infection, dyselektrolytemia, bowel and bladder perforation and large intra-abdominal hemorrhage have been reported.

Specific Investigations

Apart from basic investigations such as complete blood count, blood sugar, biochemical tests of the liver and renal function tests, additional investigations to confirm the etiology are done in children presenting with ascites. In children with short duration ascites serology for leptospirosis, dengue, *Salmonella* and markers for HAV and HEV should be done. In cirrhotic ascites, viral markers for HBV, HCV, Wilson disease work-up, auto antibodies should be included. Upper GI endoscopy is done to document varices and to perform duodenal mucosal biopsy.

MANAGEMENT

In children with non-cirrhotic ascites, definitive interventions and treatment of the underlying disease helps in the resolution of ascites. Management of cirrhotic ascites is detailed here:

Cirrhotic Ascites

Asymptomatic children with minimal ascites may not require any intervention. The weight of the child and a proper fluid intake and output chart should be monitored and recorded daily. The two components of therapy are sodium restriction and diuretics. The aim is to achieve a negative sodium balance so that the ascites decreases and then maintain a sodium balance to prevent recurrence. The management of cirrhotic ascites is shown in **Flow chart 2**.

Restriction of sodium and fluids In infants and children sodium is restricted to a maximum of 1–2 mEq/kg/day and 1–2 g/day (44–88 mEq) in adolescents. Water restriction is necessary only if serum sodium is less than 125 mEq/L.

Diuretics In cirrhotic ascites renal sodium retention is due to hyperaldosteronism. Aldosterone antagonist spironolactone is the diuretic of choice being more effective than loop diuretics in the management of ascites. The metabolites of spironolactone act on the cortical and medullary collecting tubule thereby inhibiting the binding of aldosterone.

Spironolactone is started at 2–3 mg/kg/day (max: 100 mg) given as a single dose in the morning and if necessary, increased by 2 mg/kg once in 5–7 days till the maximum dose of 4–6 mg/kg (up to 400 mg/day) is reached. The goal of therapy is to reduce body weight by 300–500 g/day until ascites resolves.

A combination of aldosterone antagonist and a loop diuretic (dual therapy) may be beneficial when there is no response with spironolactone as monotherapy, quicker response is required or recurrent ascites. Furosemide at 1 mg/kg/day (max: 40 mg) may be added to spironolactone.

Supplemental albumin When serum albumin is less than 2.5 g/dL it may be advisable to replace serum albumin since low albumin may worsen ascites.

Large volume paracentesis (LVP) Large volume paracentesis is the treatment of choice for diuretic resistant severe ascites or those with respiratory compromise. LVP is defined as removal of ascitic fluid 50 mL/kg or more of dry body weight. Studies have shown that a mean volume of 118 ± 56 mL/kg can be safely removed over one time. This is the first line treatment for tense ascites and second line treatment for refractory ascites. LVP should be done under cover of 0.5–1 g of albumin/kg or 8 g/L of AF drained.

Refractory ascites Diuretic-resistant ascites (DRA) is present if it is unresponsive to 1 week of maximum dosage of dual therapy. Diuretic-intractable ascites (DRI) is the term used when there are diuretic-induced complications that preclude the usage of an effective diuretic dosage. The various modalities of managing refractory ascites include LVP with albumin administration, continuing diuretic therapy, transjugular intrahepatic porto systemic shunt (TIPSS) and liver transplantation.

Transjugular intrahepatic porto systemic shunt Children with refractory ascites and in those awaiting liver transplantation, TIPSS acts as a bridge therapy. TIPSS lowers portal pressure and is therefore effective in decreasing ascites. Contraindications for TIPSS include severe liver failure, renal failure, sepsis and severe cardiopulmonary disease.

Peritoneovenous shunting (Leveen and Denver shunts) A conduit is created within the peritoneum for the fluid to drain into the superior vena cava via the right internal jugular vein in those with intractable ascites.

Liver transplantation This modality is the only definitive therapy for children with end stage liver disease and refractory ascites. The outcome is good if transplant is performed before the development of hepatorenal syndrome.

Newer modalities This includes atrial natriuretic peptide (ANP), terlipressin, docarpamine (an orally active prodrug), V2 receptor antagonist (OPC-3126), k-opioid antagonist (niravoline) and adenosine-1-receptor antagonist (FK352).

Prevention of SBP Since the occurrence of SBP is associated with increased mortality it is necessary to prevent SBP. Long-term oral norfloxacin at a dose of 5–7.5 mg/kg once a day is recommended.

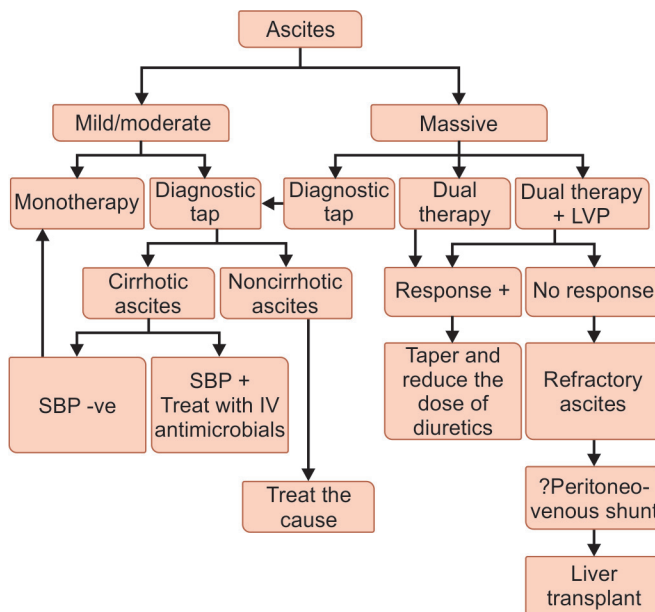

PROGNOSIS

Persisting ascites in a child with cirrhosis is a marker of decompensation. Refractory ascites and SBP are also indicators of a poor prognosis in cirrhosis.

Flow chart 2 Management of cirrhotic ascites

IN A NUTSHELL

1. Ascites is the pathologic accumulation of fluid in the peritoneal cavity.
2. The most important cause of ascites is cirrhosis.
3. Noncirrhotic causes should be considered and identified for definitive therapy.
4. Ultrasound of abdomen is an excellent noninvasive modality for diagnosis.
5. Paracentesis is a safe diagnostic and therapeutic procedure.
6. Spontaneous bacterial peritonitis should be recognized and appropriately treated.
7. Diuretics should be administered at the proper dosage and duration for effective results.
8. Liver transplant is indicated in refractory ascites and end stage liver disease.

Chapter 35.21

Intestinal Obstruction

Ketan Parikh

Intestinal obstruction is defined as failure of effective aboral progression of the gastrointestinal contents. The initial clinical presentation is similar to various other medical conditions in children and a very high index of suspicion is therefore required. Early and effective management will help to reduce the morbidity and complications which may otherwise follow. Most cases of intestinal obstruction in children are due to congenital anomalies. However, in our country abdominal tuberculosis continues to form a recognizable cause, whereas meconium ileus and Crohn's disease which are relatively common in the west are less common.

ETIOLOGY

The failure of the aboral progression may be either due to a mechanical obstruction of the GI tract (dynamic) or the ineffective propulsive peristalsis (adynamic). The mechanical obstruction may be due to pathology of the wall of the intestinal tract, external compression of the intestinal tract; an intraluminal occlusion of the passage; or a combination of two of the above acute or chronic obstruction. Common cases are listed in **Box 1**.

BOX 1 Common causes of intestinal obstruction in children

- Intestinal atresias—duodenal, ileal, jejunal and colonic in that order of frequency
- Volvulus neonatorum due to intestinal malrotation
- Hirschsprung disease
- Anorectal malformations—not classically described as intestinal obstruction
- Intussusception
- Strangulated hernias—(external–inguinal/umbilical); Internal due to bands like persistent vitellointestinal bands, Ladd bands or other various unnamed bands and mesenteric defects
- Meconium ileus
- Inflammatory or postoperative adhesions
- Ascariasis bolus
- Tuberculous adhesions, cocoon formation, strictures
- Intestinal duplication cysts or mesenteric cysts.

PATHOPHYSIOLOGY

Once mechanical obstruction sets in, the bowel proximal to the obstruction undergoes dilatation due to the accumulated contents. There is hyper-peristalsis in an attempt to overcome the obstruction and this leads to colicky pain. If the obstruction is gradual or chronic, then this proximal bowel also undergoes hypertrophy. The persistence of obstruction and dilatation may initiate reverse peristalsis in the proximal bowel and this may cause vomiting. The dilatation of the obstructed bowel also increases the quantity of the intestinal secretions. While the pylorus normally prevents the reverse egress of the duodenal (bilious) contents into the stomach, the dilatation and reverse peristalsis of this portion of the bowel leads to bilious vomiting or gastric aspirates. The stagnant intestinal contents provide a potent medium for the overgrowth of intestinal commensals. This leads to mucosal inflammation, increased intestinal secretions and formation of increased amounts of gas.

Occasionally, the dilated proximal loop of bowel may twist or kink on itself thus creating a secondary obstruction more proximally—*closed loop syndrome*. This sequestered section which is obstructed

both proximally and distally gradually dilates due to accumulated gas and intestinal secretions with potential chances of perforation. Prior to perforation, the bowel undergoes massive dilatation with resultant ischemia of its wall. At this stage the pain is severe and usually unresponsive to most antispasmodics. Once the bowel perforates, the dilatation settles due to leakage of the contents into the peritoneal cavity and the pain settles giving a false sense of recovery. Gradually the leaked bowel contents lead to localized or generalized peritonitis and progressive deterioration of the general condition. The high gastric aspirates or the sequestered fluid in the dilated bowel lumen and the edema of the bowel wall collectively contribute to massive fluid losses (overt and covert) and electrolyte disturbances. Before perforation, infected foci may develop in the ischemic areas of the bowel wall leading to portal pyemia and rapid deterioration.

Adynamic obstruction is usually secondary to a pre-existing condition. Electrolyte disturbances, sepsis, metabolic disturbances and drugs are the few common causes. Perforation may occur secondary to a closed loop obstruction but severe fluid and electrolyte disturbances are common complications.

CLINICAL FEATURES

Children present with a variable combination of the following features: vomiting—initially nonbilious but gradually becoming bilious; abdominal distension; constipation; and abdominal pain. The mode of presentation depends on the following factors:

- *The type of obstruction:* Adynamic obstruction usually has an underlying primary pathology. Abdominal distension is a prominent feature and pain is a late symptom. Constipation may not be absolute and the patient may pass intermittent mucoid discharge with or without fecal matter.
- *The age of the patient:* In an infant, pain may manifest only as excessive crying and thus may be missed for some time.
- *The level of obstruction:* In high obstructions, the primary presentation is vomiting whereas abdominal distension may never be seen or is restricted to the upper abdomen. Additionally, the patient (even a newborn) may pass some stools but a careful history reveals that these are generally pale (mucoid). However, the patient tends to lose excessive fluids in vomiting and gastric aspirates. In lower intestinal obstructions, vomiting is a late sign whereas constipation is the primary symptom.
- *The stage of intestinal obstruction:* In patients, who present late, pain may reduce after perforation of the bowel and features of sepsis and metabolic disturbances may predominate rather than abdominal signs.

DIAGNOSIS

Bilious vomiting is the strongest clinical indicator of an intestinal obstruction. Passage of pure mucoid discharge per rectally is also a strong indicator. Abdominal colics unresponsive to oral medications and passage of blood stained mucus per rectum are warning signs of compromised bowel vascularity. Sudden fall in platelet count in a sick child may be the earliest indicator of bowel gangrene.

IMAGING

A plain vertical or lateral decubitus film of the abdomen is the most informative.

- The presence of fluid levels is indicative of obstruction; the number of fluid levels suggests the level of obstruction (**Fig. 1**).
- If the colon is also dilated, it indicates either a low obstruction or adynamic obstruction.
- A supine film (although may not show fluid levels), shows the bowel pattern better and if showing an isolated massively small bowel loop may suggest a closed loop obstruction and thus an indication for early intervention.

Figure 1 Fluid levels in a child with intestinal obstruction

- If the dilated bowel loops are seen in a relatively white background, it may indicate excessive peritoneal fluid/thickened (edematous) bowel wall due to peritonitis (**Fig. 2**).
- Pneumoperitoneum is a rare finding even in the presence of bowel perforation thus its absence has negligible relevance. A large pneumoperitoneum is seen only in gastric or duodenal perforations or in colonic perforations.
- Intramural air or air in the portal vein is indicative of bowel wall necrosis with gas forming bacteria.
- Air in the rectum in a case of multiple fluid levels suggests an adynamic obstruction.

Ultrasonography

Ultrasonography of the abdomen may additionally confirm the presence of fluid in the peritoneal cavity and the nature of the fluid (thick fluid suggesting pus). It may also identify pathologies like intussusception; and may identify an adynamic bowel loop. A concomitant Doppler study may indicate its vascularity. CT imaging of the abdomen is rarely done in children. It may yield information on localized inflammatory pathologies of the bowel and also help identify internal hernia.

Figure 2 Fluid levels surrounded by ground glass appearance—peritonitis

MANAGEMENT

Most children with intestinal obstruction are given a trial of conservative management, traditionally referred to as *drip and suck*. This involves keeping the patient nil orally and intravenous supplementation along with a regular deflation of the proximal GI tract with regular aspiration through a nasogastric tube. It decreases the pressure on the bowel wall, reducing the edema and may result in opening out the narrowed portion of the bowel. Supplementation of electrolytes and judicious use of antibiotics are necessary in most cases. The indications for surgery are listed in **Box 2**.

BOX 2 Indications of surgery in intestinal obstruction

- Suspicion of closed loop obstruction (fear of perforation)
- Volvulus neonatorum
- Suggestion of strangulated hernia
- Any suggestion of perforation
- Suggestion of peritonitis
- Any suggestion of vascular compromise of section of bowel
- Associated peritonitis
- Failure of conservative treatment.

OUTCOME

The outcome depends primarily on the nature of the obstruction and the associated complications, if any. In most cases of pure obstruction with negligible complications, the outcome is excellent even if surgical correction is required. Presence of sepsis and associated comorbidities may affect the final outcome.

IN A NUTSHELL

1. In children with bilious vomiting, intestinal obstruction should be suspected.
2. Abdominal pain which is not relieved with antispasmodics should raise a suspicion of compromised bowel vascularity.
3. Non-feculent passage of blood or mucus per rectum should raise the possibility of intestinal obstruction in a child with acute abdomen.
4. A vertical plain film of the abdomen is the single most helpful imaging modality.

Chapter 35.22

Intussusception

Ketan Parikh

Intussusception is characterized by the telescoping of one part of the intestine into another (**Fig. 1**). Even though it may occur at any age, the most common age of presentation is 8–10 months. Hence, rotavirus infection may play a role.

ETIOLOGY

- **Idiopathic** This is the most common variety of intussusception and occurs in the infant. It is usually linked with the period of weaning.
- **Secondary intussusceptions** Occur due to an intraluminal pathology or growths like polyps, submucosal masses, etc. (**Fig. 2**) which act as lead points. Submucosal hematomas seen in Henoch-Schönlein purpura may also contribute.

PATHOGENESIS

The most common site of the idiopathic variety is the ileocecal region, and the most common lead point is a hypertrophied Peyer's patch. This hypertrophy occurs due to a change in the bacterial flora during weaning or gastrointestinal infection or following ingestion of infected respiratory secretions. The telescoped bowel carries with it its attached mesentery. The resultant compression of the mesentery progressively leads to lymphatic and venous congestion of the involved segment of the bowel and finally arterial compression. The congested and hyperemic mucosa of the innermost layer of intussusception causes secretion of blood and mucus, characteristically labeled as *red currant jelly stool*. Further vascular compromise may then lead to gangrene of a portion of the bowel (**Fig. 3**).

CLINICAL FEATURES

Disease usually occurs in a classically healthy, well-nourished child, less than one year of age. There may be a prior history of an upper respiratory tract infection. Colicky pain occurs in short bursts with intermittent periods of remission. Vomiting is bilious only in late cases. The hallmark of diagnosis is red currant jelly stools—usually with no fecal matter (a differentiating feature from dysentery) (**Fig. 4**). On abdominal palpation, intussusception may be felt as a banana-shaped mass with the concavity towards the umbilicus. Occasionally, the mass can be felt per rectally. In late cases, features of septicemia and peritonitis may be seen.

DIFFERENTIAL DIAGNOSES

Intussusception is very commonly mistaken for dysentery and hence the diagnosis may be delayed. In intussusception, the stool contains mainly blood and mucus without fecal matter. Intestinal obstruction (fluid levels) and peritonitis are very late signs and one should never wait for them to appear.

APPROACH TO DIAGNOSIS

Clinically, a palpable (banana shaped) bowel mass is suggestive. Ultrasound of the abdomen can be diagnostic (**Fig. 5**). It shows the *pseudo-kidney* sign or the *bowel-in-bowel* sign. A Doppler study performed simultaneously may indicate the blood flow to the portion. Alternatively, a barium enema may show the *coiled spring* sign or the *claw sign* (**Fig. 6**). Laboratory studies may show evidence

Figure 1 Diagrammatic representation of parts of intussusception

Figure 2 Luminal sessile polyp, a lead point for a secondary intussusception

Figure 3 Diagrammatic representation showing the compression of the mesentery and resultant mucosal ischemia

Figure 4 Rectal bleeding without fecal matter

Figure 5 Ultrasonographic picture of intussusception

Figure 6 Barium enema showing *coiled spring sign*

of blood loss, dehydration and electrolyte imbalance. A CT scan is rarely indicated except in cases where there is excessive gas in the bowel loops which precludes a good sonographic assessment.

MANAGEMENT

Once suspected, the patient should be kept nil orally and a nasogastric decompression initiated as soon as possible. Correction of metabolic disturbances, including intravenous supplementation of fluid should be started before attempting any hydrostatic reduction. If necessary, blood transfusion may be started along with broad-spectrum and antianaerobic antibiotics.

Definitive Treatment

If diagnosed within 24 hours of onset, hydrostatic reduction (under sonographic or radiological control) may be attempted by a pediatric surgeon, with facilities for immediate surgery kept ready in case of complications. *It is important that any patient taken up for hydrostatic reduction should be ready to be taken to the operation theater immediately in case of a leak or perforation.* Therefore, such a procedure must be undertaken only in the presence of a surgeon after initial resuscitation of the patient. Reduction may be attempted under laparoscopic monitoring in those patients where bowel vascularity is suspect. If hydrostatic reduction fails or is contraindicated, exploratory laparotomy with operative reduction or if necessary, resection and anastomosis may have to be undertaken.

IN A NUTSHELL

1. Intussusception is one of the most common abdominal emergencies in infants with disastrous consequences, if not treated in time.
2. In any infant with severe colicky pain or bleeding per rectum, intussusception should be ruled out.
3. A good ultrasonographic evaluation is reasonably reliable to diagnose intussusception.
4. Hydrostatic reduction should not be initiated on an out patient basis without intravenous resuscitation.

Chapter 35.23

Appendicitis

Prakash Agarwal

Appendicitis is a medical emergency that requires prompt surgery. It is one of the most common acute surgical problems in children and is most commonly misdiagnosed. Left untreated, an inflamed appendix will eventually perforate leading to peritonitis. The incidence of appendicitis varies worldwide. In India more than 2,70,000 cases are reported annually. Although it can strike at any age, appendicitis is rare under age 2 and most common between ages 10 and 30.

ETIOLOGY

Appendicitis may be a result of luminal obstruction followed by infection due to *Yersinia*, *Salmonella* and *Shigella*. The cause of luminal obstruction may be an inspissated and calcified fecal mater (fecalith). Appendiceal lymphoid hyperplasia may cause luminal obstruction leading to appendicitis. Parasitic infection such as *Entamoeba*, *Strongyloides*, *Enterobius vermicularis*, *Schistosoma* or *Ascaris* can cause appendicitis. Enteric and systemic viral infection can also lead to appendicitis.

PATHOGENESIS

Spectrum of appendicitis evolves from a simple infection to perforation. The varying stages of appendicitis include acute appendicitis, suppurative appendicitis, gangrenous appendicitis and perforated appendicitis.

CLINICAL FEATURES

The child may complain of vague gastrointestinal symptoms before classical presentation sets in. There may be anorexia, indigestion or change in bowel habits. Initially the child may complain of pain around the umbilicus which gets localized to the right iliac fossa. The continuous inflammation of the appendix will cause distention of the appendiceal wall leading to nausea and vomiting. After a few hours of nausea and vomiting, pain sets in. As the pressure inside the inflamed appendix increases, the lymphatics get obstructed, leading to further edema and swelling. Further increase in pressure leads to venous congestion resulting in ischemia, infarction and gangrene. This leads to bacterial transmigration of the wall of appendix. As a result of mediators released by ischemic tissue, white blood cells and bacteria, child develops fever, tachycardia and leukocytosis.

An inflamed appendix coming in contact with the parietal wall triggers off pain localized in the right iliac fossa or the McBurney's point. Further increase in intraluminal pressure will lead to perforation, localized abscess formation, if omentum conceals the perforation or it may lead to generalized peritonitis. Signs of acute appendicitis are fever more than 101°F, high leukocyte count and tachycardia with tenderness in the McBurney's point. A pelvic abscess due to perforated appendix may lead to diarrhea, or tenesmus.

Younger children usually present with a complicated appendicitis because of inability to give proper history and low index of suspicion by the clinician. The most common presenting symptoms for these children will be vomiting, followed by fever and abdominal pain.

DIAGNOSIS

Appendicitis can mimic a variety of intra-abdominal conditions (**Table 1**). The clinical diagnosis of appendicitis is challenging and may be mistaken for acute gastroenteritis, viral mesenteric adenitis, Meckel diverticulitis and Crohn's disease. Extra-abdominal causes like pleurisy and pneumonia can mimic acute appendicitis.

Physical Examination

Clinically, a child with appendicitis will be quite and lie in bed with minimal movement. An older child may limp while walking with a grumpy face. They will give history of pain with every jerk while walking or coughing. If the child is asked to show the area of pain, they will usually point to the McBurney's point.

Palpation should be started away from the site of tenderness and progressed towards the site of pain. This will help in eliciting the Rovsing sign which indicates peritoneal irritation due to referred pain. A classical McBurney's point tenderness is diagnostic of acute appendicitis in conjunction with an elevated total leukocyte count, tachycardia and fever. Tenderness may be mild during the initial stages and can be elicited by palpation or percussion. The pain of retrocecal appendix may be elicited midway between the 12th rib and posterior superior iliac spine. Rectal tenderness will suggest a pelvic appendicitis.

A perforated appendicitis may present in the form of local or generalized guarding and rigidity, depending on the severity of the disease. Rebound tenderness may indicate localized peritonitis. If the diagnosis is in doubt, serial abdominal examination at intervals of 6–12 hours can be helpful.

Imaging

A plain X-ray may suggest fecaliths in 10–20% of cases but is rarely done. A chest X-ray to rule out pneumonia may be needed. An ultrasound may suggest a noncompressible appendix with an AP diameter of more than 7 mm. Presence of an appendicolith, with periappendiceal fluid may be confirmatory in the hands of a skilled radiologist. CT scan may show an enlarged appendix with thickening of the appendiceal wall, periappendiceal fat stranding

Table 1 Differential diagnosis of acute appendicitis

Gastrointestinal system	Acute gastroenteritis Acute viral mesenteric adenitis Constipation Meckel diverticulitis Crohn's disease Typhoid Appendiceal tumor, carcinoid tumor
Hepatobiliary	Hepatitis Cholecystitis
Urinary system	Hydronephrosis Pyelonephritis Ureteral or renal calculus
Uterus, ovary	Ovarian torsion Ruptured ovarian cyst
Others	Primary peritonitis Henoch-Schönlein purpura Pancreatitis Pleuritis Pneumonia Psoas abscess Torsion of appendix epiploica

and enhancement of appendiceal wall. It may help in the diagnosis due to anatomical abnormality such as malrotation or situs inversus. The sensitivity of CT scan is over 90% and its specificity is over 80%. Serial examination by the same examiner is the safest and the most accurate diagnostic tool.

Hematology

Leukocytosis with neutrophilia and increased CRP may be seen but are not diagnostic.

MANAGEMENT

In early noncomplicated appendicitis only perioperative antibiotics are required.

The gold standard treatment for appendicitis is prompt surgery. Majority of the appendicitis today are operated by laparoscopic methods (**Fig. 1**). Open appendectomy is becoming rarer in surgical practice though the trainee should be aware of it if having problems in performing laparoscopic appendectomy. The advantages of laparoscopic appendectomy are many fold including shorter hospitalizations, better scar, decreased

postoperative pain, decreased wound complications, increased ability to diagnose coexisting conditions or other pathological conditions, surgical ease in obese patients and faster postoperative recovery. Laparoscopic appendectomy for complicated appendicitis is becoming popular.

If not treated in time acute appendicitis may lead to complications like perforation and peritonitis. With the advent of higher antibiotics and awareness there is a decline in the incidence of complications. Complications of appendicitis include wound infection, intra-abdominal abscess formation, postoperative intestinal obstruction, prolonged ileus and enterocutaneous fistula. Acute appendicitis in females should be treated with a low threshold for surgery as complicated appendicitis may lead to fertility problems in the future.

In recent years due to broad spectrum antibiotics the mortality due to complicated appendicitis is almost nil. Antibiotics have markedly decreased the incidence of various complications listed above. Although the length of hospitalization and morbidity due to complicated appendicitis still far exceeds those with simple appendicitis, the overall morbidity in children with complicated appendicitis is less than 10%.

Figure 1 Laparoscopic view of a case of acute appendicitis

IN A NUTSHELL

1. Appendicitis remains the most common acute surgical condition of the abdomen in children.
2. Luminal obstruction due to fecalith remains the most common cause of acute appendicitis.
3. Salient clinical features of acute appendicitis are—right iliac fossa pain, nausea and vomiting, fever associated with tachycardia and elevated leukocyte count.
4. The gold standard treatment for appendicitis is laparoscopic appendectomy.

Chapter 35.24

Testicular Torsion

Prakash Agarwal

Torsion of the testis is a surgical emergency which results in occlusion of the gonadal blood supply. If unrelieved within hours it may lead to necrosis. It occurs usually in fully descended testis but may be seen in undescended testis as well. Previously the incidence of torsion in an undescended testis was very high. However due to the present practice of earlier surgical intervention torsion in an undescended testis is now rare.

PATHOGENESIS

Torsion may be intravaginal or extravaginal. Intravaginal torsion is more common due to high investment of the spermatic cord by the tunica vaginalis. Extravaginal torsion is less common and confined to the perinatal period.

In *intravaginal torsion*, the long narrow mesorchium allows the testis to lie horizontally rather than fixed vertically as in the normal testis. The pendulous testis with a high investment of the cord has a horizontal lie and allows the testis to be readily twisted by cremasteric contractions or by a jerky movement. This phenomenon is seen more commonly in undescended testis.

In *extravaginal torsion* there is a loose areolar plane around the moving gubernaculum and testis into the scrotum, which allows the entire testis and spermatic cord to twist. Beyond the newborn period testicular torsion is almost always associated with the bell clapper deformity. Cremasteric contraction may be either the cause or the effect of torsion. The high incidence of testicular torsion in puberty is due to the increased levels of testosterone making the testis bulky and more prone for torsion. The most common age for torsion of the testicular appendix is around 11 years. This peak, just before the onset of puberty may be related to early pubertal stimulation by estrogen. Chances of necrosis of the testis are less, if the number of twists is less or there are chances of spontaneous untwisting. In adolescent boys necrosis may occur after as early as 2 hours and very likely after 24 hours. The testis has four testicular appendages of which the hydatid of Morgagni is the most frequently twisted.

CLINICAL FEATURES

Torsion of the testis is commonly seen in the adolescent age group but the testicular appendage torsion is seen before puberty. Usually there are two peaks of torsion of the testis: in the early neonatal period and in adolescent boys aged 13–16 years. Usually testicular torsion is heralded by the sudden onset of pain in the testis, lower abdomen or groin, associated with nausea and vomiting. The hemiscrotum looks red and edematous (**Fig. 1**) and if untreated leads to a bluish discoloration of the scrotum. In torsion of a testicular appendage, a bluish black spot (blue-dot) may be seen through the skin at the upper pole of the testis. This is more prominent in the white population compared to dark skin people. Palpation of this area causes extreme pain, whereas the rest of the testis is not so painful. Once secondary inflammation and edema of the scrotum occur, it may be impossible to distinguish between testicular torsion and torsion of a testicular appendage.

DIAGNOSIS

Inflammatory conditions of the scrotum like epididymo-orchitis, epididymitis may mimic torsion testis. Idiopathic scrotal edema, fat

Figure 1 Red and edematous hemiscrotum in torsion of testis

necrosis and mumps orchitis are the other differential diagnoses. Radioisotope scan and Doppler ultrasound has been used to determine whether there is blood flow to the testis or not. These tests may be more useful after puberty as the testicular volume is greater after puberty. However, exploration is recommended for all doubtful cases of acute scrotum.

MANAGEMENT

Treatment of torsion of the testis is immediate operative exploration of the scrotum. The hemiscrotum is opened in the midline with a diathermy. The testis is delivered through the incision, and inspected. If the testis is twisted it is untwisted and the viability is assessed. If the torsion is early the circulation may return within few minutes. If there is congestion, then it may be better to observe the testis for several minutes by giving warm packs and asking the anesthetist to give 100% oxygen. If there is no improvement in the viability of the testis then an orchidectomy is done by double ligation of the testicular vessels. If the testis appears viable, no further treatment is required. The appendage testis is inspected and excised, if there is torsion. In case of epididymo-orchitis removal of the edematous fluid leads to relief of symptoms. Exploration of the contralateral testis is usually done since the anomaly is bilateral and the testis is fixed in all cases which required orchidectomy.

OUTCOME

The management of a testis of doubtful viability on operation is controversial. Leaving behind such a testis is to see if they will recover any hormonal function. However it has recently been reported that children older than 10 years of age are at risk of developing antisperm antibodies. It has been seen that men who underwent fixation of ischemic testes at adolescence had poor spermatogenesis later in life. Some authors therefore recommend preservation of a doubtful testis if the boy is below 10 years and orchidectomy for those above that age.

PREVENTION

Adolescents should be made to report sudden acute or recurrent testicular pain. Prophylactic bilateral orchidopexy may be justified, especially if there is a horizontal lie of the testes on clinical examination.

IN A NUTSHELL

1. Torsion testis is a surgical emergency with a high incidence of gonadal necrosis if not treated early.
2. Torsion of the appendage of testis, epididymo-orchitis and acute scrotal edema are differential diagnosis.
3. Doppler ultrasound may suggest a reduced flow in cases of torsion but is not reliable in prepubertal children, since their testicular volume is less.
4. Diagnosis is clinical and treatment is immediate exploration. All doubtful cases also require exploration.

Chapter 35.25

Inguinal Hernia

Prakash Agarwal

Protrusion of abdominal viscus through the patent processus vaginalis in children is termed as hernia. It is one of the most common elective surgeries performed in children. The highest incidence is in premature infants (16–25%). Inguinal hernia is commonly seen during the first year of life, with a peak incidence in the first few months. Male to female ratio is between 3:1, and 60% of the hernias are right sided. In males, this is possibly the result of the later descent of the right testicle than the left. Bilateral hernias occur in 10% of cases (**Fig. 1**). Approximately 11.5% of patients have a family history of hernia.

PATHOGENESIS

Indirect inguinal hernia is the result of failure of the processus vaginalis to close. The processus vaginalis is an invagination of the peritoneum through the internal ring through which the testis passes from the 7th month to 9th month of gestation. In females the canal of Nuck corresponds to the processus vaginalis and communicates with the labia majora. Reduced release of calcitonin gene-related peptide (CGRP) has been implicated in the formation of hernia and hydrocele.

Incarcerated hernias result from entrapment of intestine, appendix, tubes and ovaries in females or other viscera within the hernia sac. If the hernia is not reduced, strangulation may occur, and blood supply to the incarcerated organ may be reduced to the point of gangrene. The patient may present with signs of peritonitis. Incarceration is seen commonly in infants below 6 months.

CLINICAL FEATURES

Parents complain of noticing a bulge in the groin, labia or scrotum. Hernias may be seen at birth or even months after birth. They are usually asymptomatic and appear during crying, coughing or conditions due to raised intra-abdominal pressure. On examination a bulge may be seen and palpated in the inguinal region over the spermatic cord. If it is not present, the spermatic cord may be palpated to determine thickening-silk string sign. A positive sign indicates thicker cord structures within the inguinal canal compared with the normal side. If a hernia is not seen on

Figure 1 Bilateral inguinal hernia in a boy

physical examination, the history given by parents can be taken as a strong evidence for operating on the child. Obstructed hernia may lead to intermittent pain and irritability, abdominal distention, vomiting and obstipation.

DIAGNOSIS

Inguinal hernia is a clinical diagnosis made by history and physical examination. Plain X-ray abdomen if done, may show bowel loops in the scrotum. Ultrasound of the inguinal region can demonstrate herniation of omentum or bowel loops intermittently. It has gained popularity as an adjunct to physical examination. It is noninvasive and has an accuracy of 97%.

SURGERY

Herniotomy is advised at the earliest, since it will not resolve spontaneously. In young infants it should be performed immediately as the chances of obstruction are very high. Most children are operated under general anesthesia as day care surgery except premature infants who are prone for apneic spells. The repair is done with absorbable sutures which do not need removal later.

Laparoscopic repair in children has been controversial. Advantages include minimal handling of the vas, less pain, earlier return to school, repair of bilateral hernias through the same ports and easier repair of recurrent hernias. Disadvantages include longer operating time and a prolonged learning curve for the surgeons and increased cost. Laparoscopy involves insertion of 3 X 5 mm ports, correct identification of the side of hernia, excising the hernial sac and purse string intracorporeal suturing and closing the hernial sac.

Since patients presenting with left sided hernias are more likely to have bilateral hernias. Many surgeons recommend routine exploration of the opposite side. In such situations laparoscopy has the advantage of allowing direct visualization of the contralateral internal ring and repairing it at the same time.

Postoperative complications Some children may develop scrotal swelling in the postoperative period, which resolves spontaneously. Acquired undescended testis after hernia repair is an uncommon complication. Recurrence after hernia repair is reported in less than 1% of children with uncomplicated hernia, but may be as high as 15% in premature infants and 20% in incarcerated hernias. Accidental transection of the vas during surgery should be repaired immediately.

IN A NUTSHELL

1. Inguinal hernia is commonly in the first year of life, with higher incidence in premature infants.
2. The most common cause of indirect inguinal hernia in children is a patent processus vaginalis.
3. Inguinal hernia is a clinical diagnosis and surgical repair is recommended at the earliest.
4. Surgery is a day care procedure except in premature infants who are prone for apneic spells.

Section 36 DIARRHEAL ILLNESSES

Section Editor AK Patwari

Chapter 36.1

Acute Watery Diarrhea

AK Patwari

Diarrhea remains the second leading cause of death globally among under-5 children. Despite a clear understanding regarding pathophysiology of diarrheal diseases and availability of a simple, inexpensive and effective intervention, i.e., oral rehydration therapy (ORT), acute diarrhea (AD) continues to kill children as a result of dehydration and its consequences. Repeated and prolonged episodes of diarrhea have even more deleterious effects and may eventually result in growth failure, intercurrent infections and problems associated with severe malnutrition and even death.

EPIDEMIOLOGY

The global annual burden of diarrhea is huge, causing 11% or 801,000 deaths among children less than 5 years of age. Most deaths occur in children of rural background in developing countries especially in Africa and South Asia due to limited access to safe drinking water, sewage disposal and health-care and reduced opportunities for personal sanitation, hygiene, and safe food preparation. Introduction of ORT has revolutionized management of diarrhea with significant reduction in diarrhea-related mortality, but the morbidity has not decreased substantially with each child less than 5 years of age experiencing an average of 3 (range 2.8–6.3) episodes of diarrhea annually. Recent data estimates roughly 20 episodes of moderate to severe diarrhea each year per 100 children under the age of 2 years (roughly one episode per five children each year). Infants are reported to have highest burden (30 cases per 100 children each year).

ETIOLOGY

In developing countries, the organisms most frequently associated with acute watery diarrhea include enterotoxigenic *Escherichia coli* (ETEC), enteropathogenic *Escherichia coli* (EPEC), *Shigella* and *Campylobacter jejuni*. Rotavirus is a common cause of severe diarrhea, vomiting and fever leading to rapid dehydration. *Vibrio cholerae* is an important organism in endemic areas and during epidemics. Nontyphoidal *Salmonella* is a common organism in areas where commercially processed foods are widely used and in hospital outbreaks. Most of these organisms cause watery diarrhea. Results of global enteric multicenter study (GEMS) report rotavirus, *Cryptosporidium*, *Shigella* and enterotoxigenic *E. coli* (specifically ST-ETEC) as most common pathogens to cause moderate to severe diarrhea (**Table 1**). Diarrhea may also be caused by antibacterial agents like ampicillin, cotrimoxazole, chloramphenicol, amoxicillin, and clindamycin. Pseudomembranous colitis is the most severe form of antibiotic associated diarrhea.

PATHOGENESIS

Most enteropathogens cause diarrhea by more than one mechanism. The clinical presentation depends upon the underlying pathophysiological changes taking place in the gastrointestinal tract (GIT). Three clinical types of diarrhea have been defined, each reflecting a different pathogenesis and requiring different approach to treatment.

Secretory Diarrhea

It is characterized by acute watery diarrhea with profound losses of water and electrolytes due to sodium pump failure as a result of the action of identified toxins. This group is at risk for rapid development of dehydration and electrolyte imbalance. Common causes are ETEC and *V. cholerae*.

Invasive Diarrhea (Dysentery)

Intestinal mucosal cells are actually invaded by the microorganisms which setup an inflammatory reaction clinically presenting with blood and mucus in the stools. This group is prone to develop other complications like intestinal perforation, toxic megacolon, rectal prolapse, convulsions, septicemia and hemolytic uremic syndrome.

Osmotic Diarrhea

Injury to enterocytes may result in brush border damage and epithelial destruction leading to decreased mucosal disaccharidase activity. Clinical presentation is characterized by passage of large, frothy, explosive and acidic stools. High osmolar solutions given orally [e.g., carbonated soft drinks and oral rehydration solution (ORS) with high sugar content] can also result in osmotic diarrhea. Another complication of osmotic diarrhea is hypernatremia.

PATHOPHYSIOLOGY

Secretory Diarrhea

In healthy adults, around 1–1.5 liters of water are ingested daily in different forms which increase to about 9 liters by the time it reaches the jejunum (**Fig. 1**). From the jejunum, around 8 liters of water is reabsorbed along with Na^+ and Cl^- ; and K^+ and HCO_3^- are secreted into the lumen. Colon receives 1–1.5 liters of water of which more than a liter is reabsorbed along with Na^+ and Cl^- ; and K^+ and HCO_3^- secreted in to the lumen.

Absorptive Processes for Na^+ in Intestinal Epithelium

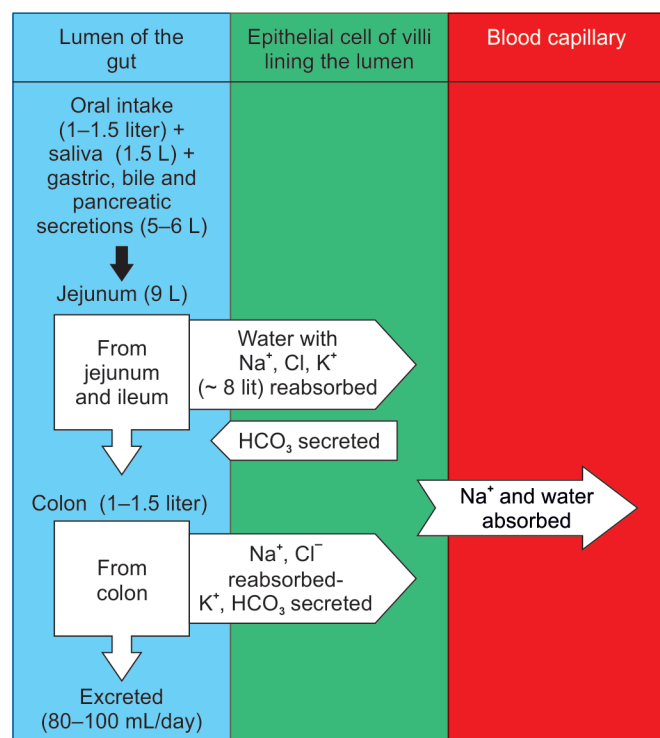

There are several pathways in the intestinal lumen which facilitate absorption of sodium and water into the capillaries thereby maintaining hydration. These pathways include glucose linked Na^+ absorption, direct absorption of Na^+ and Cl^- , Na^+ absorption in exchange for H^+ and bidirectional absorption and secretion of Na^+ and Cl^- (**Fig. 2**).

Table 1 Common pathogens for acute diarrhea in under-5 children

*Indian data (all cases of acute diarrhea)		**Multicentric data from Africa and South Asia (moderate to severe cases of diarrhea)			
Pathogen	Percentage isolated	Pathogen	Percentage isolated		
			0–11 months	12–23 months	24–59 months
Rotavirus	48.1	Rotavirus	27	25.4	14.5
<i>Vibrio cholerae</i> O1	16.4	<i>Cryptosporidium</i>	11.8	8.4	-
<i>Giardia</i>	14.2	Enterotoxigenic <i>E. coli</i> (specifically ST-EPEC)	3.0	5.8	6.1

**Figure 1** Normal absorption of water and electrolytes from the gut

Sodium Pump Failure

Organisms causing secretory diarrhea (*E. coli*, *V. cholerae*) generate several toxins that get attached to the intestinal epithelium and activates ATPase which in turn breaks down in to cyclic adenosine monophosphate (CAMP). These changes results in *sodium pump failure* which leads to disruption of proper absorption of water by opening the chloride channels responsible for releasing water from the crypts. CAMP acts on all the pathways of Na^+ absorption from the lumen, except glucose linked Na^+ absorption, and results in less absorption of Na^+ and increased secretion of Cl^- . This is followed by water, K^+ and HCO_3^- flowing into the lumen. These

**Figure 2** Absorptive processes for Na^+ in intestinal epithelium

changes lead to copious watery stools with Na^+ , K^+ and HCO_3^- (Fig. 3).

Scientific Basis of Oral Rehydration Therapy

As mentioned earlier, CAMP acts on all the pathways for absorption of Na^+ and water from the gut except glucose linked Na^+ absorption. In such a situation if a solution of water and Na^+ is given to the child, it will not be absorbed from the gut because of the blocked pathways. The unabsorbed water is excreted in addition to the diarrhea stools, thereby worsening the diarrhea. On the other hand if Na^+ and glucose are added to water in appropriate proportion, glucose linked absorption of Na^+ takes place effectively. ORT optimizes this pathway for quick replacement of losses of water and electrolytes and prevents and treats dehydration till the time effect of CAMP wanes off and all blocked pathways are opened (Fig. 4).

Figure 3 Pathophysiology of secretory diarrhea

Figure 4 Glucose linked sodium absorption in acute diarrhea

Pathophysiology of Diarrheal Dehydration

Dehydration, due to loss of water and electrolytes in the stools, is the most common life-threatening consequence of diarrhea. Young children are more susceptible to develop dehydration due to limited urinary concentration capacity of the kidneys, more insensible losses of water through skin and lungs owing to large surface area and rapid breathing, and their dependence on adults to replace their fluid losses.

Loss of water and electrolytes in the diarrheal stool results in depletion of the extracellular fluid volume (ECFV), electrolyte imbalance and clinical manifestation of dehydration. Even

though intracellular and extracellular fluid compartments are equally depleted in diarrhea, the measurement of ECFV shows mostly a depletion of this compartment. The reason is that ECFV contracts in *two directions*—out in the stools and into the cell, so that the net measured loss of volume appears to come chiefly from the ECFV. Continued ECFV contraction is at the root of all the physiological changes taking place in dehydration and reversion to normal is more readily accomplished by solutions more nearly approximating that of the ECF.

The first symptom of dehydration appears after fluid loss of 5% of body weight. When fluid loss reaches 10%, shock often sets in, and the cascade of events that follows can culminate in death unless there is immediate intervention to rehydrate. In the past, higher mortality reported soon after admission, was mostly due to uncorrected volume depletion or electrolyte imbalance. These observations highlight the importance of the *first day* in the fluid therapy of severe dehydration and the need for prompt replacement of losses which if uncorrected will result in rapidly progressing dehydration, metabolic acidosis and other electrolyte imbalances.

Compensatory Mechanisms

Contraction of the ECFV consequent upon loss of water and electrolytes in diarrheal stools, leads to increase in renin, angiotensin, aldosterone and antidiuretic hormone (ADH), and fall of glomerular filtration rate (GFR). All these changes lead to compensatory retention of salt and water but proportionately more of the later. The first palpable response to ECFV contraction is thirst and if water is administered, it will be mostly retained due to the effect of ADH. In addition, water may also be generated internally by steroids and catecholamine. Therefore, retention of water by these mechanisms results in isotonic or hypotonic dehydration. Pre-existing or uncorrected potassium deficiency can also perpetuate hypotonicity. Comparison of various intravenous (IV) regimens containing high or low sodium have shown that rational treatment should reverse all the compensatory events by restoring volume quickly, correcting acidosis and reducing potassium deficit with solutions approximating the composition of the ECF. The more hypotonic the fluid is with respect to sodium, the less well it can quickly correct the ECFV contraction.

CLINICAL FEATURES

Diarrhea is usually defined as passage of three or more loose or watery stools in a 24-hour period, a loose stool being one that would take the shape of a container. However, for practical purposes, it is the recent change in consistency and character of stool and its water content rather than the number of stools that is important. Infants who are exclusively breastfed normally pass several soft or semiliquid stools each day; for them, it is practical to define diarrhea as an increase in stool frequency or liquidity that is considered abnormal by mother.

Acute watery diarrhea refers to diarrhea that begins acutely, lasts for less than 14 days, with passage of frequent loose or watery stools without visible blood. Vomiting may occur and fever may be present. Loss of large volume of water and electrolytes can result in dehydration and dyselectrolytemia.

Classification of Dehydration

Old textbooks described severity of dehydration, based on percentage of loss of body weight, as mild (< 5%), moderate (5–10%) and severe (> 10%). However, in the absence of information on premorbid weight of the child for estimating loss of body weight, it is often difficult to use weight loss as a criterion for assessment of dehydration. Moreover, thirst and irritability are the earliest

symptoms which appear when an infant has already lost almost 4–5% of body weight. Therefore by the time signs of dehydration appear the child already has mild-to-moderate dehydration. Extreme degree of dehydration presents with alteration in consciousness, shock, acidosis and renal failure. A number of clinical signs and symptoms can help in detecting dehydration. However, a simple assessment chart, revised by World Health Organization (WHO) as a part of Integrated Management of Childhood Illness (IMCI) strategy, can be referred for quick assessment of dehydration. WHO classifies dehydration as *no* dehydration, *some* dehydration and *severe* dehydration based on the presence of a few reliable clinical signs (**Table 2**).

MANAGEMENT

Acute watery diarrhea with or without vomiting is a common illness in under-5 children and is mostly caused by self-limiting bacterial or viral infections of GIT. However, it may also be a manifestation of other systemic illnesses. Therefore a careful history and thorough clinical examination to rule out other illnesses is enough to make a diagnosis and there is no need for routine stool examination. A child with diarrhea should be assessed to determine the:

- Nature and pattern of diarrhea
- State of hydration
- Presence of other problems like blood in the stools or severe malnutrition, and
- Screening for concurrent illness like pneumonia, otitis media and meningitis.

An algorithmic approach to assess a sick child up to 5 years of age using IMCI or the Indian adapted version named Integrated Management of Neonatal and Childhood Illness (IMNCI) guidelines is helpful in identifying cases with or without other illnesses and classifying them for management.

Assessment of Dehydration

Presence and severity of dehydration can be assessed with help of IMCI/IMNCI classification tables (Refer to Chapter 51.5 on IMNCI). According to the assessment chart, a patient may be classified as *severe dehydration* (with two or more signs suggestive of severe losses of fluid and electrolytes), *some dehydration* (includes signs of mild and moderate dehydration—identified by the presence of at least two of the signs in this category in the chart) or *no dehydration* (no signs of severe or some dehydration). Depending upon the state of hydration, children with *no dehydration* (Plan A) or *some dehydration* (Plan B) can be successfully treated with ORT and the ones with *severe dehydration* should be initially rehydrated by IV therapy (Plan C) and supplemented by/changed over to rehydration by ORS as soon as the child is able to take orally (**Table 3**).

Physiological Basis for Calculation of Deficit Therapy

Severe dehydration The fluid deficit in severe dehydration is expected to be 10% body weight or more. Therefore the approach is to quickly rehydrate the child with 30 mL/kg body weight for immediate replacement of ECFV followed by 70 mL/kg body weight for correction of remaining fluid deficit. Correction of deficit is spaced over 6 (1+5) hours in infants less than 12 months and 3 ($\frac{1}{2} + 2\frac{1}{2}$) hours in older children. For correcting dehydration due to uncorrected deficit of more than 10% and ongoing losses, hydration is reassessed after 3 hours in older children and 6 hours in infants less than 1 year to decide the next treatment plan. Ringer lactate is the preferred solution for IV rehydration since it provides adequate concentration of sodium and sufficient lactate which is metabolized to bicarbonate for correction of acidosis. Normal saline can be used as an alternative if Ringer lactate is not available. To encourage oral rehydration as soon as possible, the child should be offered ORS (5 mL/kg/h) along with IV infusion as soon as he/she is able to drink orally.

Some dehydration The fluid deficit in some dehydration is expected to be 5–10% of body weight. Therefore an electrolyte solution of appropriate composition (low osmolarity ORS) is administered in the dose of 50–100 mL/kg body weight over 4 hours. Since oral intake of ORS is a good indicator to monitor oral rehydration, children can drink more ORS than the calculated amount depending upon their state of hydration and ongoing losses. After 4 hours, hydration status is reassessed to decide the next treatment plan.

No dehydration The purpose is to replace ongoing losses and to prevent dehydration. Therefore 10 mL/kg body weight of recommended home available fluids/low osmolarity ORS is given for every loose stool. The commonly recommended safe home available fluids include food based fluids, correctly prepared salt and sugar solution, plenty of water along with food and frequent breastfeeding.

Oral Rehydration Therapy

Oral rehydration therapy has radically changed the treatment of diarrheal diseases. The term ORT includes:

- ORS solution of WHO recommended composition,
- Solution made from sugar and salt (if prepared correctly),
- Food based solutions (with appropriate concentration of salt), given along with continued feeding.

The use of ORS to treat diarrhea stems from the discovery during 1960s of the coupled active transport of glucose and sodium in the small bowel resulting in the passive absorption of water and other electrolytes even during copious diarrhea. Results of several studies have shown that optimum absorption of glucose takes place from the intestines between a glucose concentration of 111–165 mmol/L and the sodium:glucose ratio between 1:1 and 1:1.4. Therefore, the standard WHO/UNICEF ORS formula

Table 2 Assessment of dehydration in a child with diarrhea

Treatment plan	Plan A	Plan B	Plan C
<i>Clinical signs</i>			
General condition	Well, alert	Restless, irritable	Lethargic or unconscious
Eyes	Normal	Sunken	Sunken
Thirst	Drinks normally, not thirsty	Drinks eagerly, thirsty	Drinks poorly, not able to drink
Skin pinch	Goes back quickly	Goes back slowly	Goes back very slowly
<i>Decide hydration status</i>	The patient has NO DEHYDRATION	If the patient has two or more signs, there is SOME DEHYDRATION	If the patient has two or more signs, there is SEVERE DEHYDRATION

Table 3 Rehydration therapy for acute diarrhea

Treatment plan	Plan A	Plan B	Plan C
State of hydration	No dehydration	Some dehydration	Severe dehydration
Percentage of body weight loss	< 5	5–10	> 10
Estimated fluid deficit (mL/kg)	< 50	50–100	> 100
Goals of management	Replacement of ongoing losses of fluid and electrolytes	Correction of existing deficits of fluid and electrolytes	Urgent replacement of existing deficits of fluid and electrolytes
Fluid therapy	Maintenance (oral)	Rehydration (oral)	Rehydration (IV)
Treatment facility	Home	Health facility	Health facility
Rehydration fluid	Home available solutions/ORS	ORS	Ringer's lactate*
Amount of rehydrating fluid	For every loose stool: 10 mL/kg body weight or Children < 2 years (50–100 mL) Children 2–10 years (100–200 mL)	50–100 mL/kg body weight (average 75 mL/kg) over 4 hours** plus Older children and adults: Free access to: drinking water in addition to ORS	Intravenous fluids Infants: 30 mL/kg × 1 hour followed by 70 mL/kg × 5 hours Older children and adults: 30 mL/kg × 1/2 hour followed by 70 mL/kg × 2 1/2 hours. plus ORS (5 mL/kg/hour) to be started orally as soon as the child is able to drink
Monitoring	Watch for vomiting for early signs of dehydration, blood in the stools, etc. Reassess after 2 days or earlier	Monitor every hour and reassess after 4 hours: – If still in Plan B, repeat as above – If rehydrated shift to Plan A on ORS	Monitor half hourly and reassess after 6 (infants)/3 hours: – If still in Plan C, repeat as above – If rehydrated shift to Plan B or A as per hydration status

* Normal saline (0.9% NaCl) or half strength Darrow's solution may be used if Ringer's lactate is not available.

** Severely malnourished children should be rehydrated slowly over 6–12 hours.

Abbreviations: ORS, oral rehydration solution; IV, intravenous.

containing sodium chloride 3.5 g, sodium bicarbonate 2.5 g or trisodium citrate 2.9 g, potassium chloride 1.5 g and glucose 20 g to be dissolved in 1 liter of clean drinking water (Na^+ 90 mmol/L, K^+ 20 mmol/L, Cl^- 80 mmol/L, HCO_3^- 30 mmol/L or citrate 10 mmol/L, and glucose 111 mmol/L) was initially introduced for prevention and treatment of dehydration. Standard WHO/UNICEF ORS has been successfully used for decades and it has saved millions of lives. However, low osmolarity ORS is now recommended for prevention and treatment of diarrheal dehydration.

Low Osmolarity ORS

In the past, numerous studies have been undertaken to develop an *improved ORS* which, in addition to known clinical benefits of ORS, would reduce stool output or have additional clinical benefits. Reduction in the osmolarity of ORS has been one of the successful attempts to reach towards this goal. Reduced osmolarity of ORS is achieved by reducing the solution's glucose and salt concentrations which minimizes possible adverse effects of hypertonicity on net fluid absorption. Low osmolarity ORS is safe and efficacious in treating children with acute noncholera diarrhea, and in children and adults with cholera. In the combined analysis of these multicenter studies with ORS osmolarity ranging from 210 mOsm/L to 268 mOsm/L and sodium between 50 mEq/L and 75 mEq/L, there was a reduction in stool output by 20% and reduction in the incidence of vomiting by 30%. Experience of using low osmolarity ORS in children from 1 month to 2 years of age with AD and dehydration in some developing countries has also

suggested that low-sodium, low-glucose ORS formulation reduces the need for IV fluids by 33%. Because of the improved effectiveness of reduced osmolarity ORS solution, especially for children with acute noncholera diarrhea, WHO and UNICEF now recommend that countries use and manufacture low osmolarity ORS (**Table 4**) in place of previously recommended standard ORS solution.

Zinc Supplementation

Zinc deficiency is common in children from developing countries because of intake of predominant vegetarian diets and the high content of dietary phytates. Moreover, increased fecal losses during repeated episodes of diarrhea aggravate pre-existing zinc deficiency. Therefore WHO and Indian Academy of Pediatrics recommends zinc supplementation as an adjunct to ORS in the treatment of diarrhea. All children older than 6 months suffering from diarrhea should receive a uniform dose of 20 mg of elemental zinc as soon as diarrhea starts and continue for a total period of 14 days. Children aged 2–6 months should be advised 10 mg per day of elemental zinc for a total period of 14 days. Zinc not only decreases the stool frequency, and duration of the acute episode, it also prevents future episodes of diarrhea in next 6 months.

Electrolyte and Acid-base Disturbances

Hypertremia Some children with diarrhea, especially young infants, develop hypernatremic dehydration which usually follows use of hypertonic drinks (canned fruit juices, carbonated cold drink, incorrectly prepared salt and sugar solution, ORS with high glucose content). Children with *hypernatremic dehydration*

Table 4 Low osmolality oral rehydration solution (ORS) formulation recommended by WHO/UNICEF

Reduced osmolality ORS	g/liter	Reduced osmolality ORS	mmol/liter
Sodium chloride	2.6	Sodium	75
Glucose, anhydrous	13.5	Chloride	65
Potassium chloride	1.5	Glucose, anhydrous	75
Trisodium citrate, dihydrate	2.9	Potassium	20
		Citrate	10
		Total osmolality	245

(serum sodium > 150 mmol/L, osmolality > 295 mOsm/kg water) are extremely thirsty, out of proportion to their other signs of dehydration and sometimes have convulsions. Patients with hypernatremic dehydration have a total body deficit of sodium, even though the concentration of this cation in serum and ECF is abnormally high. Therefore infants with overt diarrheal dehydration of the hypernatremic variety can be successfully treated with low osmolality ORS. Rapid absorption of this solution during the rehydration phase leads to expansion of intravascular compartment and increases renal perfusion. Administration of plain water provides free water for the infant's renal physiologic mechanism with which to carry out further homeostasis. However, if the child is unable to drink orally, Ringer lactate can be initially given to treat shock and later switch over to ORT with ORS alternating with plain water.

Hyponatremia Patients who ingest only large amount of water or watery drinks that contain very little salt, may present with hyponatremia (serum sodium < 130 mmol/L, osmolality < 275 mOsm/kg water) which may be clinically associated with lethargy and seizures. ORS solution is safe and effective therapy for hyponatremia also. However, in the treatment of hyponatremia, administration of ORS alone without extra water has been observed to be superior because of higher sodium intake. For children who are unable to drink orally, IV infusion of Ringer lactate can effectively treat hyponatremia.

Hypokalemia Inadequate replacement of potassium losses during diarrhea can lead to potassium depletion and hypokalemia (serum potassium < 3 mmol/L) which may result in muscle weakness, paralytic ileus, renal impairment and cardiac arrhythmias. Severe potassium depletion particularly in malnourished children may lead to acute onset flaccid paralysis ranging from neck flop to quadriplegia and respiratory paralysis. The potassium deficit can be corrected by using ORS for rehydration therapy and by feeding potassium rich foods (e.g., banana, fresh fruit juices) during and after diarrhea. Oral potassium supplementation (2 mmol/kg/day) is indicated in malnourished children. In transient flaccid paralysis due to hypokalemia, potassium can be administered parenterally by using 15% solution of potassium chloride (1 mL = 2 mmol of potassium) but not exceeding 4 mmol/kg/day and 40 mmol/L of IV fluids after ensuring adequate renal functions.

Metabolic acidosis During AD, large amount of bicarbonate may be lost in the stool. If the kidneys continue to function normally, most of the lost bicarbonate is replaced and a serious base deficit does not develop. Metabolic acidosis tends to correct spontaneously in most of the cases as the child is properly rehydrated. ORS contains adequate bicarbonate/citrate to counter acidosis in less severe cases. However, in severe dehydration, compromised renal function leads to rapid development of base deficit and metabolic acidosis. Hypovolemic shock as a consequence of rapid loss of water and electrolytes in severe diarrhea results in excessive production of lactic acid which may further contribute to metabolic acidosis. Therefore rapid IV infusion of Ringer's lactate, which

contains 28 mmol/L of lactate to get metabolized to bicarbonate, is recommended in severe dehydration. However, in the presence of circulatory failure bicarbonate precursors may not be readily metabolized in the body.

If the patient presents with severe metabolic acidosis (pH 7.20, serum $\text{HCO}_3^- < 8$ mmol/L), sodium bicarbonate in a bolus dose of 2.5 mmol/kg can be given to correct acidosis. If the facilities for acid base estimation are available accurate dose of bicarbonate can be calculated by the formula: bicarbonate dose (mmol) = desired HCO_3^- – observed $\text{HCO}_3^- \times 0.6 \times$ body weight (kg). It is preferable to increase the bicarbonate level only up to 12 mmol/L to prevent overshoot metabolic alkalosis. Attention should be paid to serum potassium concentration as correction of acidosis in a patient with low potassium can lead to life threatening severe hypokalemia.

Antibiotics

Acute watery diarrhea in under-5 children is mostly caused by self-limiting bacterial or viral infections of GIT. Therefore there is no benefit in prescribing antibiotics as they do not significantly alter the clinical course. On the contrary, they may lead to undesired side effects and consequences. Antibiotic therapy should be reserved for cases of dysentery and suspected cholera only (Chapter 36.2 Dysentery; Chapter 36.3 Cholera). Antibiotics can also be given when the child is severely malnourished or is having coexisting severe systemic infection.

Risk Factors for Diarrheal Morbidity and Mortality

Early home therapy with ORT at the onset of a diarrheal episode remains the treatment of choice in almost all cases of diarrhea. However, it may be necessary to identify on the first day of an episode of diarrhea, signs and symptoms which indicate an increased likelihood of developing dehydration. Alteration in thirst (increased in a normal child and decreased in a dehydrated child as his hydration worsens), six or more loose stools, presence of fever, vomiting and a reduction in appetite are some of the clinical features which can help to recognize potentially severe cases who should be kept under closer surveillance. Associated major infections (pneumonia, septicemia or meningitis), severe wasting and severe stunting have been reported as risk factors for fatal diarrhea and hence such children need to be identified and targeted for intensive intervention.

Nutritional Management during and After Diarrheal Episode

Diarrhea is a major cause of malnutrition owing to low food intake during the illness, reduced nutrient absorption in the intestine, and increased nutrient requirements as a result of the infection. Poor appetite, vomiting and the common practice of withholding or diluting food are some of the reasons for poor intake during an episode of diarrhea. Therefore, food intake should never be restricted during or following diarrhea. Rather, the goal should be to maintain the intake of energy and other nutrients at as high a level as possible. When this is done, even with only 80–95% carbohydrates, 70% of fat and 75% of nitrogen being actually absorbed during acute diarrhea, sufficient nutrients can be absorbed to support continued growth and weight gain. Continued feeding also speeds the recovery of normal intestinal function, including the ability to digest and absorb various nutrients. In contrast, children whose food is restricted or diluted usually lose weight, have diarrhea of longer duration, and recover intestinal function more slowly.

During an episode of diarrhea specific recommendations for feeding are determined by the child's age and feeding pattern before the illness and the state of hydration. If the child is dehydrated, during the rehydration phase breastfeeding should be continued

and normal feeding resumed after rehydration is completed. However, in severely malnourished children some food should also be offered as soon as possible during the rehydration period. *After the rehydration phase* the dietary management during an episode of diarrhea include: (1) breastfeeding should be continued, as often as the child wishes; (2) young infants who take animal milk should continue to take undiluted milk as before; (3) children 6 months of age and older should receive energy rich mixture of soft weaning foods in addition to breastmilk or animal milk; (4) energy rich food (thick preparations of staple food with extra vegetable oil or animal fats), potassium rich foods (legumes, banana), and carotene containing foods (dark green leafy vegetables, red palm oil, carrots, pumpkins) should be given to the child in sufficient quantity. In young children these foods should be particularly well cooked and soft or mashed to aid digestion. Owing to loss of appetite or vomiting, children may need considerable encouragement to eat. It is helpful to give food frequently in small amounts, i.e., six times per day or more.

After an episode of diarrhea, a child should receive more food than usual for at least 2 weeks after diarrhea stops. During this period, the child may consume up to 150 kcal/kg of body weight per day. A practical approach is to give the child at least one extra meal each day with energy rich foods.

DIFFICULT DIARRHEA

Acute watery diarrhea is a common self-limiting disorder in children which can be successfully managed with ORT, zinc supplementation and proper feeding. However, there are clinical situations where extra care needs to be taken while assessing and managing the cases because of a higher risk of complications and mortality. Diarrhea may be difficult to manage in these cases because of younger age, associated systemic infections, poor nutritional status or immune deficiency. Management of these cases may require estimation of serum electrolytes and other investigation to rule out sepsis and associated infections.

Diarrhea in Neonates

Acute watery diarrhea in neonates, especially in breastfed babies, can be a manifestation of systemic sepsis or urinary tract infection. Neonates are at a higher risk of getting dehydrated, assessment of dehydration can be difficult and risk of electrolyte imbalance is higher besides worsening of the clinical condition because of the associated problems. Therefore apart from a thorough clinical examination it may be necessary to estimate serum electrolytes and investigate the neonate to rule out sepsis. In the past several problems like risk of excessive sodium retention, slow correction of acidosis, periorbital edema, mild pedal edema and excessive irritability and higher incidence of hyponatremia have been reported with the use of standard WHO ORS. With the currently recommended low osmolarity ORS these problems have been overcome. Apart from ORS and feeding, antibiotics are also recommended in neonates with low birthweight and associated infections. Continuing and increasing breastfeeds is the best way to keep the baby well hydrated.

Diarrhea in Severely Malnourished Children

Diarrhea in severely malnourished children deserves special attention owing to certain pathophysiological changes in water and electrolyte balance peculiar to protein energy malnutrition (PEM). Children with severe PEM have an increase in total body water and sodium while potassium stores in the body are depleted. The renal concentrating capacity is poor and thus they cannot conserve water efficiently. Moreover, they cannot handle excessive fluid and salt load and can develop fluid retention. Hence,

malnourished children are more prone to diarrheal dehydration, and if given excessive fluids run a risk of developing cardiac failure. This risk is further increased by the fact that it is often difficult to judge the extent of dehydration in these children owing to absence of subcutaneous fat. Assessment of hydration status is also difficult because a number of signs that are normally used are unreliable. Marasmic children normally have sunken eyes, and the diminished skin turgor may be masked by edema in children with kwashiorkor. In both types of patients, irritability or apathy makes assessment of mental state difficult. Signs that remain useful for assessing hydration status in severe PEM include: eagerness to drink (signs of some dehydration); very dry mouth and tongue, cool and moist extremities and weak or absent radial pulse (signs of severe dehydration). It is often difficult to distinguish between some dehydration and severe dehydration in severely malnourished children and it is best to assume at least some dehydration in them if they have acute watery diarrhea.

Several studies have highlighted the need for a separate rehydrating solution for children with PEM because of a higher risk of hypo- or hyponatremia and hypokalemia with the previously used standard WHO/UNICEF ORS. However, the currently recommended low osmolarity ORS is safer in these children. Some key recommendations for managing children with PEM are summarized in **Box 1**.

BOX 1 Treatment of diarrhea in severe malnutrition

- Rehydration, particularly with intravenous fluids should be slow and monitored.
- ORT should be preferred to intravenous fluid therapy because thirst can regulate the amount of oral intake of ORS to prevent under/overhydration.
- Serum electrolyte estimation is helpful to prevent/monitor electrolyte imbalance.
- Perform relevant investigations to rule out septicemia and associated infections.
- Children with PEM should be encouraged to eat even during the oral rehydration phase. Potassium rich food should be offered to the child as soon as child has started eating.
- Apart from low osmolarity ORS, zinc supplementation and feeding, a single mega dose of vitamin A (50,000 IU in infants less than 6 months, 100,000 IU between 6 months and 12 months and 200,000 IU in children > 2 years) should also been given.
- In severe malnutrition, the usual signs of infection such as fever are often absent, yet multiple infections are common in these children. Hypoglycemia and hypothermia are often signs of severe infection. Therefore, all severely malnourished children should be treated with antibiotics. Initiate therapy with broad spectrum parenteral antibiotics like ampicillin or crystalline penicillin with gentamicin.
- Treat micronutrient deficiencies and comorbidities.

Abbreviations: ORT, oral rehydration therapy; PEM, protein energy malnutrition; ORS, oral rehydration solution.

Diarrhea in HIV-infected Children

Diarrhea occurs more commonly in HIV-infected children and these children have a higher risk of mortality in comparison to uninfected children. Cryptosporidium is recognized as a common pathogen to cause diarrhea in these children. These children are likely to have recurrent episodes of acute watery diarrhea as well as persistent diarrhea. Each episode of diarrhea in HIV-infected children is influenced and at times complicated by their immunological status, infection with opportunistic organisms, associated malnutrition and presence of other infections that

increase susceptibility, GI manifestations of primary HIV disease and GI symptoms associated with antiretroviral drugs. Response to oral rehydration may also be unsuccessful in some cases. Therefore apart from standard case management of acute watery diarrhea, these children need to be thoroughly assessed for associated problems and closely monitored for any additional intervention.

Situations when ORT may not be Successful

Some children with *no* or *some* dehydration may require to be given IV fluids with or without ORT in the presence of high rates of purging (watery stools >15 mL/kg/hour), persistent vomiting, (four or more episodes of vomiting/hour) or inability to drink (due to severe stomatitis, fatigue, central nervous system depression induced by antiemetics or antimotility drugs). Glucose malabsorption following intake of ORS is not very common but can cause worsening of diarrhea. In such situations ORS should be withheld and rehydration done with IV fluids.

PREVENTION

Comprehensive diarrhea prevention package includes vaccines, nutritional interventions and improving hygiene and sanitation. Rotavirus accounts for 30–50% of all hospitalizations for acute diarrhea. Improving hygiene and sanitation alone may not prevent rotavirus infection. Natural protection against a subsequent infection with rotavirus has been reported only in 40% children after a single natural infection. Therefore immunization of young children with a rotavirus vaccine is an effective way of preventing at least episodes of severe watery diarrhea in children. Effective vaccines against rotavirus are commercially available. Improving measles vaccine coverage is also expected to have an impact on the prevalence of postmeasles diarrhea.

Promotion of exclusive breastfeeding, zinc and vitamin A supplementation and management of undernutrition are key nutritional interventions for preventing diarrhea in children. Handwashing, safe disposal of stools, preventing water contamination and food-borne transmission, discouraging bottle feeding and fly control are some of the effective measures for improving hygiene and sanitation.

IN A NUTSHELL

1. Acute watery diarrhea is a self-limiting disorder and is successfully managed with ORT, zinc supplementation and continued feeding.
2. Acute watery diarrhea is frequently caused by ETEC, EPEC and rotavirus but antibiotics do not have any beneficial role and therefore not recommended.
3. Oral rehydration therapy is the cornerstone of management of acute watery diarrhea. Intravenous fluid therapy is indicated only in severe dehydration and in the presence of high purge rate, persistent vomiting, inability to drink and glucose malabsorption.
4. Feeding should be started as soon as the child is rehydrated. Feeding should be started during rehydration phase in children with severe malnutrition.
5. Breastfeeding should be continued.
6. Diarrhea in neonates, severe malnutrition and HIV positive children deserves special attention.
7. Handwashing, safe disposal of excreta and maintaining personal and domestic hygiene can help prevent diarrheal episodes.
8. Rotavirus vaccine is an effective intervention to prevent severe episodes of dehydrating diarrhea.

Chapter 36.2

Dysentery

AKM Iqbal Kabir, Lazina Sharmin

Dysentery, also called as invasive diarrhea and manifested by blood in the stool, is a major public health problem in less developed countries. The common causes of dysentery in south Asia are shigellosis, amebic dysentery, *Campylobacter spp.*, and *Salmonella spp.* Other viral, bacterial and parasitic agents known to cause dysentery are listed in **Table 1**.

SHIGELLOSIS

The World Health Organization (WHO) estimates that shigellosis accounts for about 140–160 million cases each year. The vast majority of cases occur in developing countries among children aged less than 5 years. About 1.1 million people are estimated to die due to shigellosis globally each year and 60% of deaths are among very young children.

Epidemiology

Since first description of genus *Shigella*, there was a major global shift in the prevalence of four species. Until World War 1 and 2, *Shigella dysenteriae type 1* was predominant isolate which had caused a severe and devastating epidemic that affected Europe, particularly in eastern European countries during the two world wars. It was said that more people died due to shigellosis than the number of people died directly from bullets during these two world wars.

In the recent past there was another pandemic affecting Central America and caused several deaths due to *S. dysenteriae 1*. The epidemic was first noted in Guatemala and quickly spread to other countries such as Panama, Mexico and Costa Rica, caused more than 30,000 deaths within short span of time. During the same time period (1969–1973) another pandemic occurred in South Asia affecting Bangladesh, India and Sri Lanka. This epidemic seems to start in southern part of Bangladesh and then spread to India and Sri Lanka. The causative organism was found to be multidrug resistant *S. dysenteriae 1*.

Table 1 Bacterial, parasitic and viral causes of dysentery

Bacteria:
1. <i>Shigella spp.</i>
2. <i>Salmonella spp.</i>
3. <i>Campylobacter jejuni</i> and <i>Campylobacter coli</i>
4. Enteroinvasive <i>E. coli</i>
5. <i>Yersinia enterocolitica</i>
6. <i>Vibrio parahaemolyticus</i>
7. <i>Aeromonas hydrophila</i>
8. <i>Plesiomonas shigelloides</i>
Parasites:
1. Amebic dysentery (<i>E. histolytica</i>)
2. Bilharzial dysentery (<i>Schistosoma</i>)
3. <i>Balantidium coli</i> and <i>Isospora hominis</i>
4. <i>Strongyloides stercoralis</i>
5. <i>Trichuris trichiura</i>
Viruses:
1. Cytomegalovirus
2. Herpes simplex

Pathogenesis

Shigellae are divided in four groups or species containing 39 serotypes. Group A (*S. dysenteriae*), group B (*S. flexneri*) and group C (*S. boydii*), contains several serotypes, while group D (*S. sonnei*) contains of single serotype.

Mode of Spread

The transmission is through feco-oral route. Shigellae are orally ingested and pass down to stomach. Only few organisms as low as 100 bacteria can cause infection and disease because they can survive in a low pH and can survive the gastric acid barrier. In contrast, a few millions of bacteria are needed to cause diarrhea due to *Escherichia coli* or *Vibrio cholerae*. Most cases of shigellosis result from of person-to-person transmission through contaminated food and water. Transmission rates also correlate with poverty, poor sanitation, personal hygiene, and overcrowding. Only human and higher primates are natural host and reservoir of *Shigella* organisms. In order to produce the disease, *Shigella* organism must possess a smooth lipopolysaccharides (LPS) O antigen, must have genes encoding ability to invade epithelial cells and proliferate therein, and elaborate a cytotoxin for causing cell invasion.

The essential step in pathogenesis is invasion of colonic epithelial cells and parallel cell-to-cell spread of infection. This step involves initial attachment of the organism to the colonic cells followed by entry to the cells by endocytic mechanism. Then the organism invades the adjacent colonic cells. Although, invasion is initially innocuous, subsequently intracellular multiplication occurs, and causes cell damage by inhibiting deoxyribonucleic acid (DNA) synthesis, which ultimately causes cell death resulting in mucosal ulceration. These events are complicated, and require the functions of multiple genes and regulatory elements encoded on both chromosomes. The virulent factor for cellular attachment and penetration are determined by special gene coding.

Shigella has the ability to produce three distinct types of toxins, such as *enterotoxin* that is believed to produce watery diarrhea, *cytotoxin*, that cause dysentery or bloody diarrhea, and a *neurotoxin* which causes neurological manifestations. The enterotoxic property of the organism has been documented in experimental studies with rabbit ileal loops, where injecting shiga toxin produced fluid secretion like enterotoxigenic *Escherichia coli* (ETEC), or cholera toxin. Secretion of shiga toxin is mediated by cyclic-adenosine monophosphate (c-AMP), similar to cholera toxin. The initial phase of watery diarrhea is thought to be due to this mechanism. The cytotoxic ability has been documented by experimental study *Serény test*, where shiga toxin was put to guinea pig eyes that produce keratoconjunctivitis. When Shiga toxin was injected in rabbit, which caused paralyses of limbs and produced convulsions in animal. These might explain association of encephalopathy and convulsions in young children with shigellosis.

Clinical Manifestations

Symptoms

A child with typical shigellosis presents with an acute onset, usually moderate to high fever, malaise, headache, initially watery diarrhea, abdominal pain with cramp, followed by frequent passage of bloody mucoid stools along with straining and tenesmus during defecation. The fever is usually high in young children and sometime associated with convulsions. The initial phase of watery diarrhea usually lasts for 1–2 days, and is followed by bloody diarrhea. Some of shigellosis cases, particularly infected with *S. sonnei*, or *S. boydii* may have a short lasting episode of watery diarrhea and may not proceed to frank bloody diarrhea.

Most cases with *S. dysenteriae type 1* and *S. flexneri* present with bloody mucoid stool. Vomiting is not a major symptom of shigellosis. Severe anorexia and loss of appetite is a major feature of shigellosis in children. Studies have shown several cytokines such as interleukin 1 and 2, alpha-tumor necrosis factor (α -TNF) are involved in producing anorexia. High fever and abdominal pain/discomfort also contribute to anorexia.

Stool frequency is one of the major indicators for identifying shigellosis. Usually mother complains that the child passes more than 10–15 stools per day, and in severe cases the number of stool is as high as 25–30 per day. This is in contrast with amebic dysentery with a usual stool frequency less than 10 per day.

Shigella encephalopathy presents with altered sensorium, vomiting, convulsions, and other upper motor neuron signs.

Clinical Signs

The child is febrile, toxic and irritable. The abdomen is tender usually over the left colon, the affected area of distal colon. Occasionally, a patient may have first degree rectal prolapse, i.e., rectal prolapse during straining and defecation. Third degree rectal prolapse is very uncommon which may be seen in very young children with severe malnutrition. Meningismus may be associated with in *Shigella* encephalopathy.

Complications

Hemolytic-uremic Syndrome

Hemolytic-uremic syndrome (HUS) characterized by microangiopathic anemia, thrombocytopenia, and acute renal failure is primarily a complication occurring in children infected with *S. dysenteriae type 1* and less frequently in patients with *S. flexneri*. The actual pathogenesis is not clear, but it is speculated that shiga endotoxin is involved. Experimental studies suggest that leukocyte mediated intravascular deposition of fibrin occurs in renal vessels.

Seizure

It is one of the neurological complications mostly observed in children and is often associated with high fever. However, some patients may develop convulsions without pyrexia, and Shiga neurotoxin may be involved to cause encephalopathy.

Bacteremia and Sepsis

Bacteremia due to *S. dysenteriae 1* and *S. flexneri* is not uncommon. In about 10% of hospitalized patients with shigellosis, *Shigella* or other gram-negative organism are isolated from blood. Younger age, lack of breastfeeding, and severe malnutrition are associated with a high mortality.

Hyponatremia

Hyponatremia is mostly seen in children infected with *S. dysenteriae 1*. The exact mechanism is not known, however plasma antidiuretic hormone was found to be significantly higher in patients who had hyponatremia, suggesting that syndrome of inappropriate antidiuretic hormone secretion (SIADH) may be responsible.

Malnutrition

Malnutrition as a consequence of shigellosis usually occurs due to several factors such as, loss of appetite, increased catabolism due to high fever, traditional practice of food withholding, and loss of nutrients in the stool. Protein-losing enteropathy is an established mechanism through ulcerated gut. Undernutrition and stunting are the consequences in untreated patient who have a prolonged episode of dysentery causing persistent diarrhea.

Investigations

The white blood cell (WBC) count is usually elevated, but may be normal with shift to left and presence of band cells. Leukemoid reaction (WBC $>50,000/\text{mm}^3$) have been detected in 4% of hospitalized patients with shigellosis in Bangladesh. *S. dysenteriae* was the causative agent in 71% cases and over 70% of patients were children less than 5 years. In complicated HUS, the total WBC count may go up to 60,000–100,000/ mm^3 . Stool microscopy will show plenty of fecal leukocytes, red blood cells and macrophage. Stool culture will grow one of four *Shigella* spp.

Endoscopy of large intestine shows a diffuse colitis, most common in rectosigmoid area, but may extend proximally with longer duration of disease. The intestinal mucosa is erythematous with mucosal edema, friable, and bleeds when touched, and covered with a mucopurulent adherent layer. Histopathological findings from colonic biopsy will show denuded epithelium with microulceration and infiltration of polymorph cells in lamina propria. Crypt abscesses are seen in the mucosa.

Management

Antibiotics

Several clinical studies have shown that appropriate antibiotic therapy reduces the duration and severity of diarrhea, fever, abdominal pain and excretion of pathogens in stool. Choice of antibiotic depends upon the drug sensitivity patterns, availability and the cost. Multidrug resistant *Shigella* infections are common in children and pose a public health challenge. Besides spontaneous chromosomal mutational resistance, transferable drug-resistance mediated by R-Factor is the most important mode of drug resistance in shigellae. Acquisition of an R-Factor simultaneously may confer resistance against several drugs. Therefore information on local sensitivity pattern of *Shigella* isolates can be beneficial while choosing the antibiotics. In view of the fast changing sensitivity pattern, regular monitoring of drug resistance is critical for effective management of shigellosis.

Currently, ciprofloxacin is the drug of choice in most countries, particularly in South Asian countries where shigellosis is prevalent. However, *S. dysenteriae type 1* and *S. flexneri* are becoming increasingly resistant to ciprofloxacin in many countries. Pivmecillinam and ceftriaxone have been found to be effective in those cases. Ciprofloxacin in a dose of 15 mg/kg/dose in a 12 hourly for 5 days is recommended. Oral cefixime is started if there is no response in 48 hours to fluoroquinolone. This treatment is continued for 5 days. For sick children who need hospitalization, injection ceftriaxone is advised (80–100 mg/kg/d \times 5d). Some studies have observed azithromycin to be effective in multidrug resistant shigellosis but recently drug resistance has been reported with azithromycin as well.

Fluid Therapy for Dehydration

Most of the patients have mild to moderate dehydration and oral rehydration with standard oral rehydration solution (ORS) is recommended. However, some young children may have severe watery diarrhea, and may need intravenous (IV) fluid therapy.

Zinc

Administration of zinc, similar to acute watery diarrhea, is recommended for 14 days in all under-5 children with acute dysentery.

Supportive Care

If the patient is febrile and having convulsion, tepid sponging should be done to bring down the temperature. If convulsion is prolonged and recurrent, injection diazepam or phenobarbital

may be required. For managing HUS, whole blood transfusion and early dialysis have been found to have a better outcome. In severe hyponatremia, a slow infusion of a hypertonic NaCl solution (3% NaCl) results in a dramatic improvement in neurological status.

Dietary Management

Shigellosis is usually associated with malnutrition, particularly in young children in developing countries. It is therefore important to maintain calorie intake during acute phase and give additional food during convalescence. Studies done in Bangladesh and elsewhere have shown that a high-energy protein diet for 3 weeks can prevent growth faltering and achieve a rapid catch-up growth.

AMEBIASIS (ALSO SEE SECTION 32 CHAPTER 32.4)

About 10% of world's population is infected with *Entamoeba*, the majority with *Entamoeba dispar*. Amebic dysentery is caused by an intestinal protozoa *Entamoeba histolytica* manifested as prolonged dysentery, a major cause of bloody diarrhea in developing countries. Infection occurs with ingested food containing cyst of *E. histolytica*. Trophozoites of *E. histolytica* invade the gut mucosa. Amebic dysentery has an insidious onset and clinical dysentery usually appears after 2–6 weeks after ingestion of cyst. Patient complains of lower abdominal pain, mild diarrhea that is gradually followed by frank bloody-mucoid stool. The usual stool frequency is 10–12 per day. Stool contains little fecal matter, blood and mucus and have foul smell. Most of the patients will not have high fever like acute shigellosis. Straining and tenesmus are uncommon.

Metronidazole remains as first line of drug for acute intestinal colitis.

CAMPYLOBACTER DYSENTERY

Campylobacter is a gram-negative, motile rod and nonspore forming zoonotic organism and transmitted to humans through animals such as poultry, cattle, and other household animals. *Campylobacter jejuni* and *Campylobacter coli* are major organisms that cause diarrhea and dysentery. In most cases the organism is transmitted through uncooked or raw food products such as meat and milk, and also animal handlings. Although, campylobacter infection occurs in both developed and developing countries, it is highly prevalent and hyperendemic in some areas in South Asia.

Pathogenesis

The organism produces two types of toxins, one *E. coli* heat-labile toxin (LT) like toxin that is responsible for secretory or watery diarrhea, other cytotoxin (CT) that causes bloody diarrhea and dysentery.

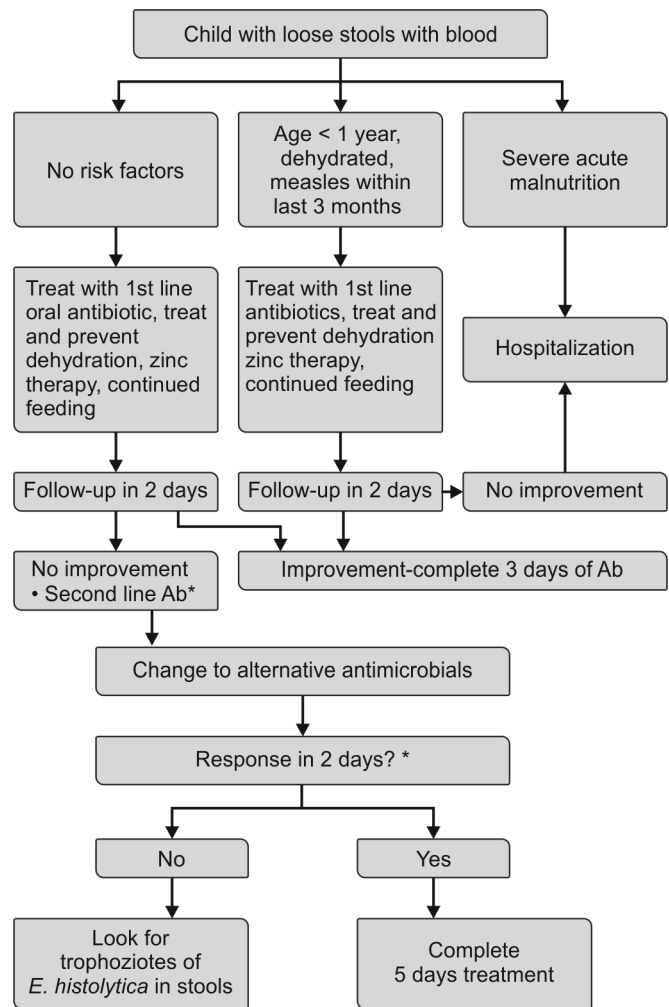

Clinical Features

The clinical presentation is varied, some patients may have profuse watery diarrhea, and some will have severe bloody diarrhea. A typical patient will give a history of fever, nausea, vomiting, initially watery diarrhea followed by bloody mucoid stool. Most patients will complain of abdominal pain with cramps and may mimic acute appendicitis.

Treatment (Flow chart 1)

Diarrhea is usually self-limited, and rehydration with ORS is sufficient in mild to moderate dehydration. Those with severe dehydration require IV fluid therapy. Patients with severe disease with high fever, bloody stool and septic shock require antibiotic therapy. The first line of treatment is erythromycin, given at a dose of 50 mg/kg/day in four divided dosage for 5–7 days. Alternative drugs are clarithromycin, azithromycin and ciprofloxacin.

Flow chart 1 Treatment algorithm of dysentery. Ciprofloxacin and cefixime are the recommended first-line and second-line antibiotics for dysentery, respectively

*Not better in 2 days with first line antibiotic

ENTEROINVASIVE AND ENTEROHEMORRHAGIC E. COLI DYSENTERY

Most *E. coli* [ETEC and enteropathogenic *E. coli* (EPEC)] cause watery diarrhea. However, Enteroinvasive *E. coli* (EIEC) and Enterohemorrhagic *E. coli* (EHEC) cause invasive diarrhea and severe dysentery with bloody stool. The most common serotype is O157:H7 which causes severe dysentery with bloody diarrhea and associated with some life-threatening complications like HUS. It is prevalent in Northern America and some of European countries and usually been associated with outbreaks. Very few cases are reported from South Asia. EIEC and EHEC produce a CT which is like *Shigella* toxin and is named as Shiga-like toxin (SLT) or verotoxin (VTEC). The clinical features include high fever, abdominal pain and frequent passage of bloody stool. Some patients may present with HUS as a complication. Third generation cephalosporins are the treatment of choice.

DYSENTERY DUE TO OTHER CAUSES

Beside these organisms that cause dysentery in majority of cases, other organisms such as *Aeromonas hydrophila*, *Plesiomonas shigelloides*, and *Vibrio parahaemolyticus* have been implicated

to cause dysentery. Anaerobic Gram negative bacteria such as *Clostridium difficile* and *Clostridium perfringens* are two major organisms to produce severe colitis and bloody diarrhea. Any antibiotic that is used for longer duration have been found to be associated with pseudomembranous colitis, details are discussed in a separate chapter on antibiotic associated diarrhea.

2. The common causes of dysentery in south Asia are shigellosis, amebic dysentery, *Campylobacter spp.*, and *Salmonella spp.*
3. More than a million people are believed to die due to shigellosis globally each year and 60% of these deaths are among very young children.
4. *Shigella* group of organisms can survive in a low pH and pass through gastric acid barrier, and therefore only few ingested organisms can cause infection and disease.
5. Multidrug resistant *Shigella* infections are common in children. Therefore knowledge of local sensitivity pattern and regular monitoring of drug resistance is critical for effective management of shigellosis.
6. Ciprofloxacin is the drug of choice for dysentery, non-responders are given cefixime. Serious hospitalized patients are treated with ceftriaxone. Zinc is coadministered in all cases for 14 days. Nutritional support during and after an episode of dysentery is important to prevent malnutrition.
7. Apart from shigellosis, amebiasis and gut infection with *Campylobacter spp.*, Enteroinvasive *E. coli* (EIEC) and Enterohemorrhagic *E. coli* (EHEC) cause invasive diarrhea and severe dysentery

Chapter 36.3

Cholera

Piyush Gupta, Rashi Singhal

Cholera is a toxin mediated acute diarrheal disease caused by contamination of food or water by certain strains of *Vibrio cholerae*. It accounts for approximately 3–5 million cases and 1–1.2 million deaths each year worldwide. Short incubation period and virulence of certain strains like O1 and O139 is responsible for the high fatality.

EPIDEMIOLOGY

In 1883, Robert Koch proved that cholera occurs due to the bacteria *Vibrio cholerae*. However, it was Petten, Kofer and Emmerish, who publicly drank a culture of *V. cholerae* and suffered from the disease, proving beyond doubt the etiological association of *V. cholerae* with cholera. Six pandemics of cholera were reported between 1817 and 1923. Most of these originated from the Gangetic basin of India and Bangladesh. The seventh pandemic (origin: Indonesia, 1961) is currently continuing. It differed from the previous pandemics in two aspects: (1) it was caused by a new organism El Tor *Vibrio*; and (2) it was associated with a low mortality rate, mainly due to advent of oral rehydration solution (ORS) therapy. A new strain of cholera, named O139 emerged in India in 1992. It spread west to Pakistan and east to China, and in the early months of 1993 caused an estimated 100,000 cases and 1,000 deaths in Bangladesh.

Only O1 and O139 strains of cholera result in epidemics. Cholera was reported to be endemic in 80 countries in 1993, affecting millions. But there has been a steady decline in the incidence since then and the number of countries reporting cholera declined to only 48 in 2012 (**Fig. 1**). Africa and Asia account for 96% and 3%

of the global total cases of cholera, respectively. Case fatality rate is now reported as 1.2% as compared to 3.6% in 2000.

MODE OF SPREAD

Cholera is spread through water contaminated with fecal matter. This is mainly related to inadequate facilities for disposal of sewage and provision of portable drinking water. Direct spread by contact does not occur, though the infection may be spread from person to person by contaminated hands and fomites. In developed countries, consumption of raw shellfish or moist grains has been observed to be associated with the disease spread.

PREDISPOSING FACTORS

Cholera is predominantly a disease of young children. Under-5 carry a 10 times higher attack rate as compared to adolescents and adults. In the presence of normal gastric pH, a large inoculum (10^8 – 10^{10} organisms) is needed to overcome the protective barrier and cause disease. Reduced gastric acidity or achlorhydria provides a suitable environment for growth of *V. cholerae* and as low as 10^4 – 10^6 inoculum is sufficient to cause the disease. Blood group O, malnutrition and immunocompromised state are also associated with increased risk for the disease.

Cholera occurs more in tropical countries across the globe and more during warm months. Other environmental factors like poverty, overcrowding, and lack of adequate sanitation and safe drinking water also play a role. In a country like India where nearly two-thirds of the population live in rural areas and only 28% of households use piped drinking water and 26% of households have access to good sanitation, it is not surprising that cholera is endemic. During human congregation, such as festivals, fairs (e.g., *kumbh melas*), following natural calamities (floods, earthquakes) and because of migration of rural population to urban areas, epidemics of cholera are frequent due to overstretching of the normal sanitary arrangements.

Flow chart 1 Serotypes, biotypes and serogroups of *Vibrio cholerae*

MICROBIOLOGY

Vibrio cholerae, the causative organism, is a gram-negative, rod shaped curved, motile bacillus. They are fresh, brackish, or saltwater dwelling anaerobes with fermentative metabolism. Vibrios are highly halophilic, heterophilic motile organisms that travel with a single flagellum, and depend on saccharose sugar and starch for their growth and development.

V. cholerae possesses both somatic O and flagellar H antigens. Serological differentiation is based on polysaccharide somatic O antigen. There are over 200 serogroups of *V. cholerae*, but only two serogroups (O1 and O139) are associated with outbreaks of severe disease in man. Other strains may cause mild diarrhea in a sporadic manner. O1 has two biotypes, classical and El Tor; each biotype is further classified into three serotypes based on presence or absence of three antigenic determinants (A, B, C) on the O antigen. These are Ogawa (A and B), Inaba (A and C) and Hikojima (A, B and C) strains (**Flow chart 1**). Among the strains, *V. cholerae* O139, isolated in the Bay of Bengal in 1992, is confined to Southeast Asia.

ETIOPATHOGENESIS

Vibrio cholerae generates several toxins that are responsible for the disease. The major toxin is the cholera enterotoxin called cholera toxin (CT). The *ctxAB* gene encoding the CT is mapped on the genome of a lysogenic filamentous bacteriophage, called *CTXphi*. Horizontal transmission of the genome by bacteriophage might be responsible for the emergence of new strains like O139. CT has 2 subunits—(1) subunit A and (2) subunit B. The A subunit is cleaved to produce A1 and A2 fragments, of which A1 fragment is the active enzyme while the A2 subunit attaches A1 to the B subunit. The B subunit is a pentamer that binds the toxin to the enterocyte surface receptor, the ganglioside GM1. Following binding and internalization of the toxin, A1 catalyzes the ADP-ribosylation of a GTP-binding protein, leading to persistent activation of adenylate cyclase. This results in increased cyclic adenosine monophosphate (cAMP) in the intestinal mucosa that causes increased chloride secretion and decreased sodium absorption, producing the massive fluid and electrolyte loss characteristic of cholera. CT may also lead to increased prostaglandin production, which adds to gastrointestinal loss of water and electrolytes. The cholera enterotoxin (CT) is similar in structure and function to the *Escherichia coli* enterotoxin (LT).

V. cholerae also produces other toxins like neuraminidase, disulfide isomerase, hemagglutinin protease, hemolysin-cytolysin and thermostable direct hemolysin (TDH). All these toxins help in increasing the binding ability of the bacteria and potentiating

CT toxin. Researchers have also postulated the activation of certain other chloride channels like cystic fibrosis transmembrane regulator (CFTR) and calcium activated chloride channels (CaCC) which are activated during infection. Further research is required to explore their exact role in pathogenesis as well as possibility of selective channel blockers for treating cholera.

Intestinal Colonization

Following entry into the gut through contaminated food, the vibrio colonizes the small intestinal epithelium. *V. cholerae* produces a pilus called the toxin-coregulated pilus (TCP), which is absolutely required for colonization of the small intestine. This is encoded by the *tcpA* gene but the expression of gene varies with the biotype. Hemagglutinins act as adhesion factors. They do not have a major effect on virulence but help in activating cholera toxin by nicking the A subunit. Accessory colonization factor and porin-like proteins are the other factors playing a role in colonization.

CLINICAL FEATURES

The incubation period of *V. cholerae* is very short, ranging from 2 hours to 5 days. Man is the only natural host, but free living *V. cholerae* have been recognized in aquatic environment. A case is infectious as long as the person continues to excrete the bacilli. Usually the disease is communicable for 3 days before the onset of symptoms (incubatory carrier period) and 7–10 days thereafter. The ratio of severe cases to subclinical cases is around 1:10. These subclinical cases continue to harbor the bacteria in their feces for 7–14 days after infection and shed back the virus into the environment, potentially infecting other people. Asymptomatic cases serve to maintain the infection in the community. Most of the carriers are temporary, though chronic gallbladder carriage has also been reported up to as late as 11 years (Cholera Dolores). Temporary convalescent carriers may continue to excrete *V. cholerae* for 3–4 weeks.

Most patients (75%) infected with toxigenic *V. cholerae* serogroup O1 or O139 are asymptomatic. Only 20% have only a mild to moderate diarrheal illness and approximately 5% develop the classic symptoms and signs of severe cholera (*cholera gravis*). Diarrhea is usually abrupt, painless and profuse. The stools are voluminous (10–20 mL/kg up to 1 liter per stool), isotonic, and rice watery, with flecks of suspended mucus. This is associated with profound vomiting of clear watery fluid. If fluid losses are not corrected rapidly, patient develops features of severe dehydration and lapses into hypovolemic shock. The child becomes apathetic and lethargic that progresses rapidly to obtundation, hypotension, renal failure and shock. Loss of bicarbonate in stool and lactic acidosis from poor perfusion may result in Kussmaul breathing. Muscle cramping and weakness are common due to loss of potassium and calcium.

Renal failure with acute tubular necrosis may occur as urine output decreases. In children, depletion of glycogen stores and inadequate gluconeogenesis can lead to symptoms of severe hypoglycemia or even coma. The natural course runs for 2–7 days. The purge rate is usually very high (10–20 mL/kg/h up to 1,000 mL/h) and if untreated proves fatal. Death may be attributed to hyponatremic shock, acidosis, and renal failure.

COMPLICATIONS

Rare complications include aspiration pneumonia and septicemia. An unusual and rare presentation of the disease is *Cholera sicca* in which fluid accumulates in the intestinal lumen leading to circulatory collapse and death characteristically in the absence of diarrhea.

DIAGNOSIS

Case Definitions

While management of patients with acute watery diarrhea is similar regardless of the illness, it is important to identify cholera because of the potential for a widespread outbreak. According to WHO, cholera should be suspected if:

- A patient older than 5 years develops severe dehydration from acute watery diarrhea (usually with vomiting); or
- Any child above the age of 2 years has acute watery diarrhea in an area where there is an outbreak of cholera, especially patients who pass the *rice watery* stool typical of cholera.

A case of cholera is confirmed when: *Vibrio cholerae* O1 or O139 is isolated from any patient with diarrhea. Whenever such cases are suspected and confirmed, reporting to health officials becomes mandatory.

Routine Investigations

There is a rise in hematocrit, increase in serum specific gravity and elevation of serum total proteins due to hemoconcentration. There is leukocytosis without left shift, hyponatremia (serum sodium < 135 mEq/L), deranged renal function tests and metabolic acidosis due to enormous intravascular volume loss. Initially potassium remains normal due to exchange with hydrogen ions at the distal tubules but later hypokalemia (serum potassium < 3.5 mEq/L) develops, causing paralytic ileus, muscle weakness, and neck flop.

Stool Examination

Bedside diagnosis rests on the presence of rice water stools coupled with demonstration of darting motility in wet mounts of the stools (*hanging drop preparation*) identified under a dark field microscope at 400X magnification. Isolation and identification of *V. cholerae* serogroup O1 or O139 by culture of a stool specimen remains the gold standard for the laboratory diagnosis of cholera. Identification as well as isolation of the organism is done using selective thiosulfate-citrate-bile salts agar (TCBS) medium. Cary Blair media is used for transport.

Commercially available rapid test kits are available (Crystal VC® immunochromatographic dipstick test for *V. cholerae* O1 and O139, Span Diagnostics Limited, India) to identify an epidemic outbreak especially in resource poor settings. The dipstick is dipped into a stool sample. If two red lines appear on the dipstick, then the patient has cholera. The test takes between 2 minutes and 15 minutes. It is more sensitive (93–98%) than specific (67–96%) which makes it less useful for individual case management in an endemic country like India. However, in the setting of an outbreak of acute watery diarrhea, in which the epidemiological and clinical evidence suggest that 10 or more persons are suffering from the same illness, the overall sensitivity and specificity of the test for the diagnosis of an outbreak of cholera improve. If the cause of the outbreak is cholera, most (an estimated 8–9) of the rapid test results from the 10 individual patients will be positive; if the outbreak is the result of another cause, most of the rapid test results (an estimated 6–7) will be negative. The difference (≥ 8 positive tests vs. ≤ 4 positive tests) should be sufficient to provide a clear indication of whether or not the outbreak of acute watery diarrhea is due to cholera. The test does not provide any information regarding antimicrobial susceptibility testing and subtypes responsible for the outbreak.

Differential Diagnosis

All causes of acute watery diarrhea including rotavirus, *Cryptosporidium* and enterotoxigenic *E. coli* (ETEC) can present with similar manifestations. Presence of rice watery stools in the

setting of an outbreak, high purge rate and rapid and profound fluid loss helps in establishing the diagnosis of cholera.

TREATMENT

Management of Dehydration and Electrolyte Imbalance

Rehydration is the mainstay of therapy. Rehydration therapy reduces the risk of mortality from 10% to 0.5%. Patients are treated as per WHO guidelines for acute watery diarrhea. WHO ORS standard sachets are the mainstay of rehydration therapy. Patients with no dehydration are given home management (Plan A); for those with some dehydration, ORS therapy under supervision is allowed (Plan B). Intravenous (IV) fluid administration (Plan C) is reserved for severely dehydrated patients. For details please see Chapter 36.1 on Acute Watery Diarrhea.

Children with cholera are at a great risk for hyponatremic dehydration and the appropriate choice of fluid used for rehydration is crucial. Usually 0.45% normal saline with 5% dextrose with maintenance potassium or Ringers lactate is preferred for fluid correction once initial boluses have been administered for features of hypovolemic shock as it contains both potassium and bicarbonate which are equally lost in stools. Special solutions like *Dhaka Solution* in endemic areas and *Hartmann Solution* can also be used if available for IV rehydration therapy. Fluid replacement in cholera reaches up to 200–350 mL/kg over the first 24 hours. WHO advocates the use of low osmolarity ORS sachets to be equally effective as the standard ORS sachets for rehydration therapy. However, the chances for biochemical hyponatremia with low sodium ORS sachets are more than the standard ORS sachets even though patient remains asymptomatic (Murphy et al. 2009). Rice based ORS is also proven to be equally efficacious to the standard ORS for rehydration in cholera.

Antimicrobial Treatment

Appropriate antibiotics are essential in the management of cholera as they decrease the duration of diarrhea, reduce the volume of rehydration fluids needed by almost 50%, and shorten the duration of *V. cholerae* excretion to 1–2 days. Options include tetracyclines, fluoroquinolones and macrolides. Among tetracyclines, single dose of doxycycline is equally effective as a 3 day course of tetracycline in terms of stool output, duration of diarrhea, vomiting, and requirement for rehydration therapy. Single dose of ciprofloxacin has proven to be more effective than doxycycline. However, the increasing resistance among the strains of *V. cholerae* against ciprofloxacin in Asia and Africa has restricted its use. Macrolides offer a good alternative in children where tetracyclines are contraindicated. Azithromycin (single dose) and erythromycin have proven to be equally efficacious in terms of clinical and bacteriological cure with rare occurrence of resistance and shown to be better than fluoroquinolones. Cotrimoxazole and furazolidone are rarely used as most *V. cholerae* O139 strains and many O1 El Tor strains are resistant to them. Drug treatment of cholera is summarized in **Box 1**.

BOX 1 Antimicrobials for treating cholera

Antimicrobial	Dose
Doxycycline	4 mg/kg single dose < 15 years, 200 mg stat > 15 years
Tetracycline	12.5 mg/kg/dose 4 times/day for 3 days
Ciprofloxacin	20 mg/kg single dose
Erythromycin	12.5 mg/kg/dose 4 times/day for 3 days
Azithromycin	20 mg/kg single dose
Furazolidone	12.5 mg/kg/dose 4 times/day for 3 days

Zinc Supplementation

Oral zinc supplements (10 mg/day for children less than 6 months and 20 mg/day for those between 6 months and 5 years) for 14 days shortens the duration of illness, decreases the stool volume, decreases the purge rate, and reduces further episodes as in other watery diarrhea. It also has a direct inhibitory action on the CT toxin. However, role of zinc in children older than 5 years with cholera is yet to be proven.

PREVENTION AND CONTROL

Prevention is based on ensuring a safe water supply and adequate facilities for sanitation. In urban areas, properly treated drinking water should be made available through piped supply. The minimum level of free residual chlorine in a piped system should be at least 0.5 mg/L. In rural areas, water can be made potable by boiling or adding a chlorine releasing chemical.

Appropriate facilities for disposal of human waste and excreta should be constructed with the help of the community. Education regarding the use of existing toilet facilities and importance of washing hands must be given utmost importance. In the event of large fairs, festivals, etc., special care should be taken for safe waste disposal.

Community at risk of developing an outbreak of cholera should be educated with regard to importance of healthy feeding practices. Mass chemoprophylaxis, vaccination, and travel restrictions are ineffective in controlling an outbreak. Selective chemoprophylaxis may be useful for members of a particular family who are sharing food with a cholera patient.

Cholera Vaccines

Two types of oral cholera vaccines are available which have proved to be safe, immunogenic and effective: (1) killed oral vaccines (Dukoral, Shanchol) and (2) live oral vaccine (CVD 103-HgR). Parenteral vaccines are withdrawn due to low efficacy (50%), no herd immunity and failure to prevent development of carrier state.

Dukoral (Whole Cell with Recombinant B Subunit)

Dukoral is a monovalent vaccine based on formalin and heat-killed whole cells (WC) of *V. cholerae* O1 (classical and El Tor, Inaba and Ogawa) plus recombinant cholera toxin B subunit. The vaccine has a shelf life of 3 years at 2–8°C and remains stable for 1 month at 37°C. Available in a 3 mL single dose vial, it is essential to be given with a bicarbonate buffer in a glass of water as B subunit is sensitive to stomach acid. Two doses, given 1–2 weeks apart, confer 80–90% protection for 6 months about 7 days after the last dose. Children aged 2–5 years should receive three doses more than 7 days apart (but < 6 weeks apart). One booster dose is recommended by the manufacturer every 6 months for children aged 2–5 years and every 2 years for adults and children aged more than or equal to 6 years in endemic areas. If the interval between primary immunization and the booster is more than 6 months for less than 5 years and more than 2 years for more than 5 years, primary immunization must be repeated. Dukoral is not licensed for children aged less than 2 years. It also offers some cross protection against ETEC strains for around 3 months, being structurally similar to CT toxin. It is not recommended in India currently due to absence of protection against O139 strain, cost and requirement of safe drinking water for its administration.

Bivalent Whole Cell Vaccines

The closely related bivalent oral cholera vaccines Shanchol and mORCVAX based on serogroups O1 and O139 are variants of

the WC/rBS vaccine containing no recombinant B-subunit and have been manufactured in Vietnam and later reformulated to meet WHO standards. Shanchol is currently recommended for use in India as it is safe, immunogenic (80% antibody response in 6 months), cost-effective and does not require a buffer or water for administration. It is also administered in two doses 15 days apart and safe above 1 year of age. Booster dose is recommended after 2 years. This vaccine has no cross protection for ETEC.

CVD 103-HgR Oral Cholera Vaccine

It is a single dose live attenuated vaccine against the O1 strain of *V. cholerae* requiring cold chain and buffer. However, the protective efficacy is less (60%) and does not protect against the O139 strain. It is mainly indicated in travelers to a developing country as it shows protection within 8 days of vaccination.

Certain other oral vaccines like Peru 15, CVD 110, 111 and 112 and Cuban 638 as well as conjugated vaccines are under trials. In 2011, the 64th World Health Assembly recognized the re-emergence of cholera as a significant public health burden and called for the implementation of an integrated and comprehensive approach to cholera control. In 2012, a technical working group initiated a coordinated global cholera management initiative by recommending the creation of a global oral cholera vaccine (OCV) stockpile for use in emergencies.

IN A NUTSHELL

1. Cholera epidemics are caused by *Vibrio cholerae* strains O1 and O139.
2. Pathogenicity is toxin mediated (cholera toxin).
3. Carrier rate is high which may last up to months to years.
4. Diarrhea is usually very severe with a very high purge rate up to 10–20 mL/kg/h.
5. Hanging drop method is a useful bedside test. Dipstick methods are also available. Stool culture is required for confirmation.
6. WHO ORS with zinc is the mainstay of therapy. Single dose of doxycycline, azithromycin or ciprofloxacin provide a good antibiotic cover.
7. Cholera vaccines offer a moderate protection benefit for 1–2 years and booster doses are required in endemic areas.
8. Mass education of adequate sanitation and provision of safe drinking water can help prevent the disease.

Chapter 36.4

Persistent Diarrhea

Shinjini Bhatnagar, Aashima Dabas, Dheeraj Shah

Persistent diarrhea (PD) is defined by World Health Organization (WHO) as diarrhea of a presumed infectious etiology that continues for at least 14 days. Almost three decades back, it was reported to contribute to almost 40% of all under-5 diarrheal deaths. A recently completed review of verbal autopsy data from seven countries surveillance sites (Bangladesh, Ethiopia, Ghana, India, Pakistan, Tanzania and Uganda) found that PD continues to play a major role in infant and childhood diarrheal deaths, especially in high burden countries. Interestingly, in this study, PD contributed to 10–61% of the overall diarrheal deaths, and accounted for more than one-third of all the diarrheal deaths in four countries (India, Pakistan, Tanzania and Ethiopia). Given the overall reduction in childhood mortality from acute diarrhea, the concern is that a major proportion of childhood diarrheal deaths maybe happening in children with PD.

DEFINITION OF PERSISTENT DIARRHEA

The duration of acute diarrhea forms a continuum, most episodes terminate within 7 days and progressively smaller proportions persist beyond 14, 21 or 28 days. WHO defines PD as a diarrheal episode that lasts for 14 or more days. This definition excludes specific conditions like celiac disease, tropical sprue, or other congenital, biochemical or metabolic disorders. The 14-day cutoff for defining PD is arbitrary but is supported by observation of a significant high case fatality rate when diarrhea extends for 2 or more weeks. A significant proportion of children with persistent episode of diarrhea develop malnutrition. These patients require careful assessment and management to reduce mortality.

EPIDEMIOLOGY

Persistent diarrhea continues to play a major role in infant and childhood diarrheal deaths, especially in high burden countries. Community-based studies have estimated that 2–6% of total diarrheal episodes become persistent. The prevalence of persistent episodes is much more common in hospitalized patients because of the referral bias and its association with severe malnutrition and systemic infections. Overall, a greater incidence of PD is reported from developing countries where accessibility to safe water, sanitation and hygiene is limited. The incidence of PD has possibly shown a decline worldwide in the last few decades, which may be attributed to improved management practices of acute diarrhea.

A clear trend towards persistence of a diarrheal episode is noted among infants. Healthy infant feeding practices like exclusive breastfeeding and adequate and timely complementary feeding provide protection against PD. Malnutrition, quantified as wasting, underweight or stunting increases the chances of prolongation of a diarrheal episode into PD. Unnecessary use of antimicrobials in acute diarrhea, vitamin A and/or zinc deficiency, and recent history of measles or HIV infection increase the risk of PD. In addition to the above, various sociodemographic factors such as absence of safe and potable water supply or storage facilities, lack of sanitary latrine, overcrowding and low maternal education have been identified as potential risk factors. Studies have shown that severity of acute diarrhea, as assessed by frequency or presence of dehydration, does not correlate with duration of diarrhea. Likewise, concurrent presence of fever or abdominal pain or vomiting is not a good predictor for PD.

ETIOLOGY

Etiology of PD is multifactorial. Persistent infection with same pathogen, sequential infection and secondary lactose intolerance are the most common reasons. The organisms which are more commonly isolated from children with PD in comparison to acute diarrhea are: Enteroaggregative *E. coli*, *Cryptosporidium spp.* and *Giardia spp.* Both *Cryptosporidium spp.* and *Giardia spp.* are water-borne infectious agents and show clustering in areas with suboptimal sanitation. Giardial trophozoites are motile and can undergo antigenic variations to evade the host immune system. The trophozoite attaches to the jejunum through its ventral disk to result in damage to the microvilli of intestinal lumen and in brush-border enzyme deficiencies, which leads to persistence of a diarrheal episode. Similarly, *Cryptosporidium* also invades the jejunal luminal lining and induces cell apoptosis leading to accelerated loss of villus enterocytes. This manifests as malabsorption and diarrhea. Few other organisms which have also been isolated in PD include non-typhoid *Salmonella*, *Campylobacter spp.* diffusely adherent *E. coli* and *Shigella spp.* Enteroaggregative *E. coli*, *Shigella* and *Cryptosporidium* have been associated with persistent infection while sequential infections are found with multiple pathogens with no clear pattern. The microbes which are less commonly isolated in PD in comparison to acute diarrhea are: Rotavirus, Enterotoxigenic *E. coli*, *Vibrio spp.* and the helminths.

Systemic infections like urinary tract infections, pneumonia and systemic sepsis are also identified in significant proportion of children with PD, especially if they are severely malnourished.

CLINICAL PRESENTATION

Majority of patients with PD pass several loose stools daily but remain well hydrated. Dehydration develops only in some patients because of the high stool output or when oral intake is reduced due to associated systemic infection. The major consequences are growth faltering, worsening of malnutrition and death during a subsequent diarrheal or non-diarrheal illness. The growth failure associated with PD also occurs due to inadequate energy intake during the diarrheal episode. This results from anorexia associated with the illness, faulty feeding practices and incorrect advice by physicians.

Most of the PD patients can be treated at home but infants younger than 6 months particularly those not breastfed, with dehydration or systemic infection or those with severe malnutrition (weight-for-length < 70% or mid-upper arm circumference < 11.5 cm or visible severe wasting or symmetrical pedal edema) are at high risk for complications and may require to be treated in hospitals. All children with PD should be carefully screened clinically for indicators for systemic infection and all those who have severe malnutrition should be assumed to have systemic infection.

MANAGEMENT OF PERSISTENT DIARRHEA

Prevention and Treatment of Dehydration

The child should be assessed for signs of dehydration and treated according to the WHO Treatment Plan A, B or C, as appropriate (as described in Chapter 36.1).

Antimicrobial Therapy

Controlled trials of empirical treatment with large doses of oral gentamicin hypothesized to act locally against the enteric pathogens and the increased small bowel bacterial overgrowth, or sulfamethoxazole-trimethoprim, and combinations of metronidazole with nalidixic acid postulated to act locally on

the enteric pathogen and any associated systemic infection did not show any therapeutic benefits. Although these studies were conducted as far back as the late 1980s and early 1990s and had small sample sizes making their effect estimates imprecise, these or other antimicrobials have not been evaluated in larger trials. Currently, antimicrobial therapy in PD is indicated only in the presence of gross blood in stools or for specific enteric pathogens against which such therapy is known to be beneficial, e.g., *Shigella*, when there is associated systemic infection, or documented urinary tract infection and in those who are severely malnourished.

Additional Drugs

Antimotility and antisecretory agents and bile salt binding resins have not been shown to give any significant clinical benefit when used to treat PD. Larger better quality trials are required to evaluate the new broad spectrum antimicrobials in children with persistent diarrhea; assessing effects on both the clinical and the nutritional outcomes. This would be particularly important in cases where specific pathogens like *Cryptosporidium* and other newer protozoal agents are identified.

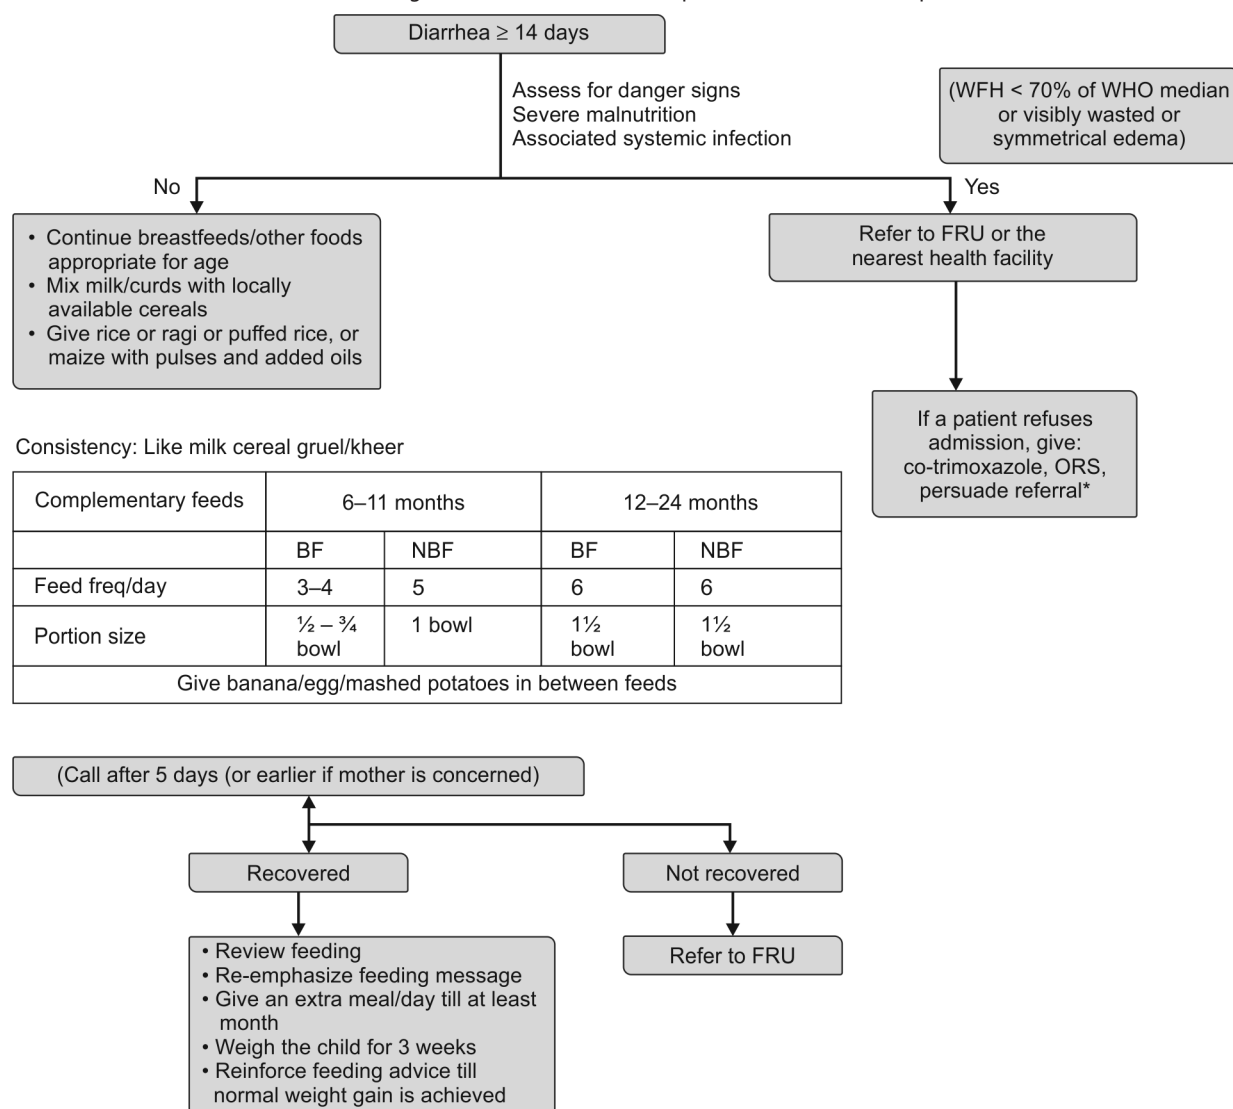

Dietary Management in Older Infants and Young Children

Nutritional therapy is the cornerstone of management of PD. Breastfeeding should be continued as breastfed infants continue to gain some weight even while passing abnormal stools for a few extra days after an acute episode of gastroenteritis. In the second and later years, breastmilk output is less and optional feeding of a mixed diet is more important.

Dietary Algorithm (Flow charts 1 and 2)

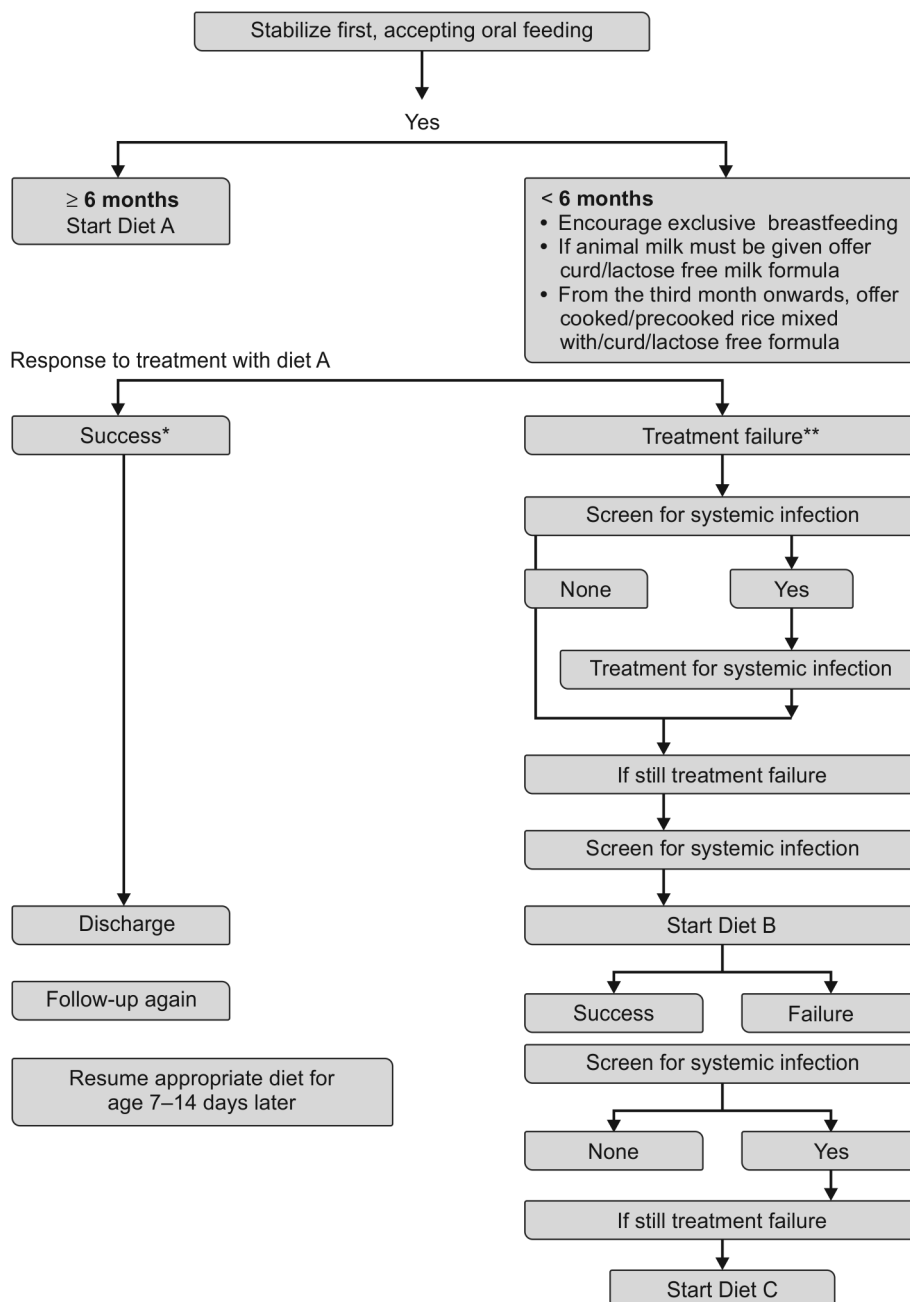

Initial evidence showed therapeutic benefits with locally prepared reduced lactose feeds (modest amounts of milk mixed with cereals or rice lentil yogurt gruels) as compared with complex lactose free diets. Milk or curd cereal mixtures were more efficacious than soy based formulae in clinical trials. These studies clearly showed that total elimination of milk is not required for initial management of PD. The scientific rationale for replacing milk partially with locally available cereals was because it reduces the lactose concentration in the diet without compromising on the protein and the micronutrient content of the diet. Additionally,

Flow chart 1 Algorithm for the treatment of persistent diarrhea in outpatients

*For severely ill children, if referral is impossible, advice to give additional intramuscular gentamicin.

Abbreviations: BF, breastfed; NBF, non-breastfed; FRU, first referral unit; WHO, World Health Organization; ORS, oral rehydration solution; WFH, weight for height

Flow chart 2 Algorithm for dietary treatment of persistent diarrhea in hospital setting

*Successful treatment with either diet is characterized by weight gain, adequate food intake, diminished number of diarrheal stool (≤ 2 liquid stools/day for 2 consecutive days), and disappearance of any fever

**Treatment failure is defined as: in the absence of initial or hospital acquired systemic infection there is:

- A marked increase in stool frequency (usually more than 10 watery stools/day) any time after at least 48 hours on the diet or,
- Return of signs of dehydration any time after initiating treatment or,
- Failure to establish weight gain by 7 days.

Give vitamin A 200,000 IU (>12 months) or 100,000 IU (6–12 months) routinely. For children <8 kg (irrespective of age) administer 100,000 IU. Give mixture of vitamins and minerals providing at least two RDA. If other minerals are difficult to provide, at least give elemental zinc 10 mg daily up to 1 week after recovery. Give antibiotics for bloody diarrhea/systemic infections/severe malnutrition. Diet C is best administered in a hospital with appropriate facilities.

Patients discharged on diet B should be given small quantities of milk as part of a mixed diet after 10 days. If there are no signs of lactose intolerance, increase milk gradually over the next few days.

cereals delay gastric emptying and facilitate better absorption of the lactose in the milk.

Based on this initial evidence WHO tested a two-step dietary algorithm in Asia and Latin America in children with PD. The initial

diet (Diet A) was a reduced lactose milk cereal mix, prepared by replacing milk partially with locally available cereals and legumes. The second level diet consisted of lactose free diet prepared with local staples, where the milk was replaced with an alternative

protein (egg/chicken/legumes—diet B). The recovery rate with diet A was 65% and after diet B was 80%.

The WHO recommended dietary algorithm with clear definitions of treatment failure, that indicated the need for change in diet and a well-defined screening protocol for associated systemic infections, was an important milestone in the management of PD. The recommended diets maintained or increased energy and protein intake, and also improved stool consistency due to higher fiber intake. These diets could be prepared easily at home, and since were highly palatable, were consumed in large amounts, and resulted in faster weight gain. Only a small proportion who did not recover on reduced lactose or lactose free diets required more complex sucrose or even carbohydrate free diets.

The dietary algorithm is currently the accepted standard treatment for PD globally and particularly in the low- and middle-income countries. It has been part of the National Guidelines for the management of persistent diarrhea in India for over two decades. Further, early evidence showed that homemade modular diets (chicken mince with oil and sugar) had significant therapeutic benefits as compared to semielemental formulae making treatment of more complicated PD easier. Use of locally available homemade diets has important public health implications in resource limited settings. The detailed treatment algorithm for the management of PD is provided later.

The initial Diet A (Reduced lactose diet; milk rice gruel, milk rava/sooji gruel, rice with curds, dalia) Total elimination of animal milk is not required routinely. Daily intake of milk should be limited to 50–60 mL/kg providing not more than 2–2.5 g of lactose/kg/day. It is not recommended to reduce the lactose concentration in animal milk by diluting milk with water as it reduces energy density critically. Milk should be mixed with cereals, e.g., some examples are milk or curd rice gruel, milk rava gruel, or dalia (**Table 1**). Feeding should be started as soon as the child can eat. In the beginning 6–7 feeds per day providing a total daily energy intake of 110 kcal/kg/day should be offered. The energy intake should be increased gradually up to 150 kcal/kg/day over the next 2 weeks if required to achieve weight gain. Many children may eat poorly in the initial 24–48 hours because of possible existing serious systemic infection and the appetite will improve as the infection is treated. In situations where there is severe anorexia nasogastric feeding is recommended.

The second Diet B (lactose-free diet with reduced starch) Some children do not respond well to the initial low lactose diet. They may have impaired digestion of starch and disaccharides other

Table 1 Preparation of the initial reduced lactose Diet A

Ingredients	Approximate quantity
Milk	40 mL
Sugar	2 g
Oil	2 g
Puffed rice powder*	12.5 g
Water	To make 100 mL
Calories/100 g	96 kcal
Proteins/100 g	2.4 g

*Can be substituted by cooked rice or rava/sooji (some examples).

Preparation

- Mix milk, sugar, rice together
- Add boiled water and mix well
- Add oil

Table 2 Preparation of the reduced starch Diet B

Ingredients	Approximate quantity
<i>Example of one diet</i>	
Egg white	15 g
Puffed rice powder*	7 g
Glucose	3 g
Oil	4 g
Water	To make 100 mL
Calories/100 g	78 kcal
Proteins/100 g	2.3 g

*Can be substituted with cooked rice.

Preparation

Whip the egg white well. Add puffed rice powder, glucose, oil and mix well. Add boiled water and mix rapidly to avoid clumping.

Example of another Diet B

Ingredients	Approximate quantity
Chicken	7 g
Puffed rice powder*	7 g
Glucose	3 g
Oil	4 g
Water	To make 100 mL
Calories/100 g	78 kcal
Proteins/100 g	2.3 g

*Can be substituted with cooked rice.

Preparation

Boil chicken, remove the bones and make chicken puree. Mix chicken puree with rice, glucose and oil. Add boiled water to make a smooth paste.

than lactose. Children who do not improve on the initial diet A should be given diet B, which should be milk (lactose) free and should provide carbohydrates as a mixture of cereals and glucose (**Table 2**). Milk protein can be replaced by chicken, egg or protein hydrolysate and the starch can be reduced by partially substituting it with glucose. Replacing only part of the cereal with glucose increases the digestibility without resulting in a highly osmolar diet, which would be the case if all the cereals were to be replaced by glucose.

The third Diet C (monosaccharide based diet) Overall 80–85% patients with severe persistent diarrhea will recover with sustained weight gain on the initial diet A or the second diet B. A small percentage may not tolerate a moderate intake of the cereal in diet B. These children should be given the third diet (Diet C), which contains only glucose and a protein source as egg or chicken. Energy density should be increased by adding oil to the diet (**Table 3**).

Monitoring the Response to Treatment

Most children will lose weight in the initial 1–2 days, and then show steady weight gain as associated infections are treated and diarrhea subsides. The weight should increase on at least 3 successive days before one can conclude that weight gain is occurring. Successful treatment is characterized by diminished number of diarrheal stools (less than or equal to two liquid stools day for 2 consecutive days), adequate food intake, and weight gain.

Table 3 Preparation of a monosaccharide based diet (Diet C)

Ingredients	Approximate quantity
Chicken or egg white	12 g
	25 g
Glucose	3 g
Oil	4 g
Water	To make 100 mL
Calories/100 g	60 kcal
Proteins/100 g	3 g

Preparation

Boil chicken, remove the bones and make chicken puree. Mix chicken puree with glucose and oil. Add boiled water to make a smooth paste.

Or

Whip the egg white well. Add glucose, oil and mix well. Add boiled water and mix rapidly to avoid clumping.

Change from the Initial Diet (Diet A) to the Second Diet (Diet B) or Diet B to Diet C

In the absence of initial or hospital acquired systemic infection, the diet should be changed when there is failure on the treatment which is normally defined as a marked increase in stool frequency (usually more than 10 watery stools/day) any time after at least 48 hours of initiating the diet or, return of signs of dehydration any time after initiating treatment or, a failure to establish weight gain by day 7. Unless signs of treatment failure occur earlier, each diet should be given for a minimum period of 7 days.

Patients with Severe Glucose Malabsorption

Poor outcome on diet C may be due to transient glucose malabsorption. This is a rare complication. These patients are identified by presence of reducing substances in stool when glucose is the only carbohydrate in diet, e.g., oral rehydration salts (ORS) solution. The diarrhea ceases promptly on fasting and intravenous (IV) fluids. The practical approach is to administer IV 10% glucose with electrolytes and continue a diet orally which contains only a source of protein (some examples are chicken, egg white) and oil.

Supplemental Vitamins and Minerals

Since most children with PD are malnourished, about twice the Recommended Dietary Allowance (RDA) of supplemental multivitamins and minerals, should be given daily to all children for at least 2–4 weeks. Iron supplements should be introduced only after the diarrhea has ceased. Zinc should be administered as recommended for treatment of acute diarrhea; 10 mg of elemental zinc should be given to infants 2–6 months and 20 mg to children above 6 months for at least 14 days. Studies evaluating the efficacy of zinc in the treatment of persistent diarrhea conducted in Asian countries where there is moderate to high risk of zinc deficiency have shown that zinc supplementation shortens the duration of diarrhea by around 16 hours. Most commercial preparations are available as zinc sulfate, zinc chloride or zinc gluconate. Vitamin A should be administered in standard where doses clinically indicated.

Additional Recommendations for the Severely Malnourished Infants and Children with Persistent Diarrhea

- A single oral dose of 200,000 IU of vitamin A for children more than 12 months or 100,000 IU for children 6–12 months should be given routinely. Children weighing less than

8 kg, irrespective of their age, should be given 100,000 IU of vitamin A.

- On day 1, 50% magnesium sulfate IM once (0.3 mL/kg up to a maximum of 2 mL) should be given. Thereafter, extra magnesium (0.4–0.6 mmol/kg daily) should be given orally for at least 2 weeks. Injection magnesium sulfate (50% which has 2 mmol/mL) can be given orally as a magnesium supplement mixed with feeds.
- 5–6 mEq/Kg/day of potassium should be administered orally or as part of IV infusion during the initial stabilization period. The usual requirement of 3–4 mEq/kg/day, should be continued for at least 2 weeks.
- The other multivitamins and micronutrients should be given as recommended in the treatment of severe malnutrition.

Resumption of Regular Diet

Children on Diet A should gradually resume a diet appropriate for age after 7–14 days. Children on diet B should be given small quantities of milk as part of a mixed diet after 10 days. If they have no signs suggestive of lactose intolerance (diarrhea, vomiting, abdominal pain, abdominal distension, excessive flatulence) milk can be gradually increased over the next few days. A normal diet appropriate for age can be resumed over the next week.

Dietary Management of Persistent Diarrhea in Infants Aged Less than 6 Months

Breastfed infants could normally be passing several soft or mushy stools each day. In such cases, the change in character of stools will be important. Breastfeeding should be encouraged. Mothers who are not breastfeeding should be assisted to re-establish lactation. In cases where only animal milk can be given, curds or a lactose free milk formula should be given with a cup and spoon. From the 6th month onwards cooked/precooked rice can be mixed with milk/curd/lactose free formula.

RECENT ADVANCES

A recent review reported low-to-moderate quality evidence for use of commercially prepared or specialized ingredients compared to home-available ingredients on any outcome in PD. The available evidence does not support the use of proprietary formulas or specialized ingredients over the use of locally produced and readily available foods. This is particularly important in resource constrained settings.

Green plantain or pectin is another intervention evaluated recently in PD. The high content of amylase rich starch (ARS) in the green banana remains undigested in the small intestine of humans, but gets fermented by resident bacteria in the colon into the short-chain fatty acids (SCFA), butyrate, propionate, and acetate. The SCFA stimulate salt and water absorption, and induce a trophic effect on the small bowel and colonic mucosa. It is also postulated to enhance mucosal resistance and promote healing of damaged tissue because of the presence of surface-active phospholipids. Pectin is the amylase-resistant polysaccharides in the cell wall and intracellular substances in green bananas and many other fruits. It contains essentially methoxylated polygalacturonic acids. The pectic substances present in green bananas are mostly α -glucans and dextrin, which hydrolyze into soluble sugars during ripening but are not digested when eaten as unripe fruit. Significant therapeutic benefits on stool output, diarrheal duration and weight gain have been seen with green plantain based diet in studies done in Bangladesh. It was also found to increase the intestinal permeability. Similar results were also reported with pectin. The added advantage of these diets is the low cost and easy local availability.

Potential use of diets made from other locally available ingredients have been explored. Better digestible foods can be

developed by modifying dietary characteristics like the osmolality or the fiber content. One interesting example would be to use amylase-rich flour in decreasing the viscosity and increasing nutrient density of diets. Other such examples need to be explored.

Role of Probiotics

The results of the recent Cochrane systematic review showed insufficient evidence to suggest a beneficial role of probiotics in treating persistent diarrhea in children. Probiotics could have a potential role as a therapeutic agent in the treatment of persistent diarrhea but methodologically well-designed and sufficiently powered trials with different probiotics are required in the future. Effects of one probiotic strain cannot be extrapolated to another one and thus specific probiotic strains and precise dosing of these strains need to be evaluated. Breastfeeding rates, cointerventions and associated comorbidity may influence the therapeutic effects of probiotics making it important to evaluate them in different host and environmental settings.

IN A NUTSHELL

1. Persistent diarrhea (PD) is defined as diarrhea of a presumed infectious etiology that has an acute onset and continues for at least 14 days. It should be differentiated from chronic diarrhea that can last longer and results from congenital, biochemical or metabolic disorders.
2. The risk factors for PD include younger age, malnutrition, irrational antibiotic use in acute diarrhea and lack of breastfeeding.
3. The causative organisms that are isolated from persistent diarrhea stools at higher frequency than in acute diarrhea include Enteraggregative *E. coli*, and *Cryptosporidium spp.*
4. Nutrition is the mainstay of therapy; breastfeeding should be continued; milk should be replaced by reduced lactose preparations such as yoghurt-cereal mix, reduced lactose milk cereal mix prepared by replacing milk partially with locally available cereals and legumes. The second level diet should consist of lactose free diet prepared with local staples, where the milk can be replaced with an alternative protein (egg/chicken/legumes). Supplemental minerals and vitamins should be given to all subjects and rehydration therapy wherever indicated.
5. Antimicrobials are indicated when there is associated dysentery, systemic infection, severe malnutrition or in cases where *Shigella* is isolated from stools.

Chapter 36.5

Chronic Diarrhea

BR Thapa, Srikanth KP, Babu Lal Meena

Chronic diarrhea, one of the most important cause of failure to thrive (FTT) in infants and children, includes a vast heterogeneous group of gastrointestinal (GI) disorders. The onset may be acute, insidious or intermittent. Elaborate investigations are required to reach to accurate diagnosis. Most of the investigation tools are not available in all the centers in India. The treatment of chronic diarrhea depends upon the underlying cause but at times it is frustrating. This chapter is aimed to elaborate practical approach in the diagnosis and the management of chronic diarrhea.

DEFINITION

Diarrhea is defined as when child passes loose stools more than three times a day. Liquidity of stools is an important component to label as diarrhea. Some authors have stressed upon the weight of the stools; in infants more than 10 g/kg/day, 1–3 years age more than 15 g/kg/day, in older children stool output more than 200 g/day and in adolescents more than 300 g/day as a criteria to define diarrhea. Chronic diarrhea is defined when duration of diarrhea is more than 2 weeks, *irrespective of the etiology*. This is accepted definition in children world over, whereas some authors believe duration of diarrhea for more than 4 weeks in adolescent and adults is appropriate. Infants and children behave differently to diarrheal insults and weight loss occurs very fast hence, growth suffers. At the same time their intake is compromised and adds to the severity of disease. All these factors may not be operating in adults; that is why the duration of 2 weeks is considered appropriate in children. *Persistent diarrhea* also refers to a diarrhea of more than 2 weeks, but it is presumed to be of infectious etiology.

Chronic diarrhea is classified depending upon the age of onset, severity, etiology, organ involved, characteristics of stools and mechanism of diarrhea (**Table 1**).

EPIDEMIOLOGY

The incidence of chronic diarrhea in general population varies from 1% to 5%. The prevalence of chronic diarrhea in young children is unknown in developing countries. According to World Health Organization (WHO) report, every year 2–4 million children die of diarrhea. Diarrhea accounts for 13.2% of all childhood deaths worldwide and 50% are due to chronic diarrhea. Bacterial and parasitic infections are more common in tropical countries whereas inflammatory bowel disease (IBD) occurs more often in western world. Underlying acquired immunodeficiency syndrome (AIDS) has created havoc in both developed and developing countries. Awareness of food allergic disorders is increasing in our country. Cow milk protein allergy (CMPA) is diagnosed in 2–5% of infants with diarrhea whereas celiac disease occurs in 1% population and maximum reported from northwestern states of India.

PHYSIOLOGY OF DIGESTION AND ABSORPTION OF NUTRIENTS

Carbohydrates

Complex starch molecules (amylose and amylopectin) are digested by action of intraluminal salivary and pancreatic amylases. The ingested disaccharides are not absorbed as such. These are broken down by brush border enzymes, e.g., lactase,

Table 1 Classification of chronic diarrhea in infants and children

<ul style="list-style-type: none"> • Age and severity <ul style="list-style-type: none"> – Less than 28 days: Neonatal diarrhea – Age under 1 year <ul style="list-style-type: none"> - Protracted or intractable diarrhea of infancy (PDI/IDI) – Acute infective episodes of diarrhea > 2 weeks <ul style="list-style-type: none"> - Persistent diarrhea – Chronic diarrhea – Well known conditions <ul style="list-style-type: none"> - With or without failure to thrive/malabsorption - With or without villus atrophy

sucrase, maltase, trehalase in proximal small intestine and by glucoamylase in ileum into their monosaccharide molecules, e.g., glucose, galactose and fructose. These molecules enter into the enterocyte through the brush border membrane by carrier molecules. Entry of glucose and galactose, occurs through the carrier protein, sodium glucose linked transporter SGLT1. Entry of sodium occurs along its electrochemical gradient. Sodium blocks glucose exit from the cell and eventually provides the energy necessary for its accumulation in the cell against a concentration gradient. The electrochemical sodium gradient is maintained by Na^+ , K^+ -ATPase located in the basolateral membrane of the enterocyte. Thus glucose and galactose absorption is indirectly active process. Mutations of the gene coding for SGLT-1 are responsible for congenital glucose-galactose malabsorption. The entry of fructose in the enterocytes is through another specific carrier glucose transporter (GLUTs).

Newborns have low amylase activity during the first few weeks of life. Deficiency of various enzymes causes maldigestion of the food. Maldigested carbohydrates are small, osmotically active molecules leading to accumulation of water inside the lumen of the gut. The increased volume of chyme leads to an increased peristaltic activity and a reduced intestinal transit time thereby decreasing the chance of digestion and absorption. In the cecum, the unabsorbed small carbohydrate molecules are readily fermented by colonic bacteria and produce carbon dioxide, hydrogen, methane and lactic, acetic, butyric and propionic acids. Lactic acid, a strong acid, leads to stool pH less than 5.5 and is responsible for perianal excoriation. This low pH disturbs sodium absorption by the colonic mucosa and tends to increase stool volume.

Fats

The digestion of fats starts in the stomach by action of gastric lipase that is active in acidic pH (4.5–5.5). The free fatty acids are released and in the duodenum pancreatic lipase gets adsorbed to lipid droplets resulting in emulsification. In neonate there is low activity of lipase in the pancreatic juice as compared to gastric lipase. The presence of bile salts leads to micelle formation and helps in absorption. During soluble lipid phase, the fat absorption occurs by diffusion through basolateral membrane of enterocytes. Medium chain triglycerides (MCT) do not require micelle formation. MCT gets directly absorbed through apical membrane of enterocytes and reach liver/blood by portal circulation, whereas all other triglycerides, fats and fat soluble vitamins require solubilization and micellization. After absorption in the enterocytes, the chylomicron formation occurs in golgi apparatus. The chylomicrons exocytose from the cell to reach intracellular spaces and are taken up by lymphatics and via thoracic duct to reach circulation.

Fats are hydrophobic so the digestion and absorption of dietary fats are dependent on many other molecules: bile salts, colipase, fatty acid-binding proteins, and apolipoproteins. Fat malabsorption may result from lipase and/or colipase deficiency; abnormal bile salt synthesis, excretion, deconjugation, and reabsorption; impaired triglyceride resynthesis; chylomicron formation and/or excretion; or obstruction of intestinal lymphatics. Isolated fat malabsorption is extremely rare. Bile salts get deconjugated by certain bacterial species in cases of bacterial overgrowth. Unconjugated bile salts are less ionized as compare to conjugated ones at the pH of the gut lumen; thus they have a lower ability to form micelles than the latter. Bacterial overgrowth is associated with other symptoms like: increased degradation of protein and vitamin B₁₂ binding proteins, fermentation of carbohydrates with production of H₂ released in breath and of volatile fatty acids resulting in diarrhea, hypoproteinemia, loss of weight, and megaloblastic anemia.

Proteins

Digestion of proteins starts in the lumen of the stomach, where gastric acid causes denaturation of protein and activates pepsinogens I and II into the pepsins I and II respectively. These are inactive at a pH of less than 5 and have a broad specificity to split the peptide bonds mostly involving phenylalanine, tyrosine and leucine. Food has good buffering capacity so gastric secretion does not play major role in protein digestion. Enterokinase activation leads to conversion of trypsinogen into trypsin, which in turn activates the other zymogens into active proteases. The endopeptidases are serine proteases and have different and strictly defined specific action to release amino acids and peptides. In contrast to carbohydrates, peptides enter enterocytes either after preliminary digestion by brush border peptidases into amino acids or as peptides. In case di- and tripeptides, get entry to the cell these are acted upon by cytoplasmic peptidases inside the cell.

Protein absorption is not affected by gastrectomy. Selective absence of pancreatic protease activities in congenital enterokinase deficiency can lead to protein losses in the stool. The pancreatic exocrine insufficiency leads to loss of nutrients in the stools (fat and starch) resulting in massive steatorrhea. Stool of these patients are often white in color, greasy, soft but not liquid, and extremely foul smelling due to excess of protein content (azotorrhea). In case of mucosal atrophy there is milder form of steatorrhea and protein losses.

The digestion and absorption of various macro and micro-nutrients in GI tract is shown in **Figure 1**.

PATHOPHYSIOLOGY OF CHRONIC DIARRHEA

Four major mechanisms have been proposed:

Figure 1 Sites of absorption of various nutrients

Secretion

There is increase in net secretion of electrolyte and fluid from the intestine without compensatory absorption, induced by endogenous secretagogues, even in the absence of an osmotic gradient. Children with a pure secretory type diarrhea will therefore, continue to experience diarrhea even while fasting. Typically, secretagogues affect ion transport in the small and large bowel both by stimulating chloride secretion via cystic fibrosis transmembrane regulator (CFTR) activation. The enterotoxins elaborated by the bacteria, viruses and the parasites interact with the receptors modulating intestinal transport and lead to increased anion secretion. In addition they block specific absorptive pathways.

The intestinal peptides produced by endocrine tumors (e.g., neuroblastoma), e.g., vasoactive intestinal peptide (VIP), calcitonin and the neurotransmitters like acetylcholine, serotonin, histamine and cytokinin produce secretory diarrhea by stimulating epithelial lining. Some drugs and poisons may also affect intracellular transporters and regulators in enterocyte. Two examples of inherited secretory diarrhea are chronic chloride diarrhea (chronic diarrhea) and chronic sodium diarrhea (CSD).

Osmosis

This is caused by the retention of water by the unabsorbed food material in the intestinal lumen. The ingestion of poorly absorbed anions, cations and certain unabsorbed sugars like mannitol, sorbitol, lactulose, lactitol, polyethylene glycol, and fiber diet lead to osmotic diarrhea. Poorly absorbed ions are magnesium sulfate and phosphate. These unabsorbed substances retain water to maintain osmolality equal to body fluids or more. In children secondary lactose intolerance is important cause of chronic diarrhea due to deficiency of lactase enzyme in the brush border of

small bowel. The unabsorbed lactose reaches the colon and leads to osmotic diarrhea. The absorption of electrolytes is not affected so there is not much loss of sodium. The osmotic gap is calculated as $290 - 2 (\text{Stool Na}^+ \text{ Stool K})$. The osmotic gap is more than 100 mOsm/L. The differences between chronic osmotic and secretory diarrhea are given in **Table 2**.

Dysmotility

Chronic diarrhea associated with intestinal dysmotility typically occurs in the setting of intact absorptive abilities. Intestinal transit time is decreased, the time allowed for absorption is minimized, and fluid is retained within the lumen. The high amplitude propagated contractions play a key role in motility disorders of the gut and have been found to be more frequent in patients with diarrhea predominant irritable bowel syndrome (IBS). Although diarrhea predominant IBS may be diagnosed in older children and adolescents, toddlers commonly present with chronic nonspecific diarrhea (CNSD). Changes in small intestinal motility also have been implicated in causation of CNSD. Thyrotoxicosis is also associated with increased motility and decreased transit time.

Inflammation

This may encompass all known pathophysiological mechanisms. Inflammation with resultant injury to the intestine may lead to malabsorption of dietary macronutrients and micronutrients which, in turn creates a luminal osmotic gradient. Additionally, particular infectious agents may induce secretion of fluid into the lumen, and blood in the gut may alter intestinal motility. Diseases such as IBD and celiac disease exemplify this mechanism.

Chronic Diarrhea is a Complex Disorder

The mechanism of diarrhea cannot be explained on the basis of osmotic and secretory pathophysiology alone. There are other factors which are responsible for chronic diarrhea. These are paracrine, immune, neural and endocrine modulators—a regulatory system abbreviated as PINES (**Fig. 2**). They affect the epithelial and smooth muscle functions of intestines and are responsible for diarrhea. The maladaptive responses are responsible for chronic diarrhea. The dysregulation of this system in gut is the main cause for the vicious cycle of chronic diarrhea with or without malabsorption.

ETIOLOGY

Chronic diarrhea is a symptom complex of varied etiologies and caused by heterogeneous group of disorders in children. Various

Table 2 Differences between the chronic osmotic diarrhea and secretory diarrhea

Characteristics	Osmotic	Secretory
Perianal redness	Present	Absent
Volume of stools	< 200 mL/24 hours	> 200 mL/24 hours
Purge	Watery stools, explosive and lots of gas	Watery nonexplosive and no gas
Response to fasting	Diarrhea stops	Diarrhea continues
Stool sodium	< 70 mEq/L	> 70 mEq/L
Reducing substances	Positive	Negative
Stool pH	< 5.5	> 5.5
Osmotic gap	> 100	< 50

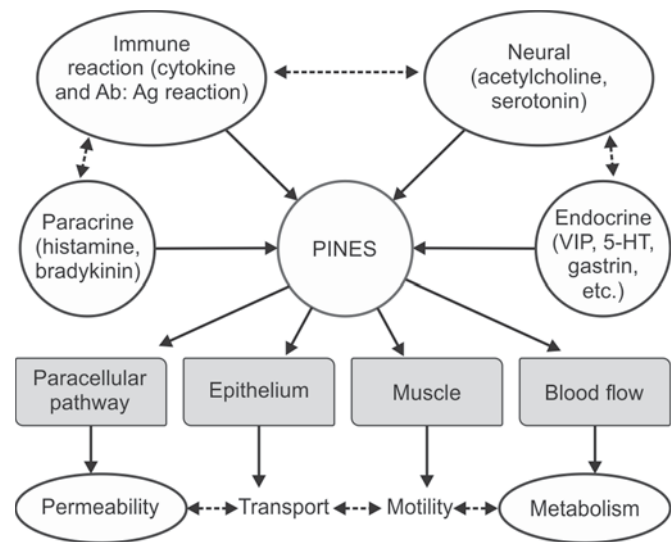

Figure 2 Paracrine-immune-neuroendocrine system (PINES) regulatory system in the gut

causes of chronic diarrhea are given in **Table 3**. The published data from PGI, Chandigarh revealed protracted diarrhea 33%, celiac disease 26%, parasites 9%, CMPA 6%, tuberculosis 5%, cystic fibrosis (CF), short gut and acrodermatitis enteropathica 8%, and unknown 13%. This pattern is similar to report from the west.

Chronic diarrhea needs to be differentiated from fecal soiling, pseudodiarrhea, encopresis, and fecal incontinence where there is uncontrolled passage of the stool in the clothes leading to embarrassing situation for the child and parents. Often parents confuse this with chronic diarrhea but stools are of normal consistency and there is no FTT.

CLINICAL FEATURES

The exact clinical manifestations depend upon the etiological cause of diarrhea and the location of the disease in the GI tract. Broadly they are classified depending upon the involvement of either the small bowel or the large bowel. The differences are shown in the **Table 4**.

APPROACH TO A CHILD WITH CHRONIC DIARRHEA

The approach to evaluate the type of chronic diarrhea is given in **Flow chart 1**. First step is to categorize the type of chronic diarrhea and second step is to investigate for the etiology of chronic diarrhea.

History

It is mandatory to know the characteristics of the stools and duration of diarrhea. The perception of the child and parents about the stools may be different. Confirm whether there is diarrhea or normal stooling pattern or incontinence or encopresis.

Age of Onset

It is important to know the age of onset of diarrhea. There are distinct conditions causing chronic diarrhea and start at different age groups.

Characteristics of Stools

The characteristics of the stools, the frequency, and bulky stools, difficult to flush, with visible oil droplets, undigested food material, with or without blood or mucus are important indicators of underlying disease states.

Table 3 Causes of chronic diarrhea in children

Infections
Bacterial: <i>Shigella</i> , <i>Salmonella</i> , <i>Yersinia enterocolitica</i> , <i>Escherichia coli</i> , <i>Clostridium difficile</i> , <i>Campylobacter jejuni</i> , <i>Vibrio cholerae</i> , <i>Mycobacterium avium complex</i>
Viral: <i>Rotavirus</i> , <i>Adenovirus</i> , <i>Astrovirus</i> , <i>Torovirus</i> , <i>Cytomegalovirus</i> , <i>HIV</i>
Parasitic: <i>Giardiasis</i> , <i>Entamoeba histolytica</i> , <i>Cryptosporidium</i> , <i>Isospora</i> , <i>Strongyloides</i>
Fungal infections
Postenteritis syndrome
Small bowel bacterial overgrowth
Tropical sprue
Diarrhea with excessive intake of: Carbonated fluids, dietetic foods containing, sorbitol, mannitol, xylitol, antacids or laxatives containing lactulose or $Mg(OH)_2$, methylxanthine-containing drinks like cola, tea, coffee, etc., cold beverages like cold drinks including fruit juices, fruits, carbohydrate rich foods, etc.
Carbohydrates malabsorption: Congenital or acquired lactase deficiency, fructose malabsorption congenital or acquired sucrose-isomaltase deficiency, glucose-galactose malabsorption
Abnormal digestion
<i>Pancreatic insufficiency:</i> Chronic pancreatitis, isolated pancreatic enzyme deficiency, hypoplasia of pancreas, cystic fibrosis, Shwachman-Diamond syndrome, Pearson syndrome, trypsin/ chymotrypsin, enterokinase deficiency
<i>Disorders of bile acids:</i> Chronic cholestasis, biliary atresia, neonatal hepatitis, progressive familial intrahepatic cholestasis, use of bile acid sequestrants, primary bile acid malabsorption, terminal ileal resection, etc.
Immune based disorders: Celiac disease, CMPA, food allergy, eosinophilic gastroenteritis, inflammatory bowel disease, autoimmune enteropathy, primary immune deficiency, HIV enteropathy
Structural defects: Lymphangiectasia, microvillus inclusion disease, tufting enteropathy, phenotypic diarrhea, heparan sulfate deficiency, $\alpha_2\beta_1$ and $\alpha_6\beta_4$ integrin deficiency
Defects in electrolyte and micronutrient transport: Acrodermatitis enteropathica, acquired Zinc deficiency, congenital chloride diarrhea, congenital sodium diarrhea, selective folate deficiency, abetalipoproteinemia
Motility disorders: Hirschprung disease, intestinal pseudo obstruction, thyrotoxicosis
Surgical causes: Congenital, acquired short bowel (secondary to stenosis, segmental atresia, malrotation)
Neoplastic diseases: Neuroendocrine hormone-producing tumors: VIPoma, APUDoma, mastocytosis

Abbreviations: HIV, human immunodeficiency virus; CMPA, cow milk protein allergy; VIPoma, tumors secreting VIP (vasoactive intestinal peptide); APUDoma, tumor arising from an APUD (amine precursor uptake of decarboxylation system) cell.

Table 4 Differences between small and large bowel diarrhea

<i>Clinical features</i>	<i>Small bowel</i>	<i>Large bowel</i>
Frequency	Low to moderate	High
Quantity	Large	Small
Consistency	Liquid/semisolid	Liquid/semisolid
Characteristics	Watery, mushy, bulky, undigested	Blood and mucus/ mucus/bloody
Pain abdomen	May or may not present	Associated
Tenesmus	Absent	Present
Etiology	Bacterial/giardiasis Tuberculosis (TB)/Crohn's disease	Bacterial/amebiasis/ ulcerative colitis, Crohn's disease/TB

Nocturnal Diarrhea

Presence of nocturnal diarrhea denotes malabsorptive diarrhea and increased frequency in case of colitis.

Dietary Factors

Relationship with intake of a particular diet like introduction of top feed (animal milk) suggests CMPA. Relationship with wheat intake and improvement of diarrhea after stoppage of wheat

products suggests celiac disease. Excess of intake of fruits, fruit juices and cold beverages indicates osmotic diarrhea. Ingestion of antibiotics and laxatives intake points towards a particular diagnosis. Intake of fat rich diet worsens diarrhea in case of pancreatic insufficiency. Relationship with intake of meals suggests gastrocolic reflux. This may be normal in breastfed infants during first 6 months of life.

Deficiency of Nutrients

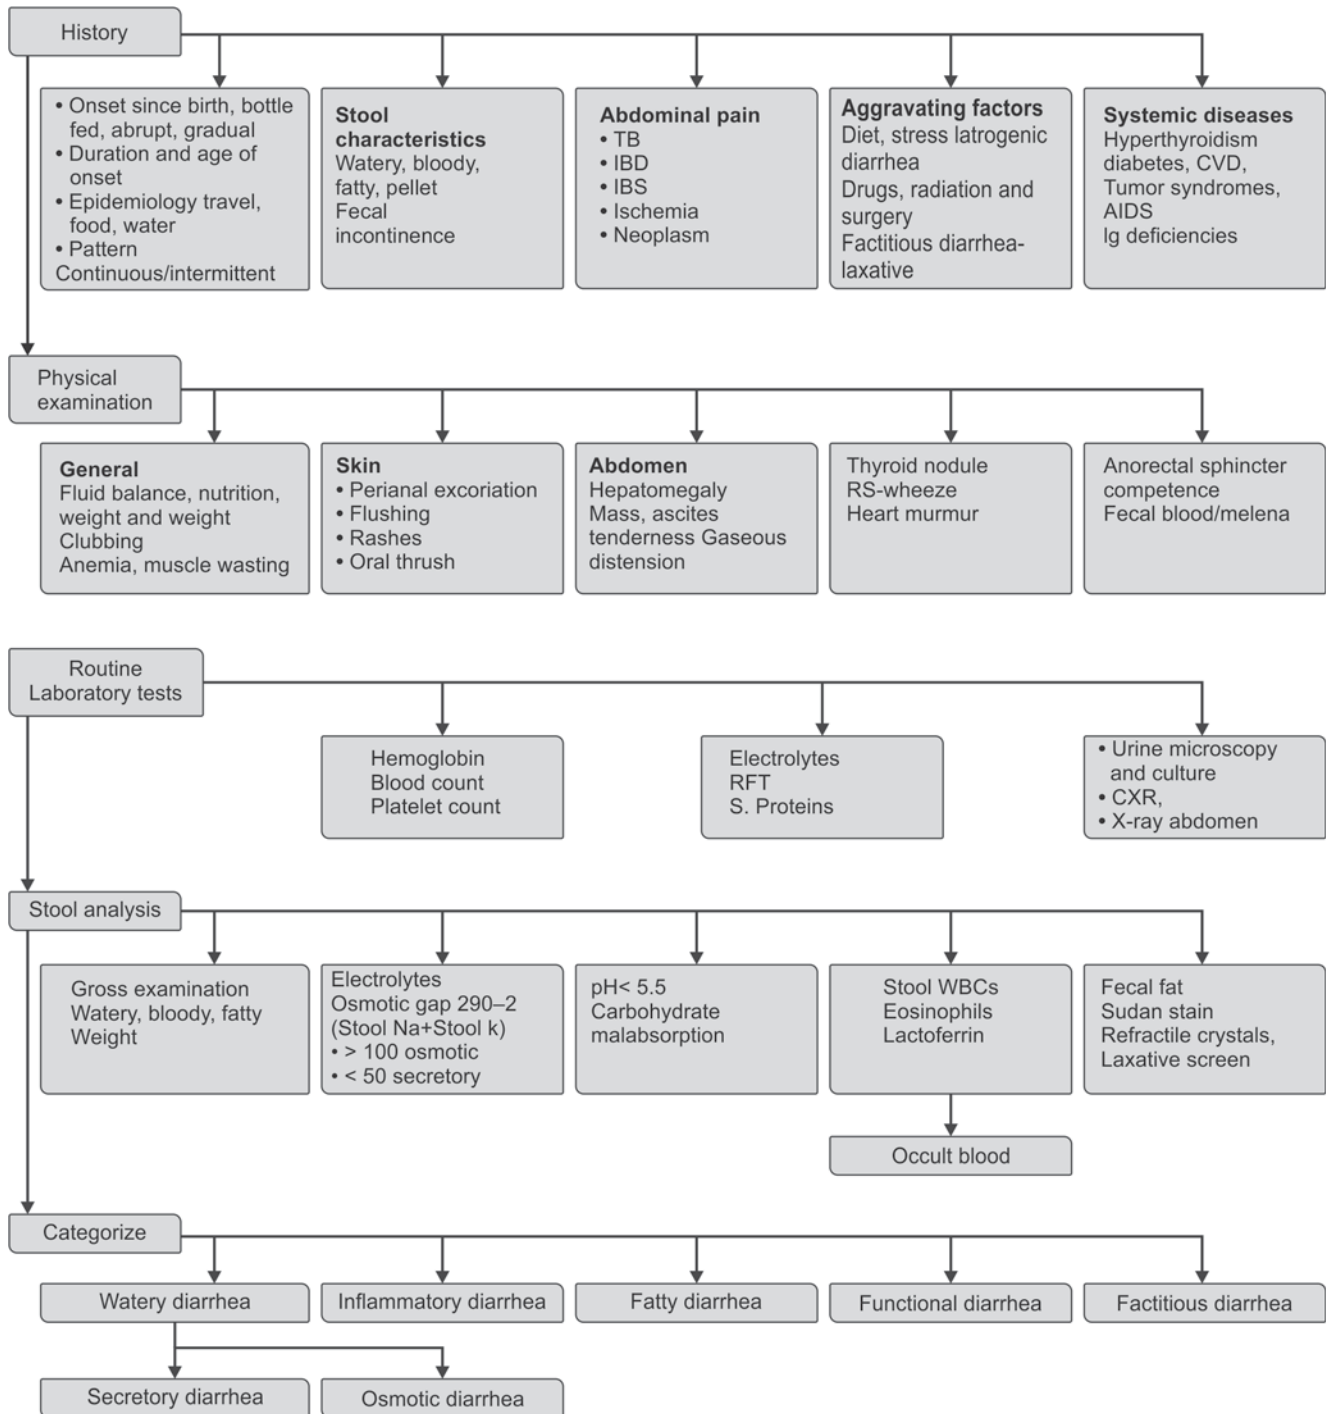

Anemia, rickets, vitamin A deficiency and vitamin B complex deficiency suggests malabsorption and will be associated with FTT. Normal growth with increased frequency of stools suggests diarrhea without FTT.

Pain Abdomen

History of significant pain abdomen is associated with tuberculosis, Crohn's disease, immunoproliferative small intestine disease (IPSID) and chronic pancreatitis. Mild discomfort with bloating can happen with malabsorption and lactose intolerance.

Extraintestinal Manifestations

Multiple systemic symptoms suggest immunodeficiency states, recurrent respiratory infections in cystic fibrosis, asthma and atopic dermatitis in food allergy and joint pains, red eyes, oral ulcers, pyoderma gangrenosum in IBD.

Flow chart 1 Practical approach to chronic diarrhea

Abbreviations: TB, tuberculosis; IBD, inflammatory bowel disease; IBS, irritable bowel syndrome; AXR, abdominal X-ray; RFT, renal function test; CXR, chest X-ray; RE, routine examination; WBC, white blood cells.

Surgical Treatment

Surgery done in the past will point towards blind loop syndrome, short gut syndrome, bile salt malabsorption and bacterial overgrowth.

Past History

Past history of immune suppression therapy and repeated exposure to antibiotics and cholestyramine helps to reach to

the cause of diarrhea. Recent history of acute diarrhea will point towards postenteritis syndrome. Any treatment taken in the past should be elaborated.

Family History

Family history is usually positive in autoimmune and allergic disorders. Polyhydramnios is associated with congenital chloride or sodium diarrhea.

Early Life Diarrhea

Intractable diarrhea during first few months of life suggests genetic diseases or transporter defects.

Physical Examination

Obtain a detailed *anthropometry* and plot on the growth charts to see the extent of malnutrition in terms of wasting or stunting with or without edema. See for the signs of *dehydration* if there is acute exacerbation of diarrhea, vomiting and poor intake. Look for *deficiency signs* like pallor, koilonychia, flat or spooning of nails, rickets, cheilitis, glossitis, bitot spots, conjunctiva/corneal xerosis, cutaneous bleed and peripheral neuropathy. Pedal *edema* or anasarca is associated with hypoproteinemia. *Clubbing* is seen in cystic fibrosis, Crohn's disease, celiac disease, and tuberculosis. Look for skin changes like dry, scaly skin, phrynoderma, dermatosis, and recurrent bacterial or fungal skin infections. Oral thrush may suggest human immunodeficiency virus (HIV) infection, exposure to antibiotics and severe malnutrition. Perianal area may show excoriation in lactose intolerance, zinc deficiency and fungal infection. Abdominal examination is done to look for the gaseous distension, ascites, organomegaly, any abdominal masses, previous surgical scars, hernial orifices and genitalia.

Categorize whether chronic diarrhea is small bowel or large bowel in origin. The salient points of differentiation are given in **Table 4**. It is also important to ascertain whether the diarrhea is due to maldigestion or malabsorption. The differentiating points between these two are given in **Table 5**.

Investigations

The tests should be disease specific, easily available and cost-effective.

Hematology

It is very important to define anemia and its types like microcytic hypochromic or macrocytic, megaloblastic or dimorphic. High platelets are seen in iron deficiency anemia like celiac disease and in IBD. Acanthocytes in peripheral smear give clue to abetalipoproteinemia. Erythrocyte sedimentation rate (ESR) and leukocytes are raised in inflammatory conditions whereas lymphopenia suggests intestinal lymphangiectasia. Raised prothrombin time (PT), low prothrombin index (PTI) and high international normalized ratio (INR) indicate vitamin K deficiency in malabsorption syndrome (MAS) and associated liver disease.

Biochemistry

Biochemical tests required are serum proteins, albumin, calcium, phosphorus, electrolytes and renal functions. Liver function tests are done in case of associated liver disease. Anemia due to iron deficiency can be confirmed by measuring serum iron, total iron binding capacity and serum ferritin levels. Vitamin B₁₂ and folic acid deficiency in megaloblastic anemia can be defined by their estimation in the blood.

Table 5 Differentiation between malabsorption and maldigestion

Features	Malabsorption	Maldigestion
Stool fat	++	+++
Fatty acid crystal	+++	-
Flatulence	++	-
Anemia	++	-
Hypoalbuminemia	++	-
Stool volume	++++	++

Stool Examination

Naked eye examination of stool is important whether stools are watery, malabsorptive, bulky, with or without undigested matter, greasy (oil in the stool), blood and mucus. Microscopic examination is done for ova and cyst of parasites, fat globules and fatty acid crystals. For detection of ova and cysts, stool microscopy should be done for 3 consecutive days and this improves the pick rate to 80–90%. *C. difficile* infection is diagnosed by doing *C. difficile* toxin assay and culture sensitivity. Giardia antigen can be detected by ELISA in the stool. Specific polymerase chain reaction (PCR) study can detect various kinds of opportunistic infections especially in immune compromised hosts. Osmotic gap more than 100 mOsm/L indicates osmotic diarrhea and less than 50 mOsm/L in secretory diarrhea. Presence of occult blood in stool is important to define invisible blood loss when anemia cannot be explained, this may be positive in celiac disease. Fecal elastase and chymotrypsin are estimated in stools and their concentration is reduced in pancreatic insufficiency.

Lactose Intolerance Test

Lactose 2 g/kg (maximum of 50 g) is given orally after overnight fasting, glucose sample basal and every 30 minutes or/and breath hydrogen sample (basal and half hourly for 3 hours) are taken. A blood glucose rise of less than 20 mg/dL over basal at 30 minutes or breath H₂ rise more than 20 ppm is taken positive and confirms the diagnosis. However, in an infant and young child these tests are technically difficult and can induce profuse severe diarrhea resulting in dehydration hence, should not be attempted.

Hydrogen Breath Test

The hydrogen is produced by bacteria by fermentation of unabsorbed carbohydrates normally and in case of bacterial overgrowth syndrome. The hydrogen produced by bacteria is absorbed through the wall of small and large intestine or both and reaches the lungs through blood and gets exhaled. The exhaled hydrogen can be measured by gas chromatography. Estimation of fasting breath hydrogen is required before performing breath test. Lactulose/glucose/fructose/lactose is used to perform breath test. All the samples of breath are analyzed for hydrogen and methane every 15 minutes for 2–4 hours. Small intestine bacterial outgrowth (SIBO) is diagnosed on glucose hydrogen breath test (H₂BT) showing a rise in breath hydrogen by 12 ppm above the basal. Early peak denotes small bowel bacterial overgrowth and late peak colonic bacterial overgrowth. However, gold standard test is culture of jejunal aspirate showing bacterial colonic count more than or equal to 10⁵ CFU/mL.

Fecal Fat

Fat malabsorption can be suspected when the fat globules on Sudan III stain are more than 100 per HPF in the stool. It is a crude method to define steatorrhea. The Van De Kamer method is the gold standard to measure 24 hours excretion of fat in grams. The fecal fat excretion is determined by supplementing fat 2 g/kg per day under 2 years of age and 50 g daily in children above the age of 2 years. Fat is given for 3 days and the same time stools are collected and fecal fat is measured. The fat excretion more than 4.5 g/day in children whereas in adolescents and adults more than 6.5 g/day is labeled as steatorrhea, however it is a messy and cumbersome method. Steatocrit is simple and can be easily performed to define steatorrhea. It is done by centrifuging the stool with or without acid and is calculated fat layer (FL)/(FL + solid layer) × 100. Fecal fat is calculated by formula = [0.45 (Acid Steatocrit %)]–0.43 g/24 hours. It is having low sensitivity and specificity as compared to van de Kamer method.

D-Xylose Absorption Test

This test is abnormal in mucosal disease involving the small intestine. The test is done after overnight fasting. 5 g of D-xylose is given orally and patient is encouraged to drink fluids to maintain the adequate urine output. Urine is collected for next 5 hours to detect d-xylose. 1 hour after the ingestion venous sample is taken to detect d-xylose level in the blood. D-xylose more than 1.25 g or more than 20% of the total in the urine collection and a serum d-xylose concentration less than 20 mg/dL are suggestive of mucosal malabsorption. D-xylose absorption test is normal if disease is predominantly involving distal small bowel. This test may be falsely negative in presence of dehydration, renal dysfunction, delayed gastric emptying, ascites and improper collection of urine.

Schilling Test

This test is done to define B₁₂ deficiency, whether gastric or ileal in origin. A small dose of radiolabeled B₁₂ is given orally and at the same time nonradio labeled 1000 µg of B₁₂ is given intramuscular (IM) as the flushing dose, the later saturates the B₁₂ level in the body whereas radiolabeled B₁₂ is absorbed from intestine and is excreted in urine. 24 hours urine is collected, if less than 7% of radiolabeled dose is recovered, it suggests B₁₂ malabsorption. Second phase of schilling test is administration of intrinsic factor and normalizes the schilling test in case of pernicious anemia in which there is intrinsic factor deficiency.

Endoscopy

Upper GI endoscopy is required to define changes in the duodenum and gives clue to cause of malabsorption due to the presence of grooving, scalloping of folds, nodularity, decreased height of the folds and mosaic pattern in celiac disease, white pearl like punctate lesions or vesicles due to dilated lacteals in lymphangiectasia and nodularity, deep linear ulceration in Crohn's disease, nodular duodenal mucosa is seen in giardiasis, celiac disease, Crohn's disease, *H. pylori* infection, CMPA, tuberculosis, eosinophilic gastroenteritis and IPSID. Duodenum may be endoscopically normal. Histology of duodenal biopsy is important to give the diagnosis of underlying disease responsible for chronic diarrhea. Narrow band imaging is important to have direct visualization of villus atrophy with the help of endoscope and this can avoid biopsy. Duodenal fluid can be aspirated and should be examined for giardia, bacterial culture and α heavy chain. Lower GI endoscopy (colonoscopy) is very important to make diagnosis of CMPA, ulcerative colitis, Crohn's disease, tuberculosis, amebiasis, *Strongyloides stercoralis*, cytomegalovirus (CMV) or herpes simplex virus (HSV) infection and microscopic colitis (collagenous colitis and lymphocytic colitis). Terminal ileal intubation can help to pick up ileal disease.

Small Bowel Series

Conventional barium meal follow through (BMFT) has been replaced by enteroclysis which is important to evaluate the stricturous lesions in tuberculosis, Crohn's disease, short gut syndrome, malrotation, diverticulum and internal fistulization.

Ultrasonography, Computed Tomography Scan and Magnetic Resonance Imaging Abdomen

These are used to pick up pancreatic pathology like chronic pancreatitis and hypoplasia of pancreas, thickening of the bowel, lymphadenopathy, masses, loculated ascites, fibrofatty changes, and calcification. The diagnosis of tuberculosis and lymphoma can be made by targeted fine needle aspiration cytology (FNAC) from mass and lymph nodes. The encysted fluid can be aspirated to study adenosine deaminase (ADA) in tuberculosis and abnormal cells.

Special Scan and Endoscopic Ultrasound

Malabsorption suspected due to endoscopic tumors like gastrinoma, somatostatinoma and vasoactive intestinal peptide tumor (VIPoma), Indium-III octreotide scintigraphy scan is performed, whereas endoscopic ultrasonography (US) will be useful in cases of tumor of pancreatitis origin in older children.

Specific Tests

Serological tests like antitissue transglutaminase antibody (tTGA), endomysial antibody (EMA) and deamidated gliadin peptide antibodies (DGP) are required to screen celiac disease with high sensitivity and specificity. These serological tests also have prognostic value. Antienterocyte antibodies are done when autoimmune enteropathy is suspected. Immunoglobulin levels, T-cell function, HIV serology, thyroid function tests (TFT), gastrin and other enteric hormone levels and sweat chloride and plasma zinc levels are required in specific situations.

PRACTICAL APPROACH TO CHRONIC DIARRHEA

Investigations should be directed according to the clinical features of the patient and the probability of underlying etiology of chronic diarrhea (**Flow chart 1**). Gunshot approach should be avoided as far as possible.

Chronic Secretory Diarrhea

The approach to chronic secretory diarrhea is given in **Flow chart 2**. Stools should be sent for culture to find out the any bacterial infection. At the same time microscopic examination of stool should be done for ova of worms or cyst of giardia and trophozoite of *E. histolytica* for 3 consecutive days. *Giardia* antigen can be detected in the stool. Special stains should be done to see for *Microsporidia*, *Coccidia*, *Cryptosporidium* and *Candida albicans* depending upon the high index of suspicion. Small bowel endoscopic biopsy, barium meal studies, colonoscopy, US and computed tomography (CT) scan of abdomen should be done to rule out underlying pathology. Cholestyramine given to the patient improves the bile induced diarrhea.

Chronic Osmotic Diarrhea

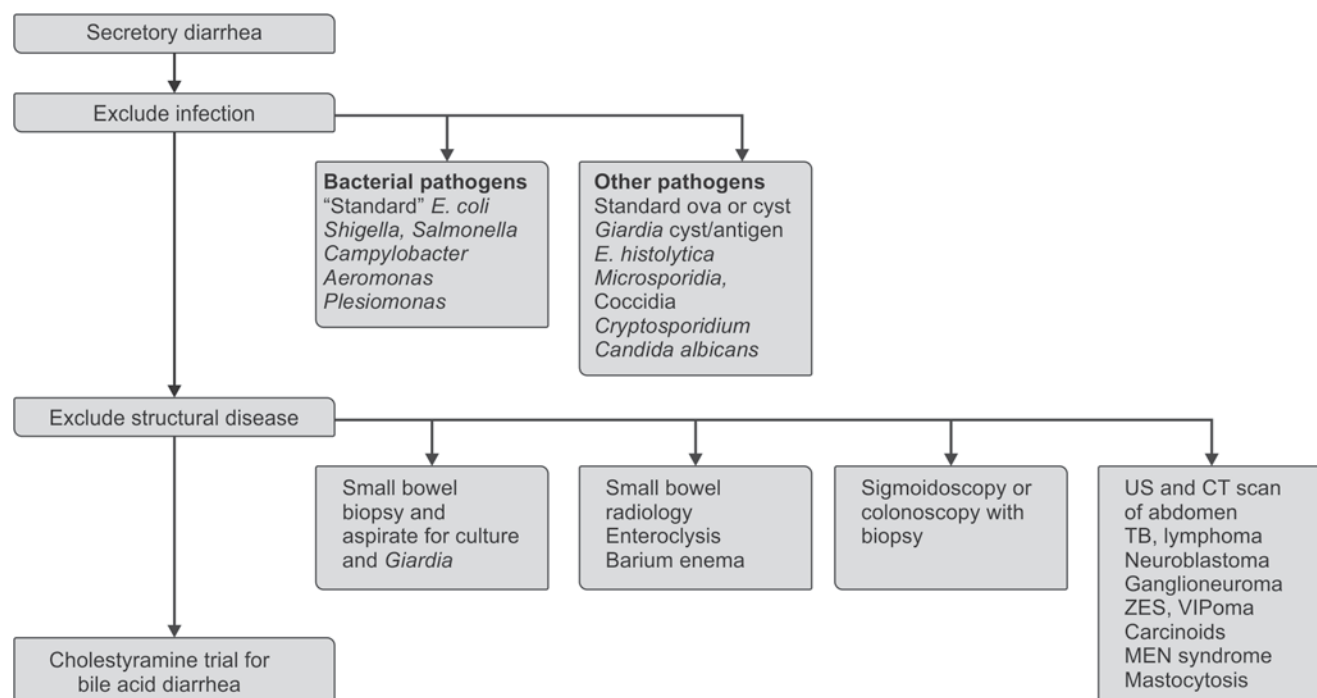

Osmotic diarrhea is characterized by large volume explosive stools and perianal excoriation. Watery stools should be analyzed for reducing substances and pH. Breath hydrogen test with lactose is positive. Lactase enzyme assay can help. Stool can be tested for magnesium and laxative. Reduction in the ingestion of high carbohydrate rich diet improves the diarrhea. Approach is described in **Flow chart 3**.

Fatty Diarrhea

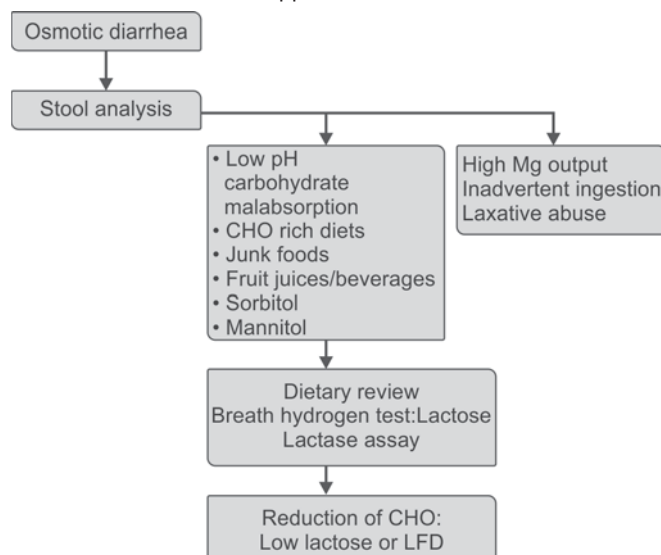

Exclude the mucosal and structural diseases of small intestine. Serological tests for the celiac disease like tTGA, antiendomysial antibodies (EMA), or deamidated gliadin peptide (DGP) antibodies can be performed. If the fecal fat is more than 14 g/24 hours pancreatic causes should be excluded. Different etiologies leading to pancreatic insufficiency may be identified by various tests, e.g., secretin, bentromide tests, stool chymotrypsin and elastase, lipase activity, radio imaging, endoscopic retrograde cholangiopancreatography (ERCP), sweat chloride, bone marrow, etc. Immune profile and HIV serology should be done as and when indicated. Approach is described in **Flow chart 4**.

Chronic Inflammatory Diarrhea

Inflammatory bowel diseases include ulcerative colitis (UC), Crohn's disease and indeterminate colitis. These disorders mainly

Flow chart 2 Approach to secretory diarrhea

Abbreviations: ZES, Zollinger-Ellison syndrome; MEN, multiple endocrine neoplasia.

Flow chart 3 Approach to osmotic diarrhea

Abbreviations: CHO, carbohydrates; LFD, low fat diet

affect the large bowel however Crohn's disease can affect any part of the GIT. Various investigations include small and large bowel biopsy, sigmoidoscopy and colonoscopy, BMFT, barium enema, US and CT scan abdomen. Stool should be cultured, sent for *C. difficile* toxin analysis; larva of *Strongyloidosis*, trophozoite of *E. histolytica*, etc. Exclude viral infections like CMV, herpes and *Candida albicans* in immune suppressed hosts. These infections can exacerbate the UC and Crohn's disease. In our country tubercular colitis should be ruled out. Approach is described in **Flow chart 5**.

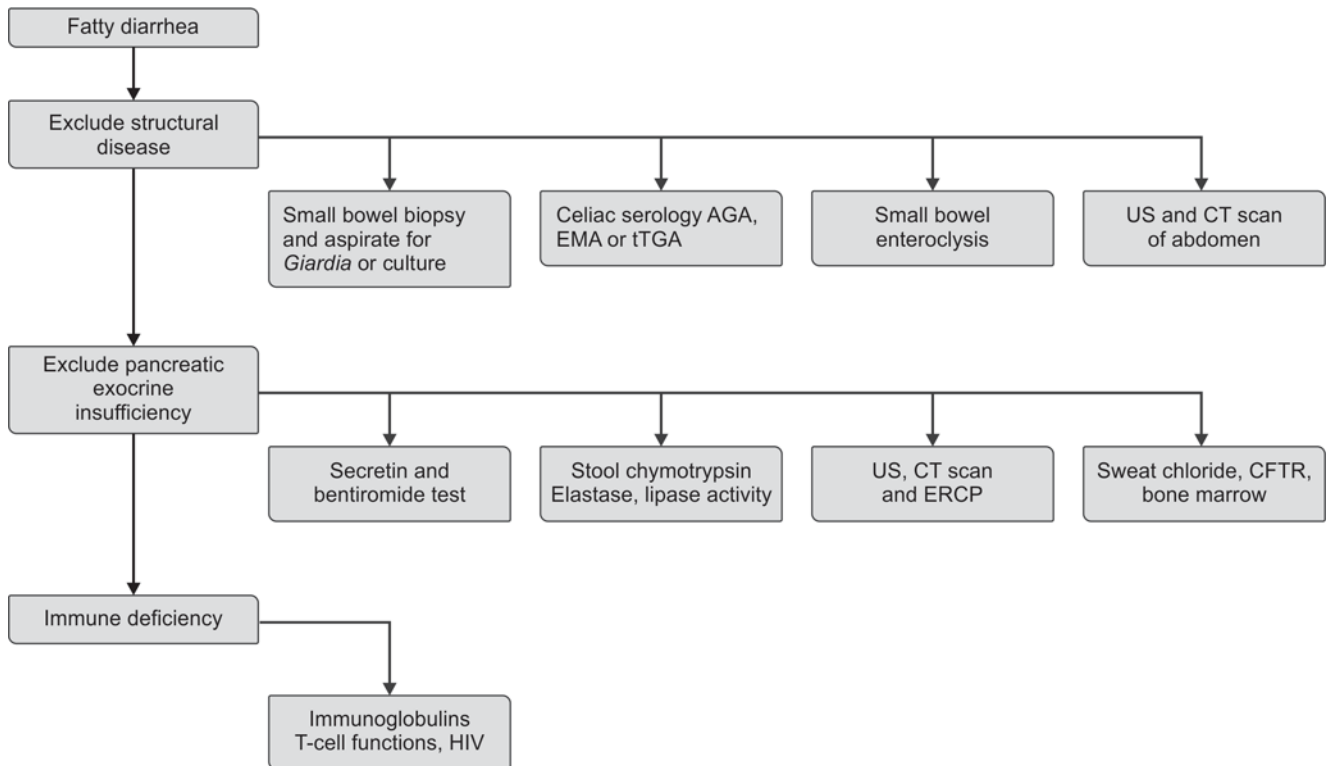

MANAGEMENT

The management of chronic diarrhea is a challenge due to associated multiple nutritional and electrolyte deficiencies, severe malnutrition, associated infections and impact of underlying specific disease state. The treatment of chronic diarrhea is discussed under supportive care and specific treatment of underlying disease leading to chronic diarrhea.

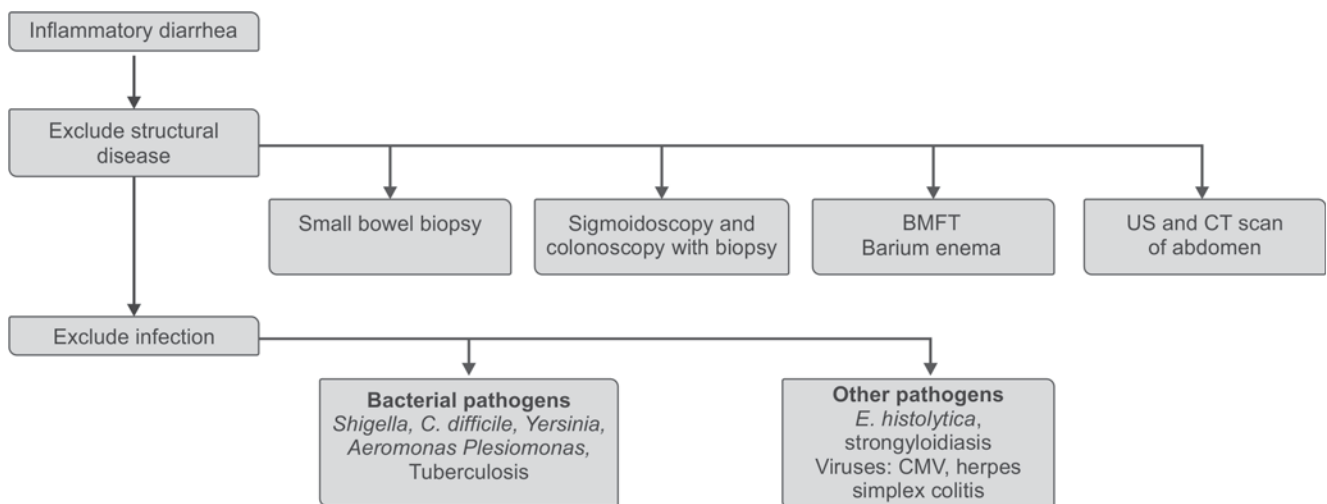

Supportive Care

Supportive care is very important for rebuilding and nutritional recovery. Dehydration is not a problem but acute exacerbation of diarrhea; vomiting and poor intake can lead to dehydration and needs correction with appropriate fluids. Hypokalemia is very common when there is severe malnutrition and need potassium supplementation. Nutrition support plays key role in the outcome. Enteral feeding (per oral or tube feed) should be continued depending upon the acceptability. The introduced diet should be palatable in the form of gruels (mix of cereals, pulses and milk) to begin with. The curd/yoghurt and milk mix diets are tolerated very well. In case of suspicion of celiac crisis patient should be kept on wheat free diet. The diagnosis can be revised later on. In case CMPA is suspected, milk and milk products should be withdrawn. In case of intractable diarrhea during neonatal period or early infancy and short gut syndrome total parenteral nutrition (TPN) is required. Vitamin A deficiency should be treated with three doses of vitamin A given on day 1, day 2 and after 14 days. In case of corneal xerosis, eye care with the help of ophthalmologist is mandatory. Other vitamins deficiency (fat and water soluble) and mineral deficiencies like zinc, iron and calcium should be treated accordingly. Symptomatic hypoalbuminemia should be managed by albumin infusion.

The calories and protein intake should be built slowly to prevent nutrition recovery syndrome also called as refeeding syndrome (RFS). It occurs due to intracellular transfer of

Flow chart 4 Approach to fatty diarrhea

Abbreviations: HIV, human immunodeficiency virus; AGA, antigliadin antibodies; EMA, endomysial antibodies; tTGA, tissue transglutaminase; ERCP, endoscopic retrograde cholangiopancreatography; CFTR, cystic fibrosis transmembrane regulator; US, ultrasonography; CT, computed tomography.

Abbreviations: US, ultrasonography; CT, computed tomography; BMFT, barium meal follow through; CMV, cytomegalovirus.

potassium, phosphate and magnesium promoted by increased insulin, cortisol and aldosterone secretion and anabolism induced by high protein and carbohydrate rich diet. The intake of protein tends to stimulate the secretion of hormones and enzymes of the body which are at low ebb. All these are responsible for developing of RFS. The patient develops hypokalemia, hypophosphatemia, hypomagnesemia and the thiamine deficiency. Clinical features of RFS are congestive cardiac failure, arrhythmia, muscle

weakness, hypotonia, altered sensorium, seizure and even death. During dietary management it is important to clinically assess these patients daily including weight for early recognition of this syndrome. Calories and protein should be slowly increased over 1 week. Initially there is weight loss but weight gain is observed after 7–14 days. Early weight gain is an alarming sign of RFS.

The treatment of specific conditions is discussed under description of particular diseases.

SPECIFIC CONDITIONS WITH FAILURE TO THRIVE

Neonatal Onset Intractable Diarrhea

Diarrhea in this age group is severe, intractable accompanied with dehydration, acidosis and malnutrition and associated with significant mortality and morbidity. The causes of neonatal intractable diarrhea are given in **Table 6**. Most often congenital disorders involving the absorption of water, minerals and other nutrients manifest within few hours of birth and the details of each condition are beyond scope of this chapter. The management of the neonate with intractable diarrhea is a challenge. Supportive care and specific antibiotics in case of sepsis are very important. The role of TPN is mandatory especially in transport defects, microvillus inclusion disease, tufting enteropathy or congenital lactase deficiency. Modified enteral feeding is important if gut is healthy and intact. Most of the congenital causes can be salvaged with small bowel transplantation.

Protracted/Intractable Diarrhea of Infancy

This entity requires a special mention among causes of chronic diarrhea in infancy. The criteria of protracted/intractable diarrhea of infancy (PDI/IDI) are (1) diarrhea duration more than 2 weeks, (2) age less than 12 months, (3) no response to conventional therapy and (4) weight loss or no weight gain. The pathophysiology involves the various etiological factors like infection, inflammation, neuroendocrine, diet and their sensitization, medications and toxins, genetic, immunological, vascular, pancreatic, hepatobiliary and other motility disorders. Among all these inciting factors, malnutrition and infection of GI tract play a dominant role leading to PDI. The causes of PDI/IDI in early infancy are elaborated in the **Table 7**. The management consists of supportive care with dietary modification, supplementation of micronutrients, TPN, and small bowel transplantation.

Disaccharidase Deficiency

This is due to deficiency of brush border enzymes like lactase, sucrase, maltase and trehalase present in duodenum and jejunum. Lactase is

responsible for digestion of lactose that is the major component of feeding of infants and children. Lactase deficiency is most common as compared to others. The undigested lactose goes down and is acted upon by the colonic bacteria which leads to production of carbon dioxide, hydrogen and methane gases and synthesize short chain fatty acids. These lead to distension of abdomen, flatulence, borborygmi, discomfort and diarrhea. The stools are watery and explosive in nature coming out with a lot of flatus. It is invariably associated with perianal excoriation. There are three types of lactase deficiencies congenital, primary and secondary.

Congenital Lactase Deficiency

This is a very rare and diarrhea starts immediately after intake of milk at birth. There are only case reports in the literature. It is very difficult to manage with lactose free formulae.

Primary Lactase Deficiency

It is also called late onset lactase deficiency or adult type hypolactasia. It is seen in 20–30% older children and adolescents with mild lactose intolerance resulting in chronic diarrhea. Diagnosis is suggested by temporal relationship with intake of milk and typical description of stooling. Stool pH is less than 5.5 and stool reducing substances are positive. Perianal excoriation may or may not be there. Other tests are lactose intolerance and H₂BT. Defining lactase deficiency from duodenal biopsy and genetic studies are not freely available though are gold standard to confirm the diagnosis of adult type hypolactasia. This can be managed by taking milk products in the form of curd or yoghurt and butter milk (*lassi*) and cheese (*paneer*) are well tolerated. Milk alone can cause problems but lactase enzyme (Tablets) can be used before intake of milk. Milk mixed with cereals is well tolerated. Supplementation of vitamin D and calcium is important.

Secondary Lactose Intolerance

Most of the diarrheal episodes are associated with some component of malabsorption of lactose. If acute diarrhea is not treated meticulously, it can get prolonged beyond 7 days. So diarrhea between 7 days and 14 days is a gray zone and leads to maximum damage. The diarrhea is profuse watery with lot of air in the stools. The bottom is sore due to redness caused by acidic nature of the stool leading to perianal excoriation that is very good indicator

of lactose intolerance. Perianal excoriation can be secondary to acquired zinc deficiency and fungal infection. Secondary lactose intolerance is also associated with celiac disease, Crohn's disease, severe malnutrition and giardiasis. The treatment is discussed under persistent diarrhea.

Postinfectious Chronic Diarrhea

Although many infectious causes of diarrhea result in an acute presentation and short course, but some pathogenic bacteria and parasites may cause chronic diarrhea. Viruses rarely cause diarrhea lasting more than 14 days. Rotavirus may cause diarrhea lasting up to 20 days. Acute bacillary dysentery caused by *Shigella* may be resistant to commonly used antimicrobials. This can lead to prolongation of diarrhea due to lingering of underlying infection and lead to chronic colitis. Other bacterial infections like *Yersinia enterocolitica*, Enteroinvasive *E. coli*, Enteropathogenic *E. coli*, *Campylobacter*, *Aeromonas* and *Plesiomonas* can lead to prolongation of diarrhea. *Entamoeba histolytica*, *Giardia lamblia* and *Cryptosporidium* can also cause chronic diarrhea.

Giardiasis

Giardia lamblia causes acute and chronic diarrhea both in healthy and immunocompromised hosts. Infection occurs in duodenum and upper part of jejunum, leading to mechanical effect, disaccharidase deficiency, villus atrophy, bacterial overgrowth and deconjugation of bile salts. All these factors lead to chronic diarrhea and malabsorption. Upper GI endoscopy shows nodularity in the duodenum (Fig. 3). *Giardia* can be detected in duodenal fluid and biopsy. Children can be treated with metronidazole, tinidazole, or nitazoxanide. It is very difficult to eradicate *Giardia* in immune deficient individuals.

Cryptosporidiosis

It can cause infection in immunocompromised and immune competent hosts. In immune incompetent hosts the disease is severe and prolonged. Diagnosis is made by details of oocyst in stools and duodenal fluid. Paramomycin and nitazoxanide are effective to achieve eradication.

Amebiasis

Sigmoidoscopy/colonoscopy shows classical small ulcers with intervening normal mucosa. These small ulcers coalesce to form large deep ulcer and thickness of colon (ameboma). Diagnosis is made by detection of trophozoites engulfing red blood cells (RBCs)

in stools or in the biopsy specimen from colon. Metronidazole is the drug of choice.

Tuberculosis

Tuberculosis is important cause of chronic diarrhea and malabsorption in tropical countries. 15–30% of abdominal tuberculosis may have chronic diarrhea due to tuberculous stricture, ulcerative lesions in bowel, lymphatic obstruction, bacterial overgrowth and malnutrition. Involvement of colon leads to chronic colitis mimicking IBD. The diagnosis is made by Mantoux test, X-ray chest, BMFT (Fig. 4), barium enema (Fig. 5), colonoscopy (Fig. 6) CT (Fig. 7), endoscopic biopsy and FNAC. Antitubercular therapy for 9 months is effective. Sometimes intestinal strictures require stricturoplasty.

Small Intestinal Bacterial Overgrowth

Small intestinal bacterial overgrowth (SIBO) is characterized by malabsorption and overgrowth of bacteria in the small intestine. This is also referred as blind loop syndrome due to recognition of this disorder in patients with predisposing anatomical abnormalities. Classic clinical manifestations are that of malabsorptive state characterized by fatty diarrhea and vitamin B₁₂ deficiency, leading to megaloblastic anemia that is not reversed by intrinsic factor. Gold

standard for the diagnosis is aspirate of small intestinal fluid for culture and bacterial count of more than 10^5 CFU/mL. Treatment includes nutritional supplementation and antibiotic therapy.

Tropical Sprue

Disease of small bowel mucosa due to varied etiology seen mainly in tropical countries including India and Caribbean and this is one of the close differential diagnoses of celiac disease. The disease manifests as chronic diarrhea, malaise, weight loss and malabsorption of various nutrients including vitamin B₁₂ and folate. Onset is typically after an episode of gastroenteritis and there is significant alteration in gut microflora with increase in enterobacteriaceae leading to damage to absorptive surface area culminating in malabsorption. Symptoms usually resolve with supportive care and antibiotics. These days this is less often encountered. Tropical enteropathy results from repeated bacterial infection in tropics responsible for blunting of villi.

Immunoproliferative Small Intestinal Disease

It is a variant of the B-cell lymphoma of mucosa-associated lymphoid tissue (MALT), which involves mainly the proximal

small intestine resulting in malabsorption, diarrhea, clubbing and abdominal pain. Immunologically, IPSID lymphomas reveal excessive plasma cell differentiation and produce truncated alpha heavy chain proteins lacking the light chains as well as the first constant domain. Treatment includes antibiotics and anti-neoplastic agents depending upon the stage and severity of the disease.

Immunodeficiency States

Both congenital and acquired immunodeficiency disorders can cause severe chronic diarrhea in infants and children.

Congenital Immunodeficiency

The most common congenital immunodeficiency disorders leading to chronic diarrhea are X-linked agammaglobulinemia or hypogammaglobulinemia, selective IgA deficiency, common variable immunodeficiency (CVID), severe combined immunodeficiency (SCID) and chronic granulomatous disease (CGD). All these conditions can manifest with intractable diarrhea due to infection by unusual microorganisms. FTT and systemic infections in agammaglobulinemia and hypogammaglobulinemia require supportive care, intravenous (IV) gammaglobulins and antimicrobial therapy. CVID can manifest during infancy and childhood with chronic diarrhea and FTT and treatment is same as in case of agammaglobulinemia. Selective IgA deficiency can manifest with giardiasis, bacterial overgrowth and enteropathy and is prone to celiac disease and Crohn's disease. There is need of treatment of underlying infections. SCID is severe form of disease manifests in the early life and untreated children dies by 1–2 years of age. Bone marrow transplantation can cure the disease. CGD can manifest with chronic diarrhea and multiple abscesses. The treatment is γ -interferon and antimicrobial therapy.

Acquired Immunodeficiency Syndrome

AIDS can manifest with acute and chronic diarrhea with lymphadenopathy and hepatosplenomegaly and patients are prone to multiple bacterial, viral, protozoal and fungal infections. Diagnosis is made by HIV positive and chronic diarrhea count less than 200 cells/mL. Attempt should be made to define microorganism from stool by microscopy, culture, antigen detection and PCR. At times if the infection is not there, chronic diarrhea could be due to AIDS enteropathy. Treatment involves supportive care, specific antimicrobials and HAART. Protease inhibitors can induce diarrhea and should be kept in mind.

Immune Suppressed States

Treatment of leukemia, lymphoma and malignant tumors require specific chemotherapy and radiation. Autoimmune diseases [autoimmune hepatitis (AIH), systemic lupus erythematosus (SLE), AI hemolytic anemia] and liver and kidney transplanted patients are treated with steroids and other immune suppressive drugs. Some of the drugs can induce diarrhea, e.g., mycophenolate mofetil. These drugs lead to immune suppression and make the individual prone to usual and opportunistic infections of gut leading to chronic diarrhea. Attempt should be made to define the microorganism responsible for diarrhea and treat accordingly with antimicrobials and supportive care. Radiation induced enteritis can lead to chronic diarrhea.

Food Allergy

Allergic enteropathy (eosinophilic enteropathy) presents with FTT, vomiting and diarrhea whereas allergic colitis occurs in relatively healthy and well thriving infants. Often allergic colitis is reported with ingestion of cow milk and soybean.

Cow Milk Protein Allergy

Cow milk protein allergy is an immune mediated reaction to milk proteins and occurs after ingestion of cow milk. It has been reported in 2–5% of infants and young children suffering from chronic diarrhea. There are two types of reactions, the immediate and late onset. Immediate reaction is IgE mediated and occurs within minutes of milk ingestion or contact. It is characterized by immediate urticaria, swelling of lips, vomiting, pallor or shock like state. The late onset reaction is a T-cell mediated reaction, occurs after 6–8 weeks of milk ingestion and has indolent course.

The presentation of late onset CMPA can be with GI and non-GI related symptoms. The GI related symptoms occur in 50–60% of cases. These occur in form of proctocolitis in young healthy infants in 2–4 months of age and are characterized by passage of blood and mucus in the stool mimicking late hemorrhagic disease, acute infective colitis or UC. Whereas in older infants and young children present with intractable diarrhea with FTT due to malabsorption. Other manifestations are vomiting mimicking gastroesophageal reflux disease (GERD), chronic constipation, anemia and hematemesis secondary to hemorrhagic gastritis.

The non-GI presentations of CMPA are related to skin and respiratory system. The skin manifestations are atopic eczema, urticaria and angioedema whereas respiratory symptoms are nasal stuffiness, sneezing and chronic cough with wheeze mimicking asthma.

Diagnosis is based on high index of suspicion with temporal relationship of intake of cow milk or top feeding in infants. IgE mediated CMPA can be diagnosed by immediate reactions, positive skin prick test to cow milk protein, a reaction of more than 3 mm and raised specific IgE immunoglobulin. Stool examination shows eosinophils, leukocytes and RBCs whereas culture will be negative to distinguish from infective colitis. The diagnosis of T-cell mediated disease can be made by endoscopy and histology of the biopsy sample. Upper GI endoscopy reveals erosive gastritis (rare) and nodularity in the duodenum and histology of biopsy shows lymphoid hyperplasia, eosinophilic infiltrate and villus atrophy. Sigmoidoscopy will show small superficial ulceration, hyperemia, edema, nodularity, and aphthous ulcers (**Fig. 8**). Histology of biopsy shows lymphoid hyperplasia and eosinophilic (>6/HPF) infiltrate.

The gold standard for diagnosis of food allergy is elimination and challenge test. The symptoms stop after withdrawal of milk and recur within 48 hours of milk intake. Goldman suggested

Figure 8 Sigmoidoscopic picture showing loss of vascular pattern, edema and multiple aphthae in a case of cow milk protein allergy (CMPA)

three such positive challenges for making the definite diagnosis but it is too cumbersome and very difficult to fulfill the criteria. Relationship of clinical symptoms with milk intake, endoscopic findings, and biopsy characteristics, disappearance of symptoms after milk withdrawal and demonstration of normal histology are good enough to make the diagnosis.

Introduction of milk should be done at least after 1 year of withdrawal. In case symptoms reoccur, milk should be stopped and rechallenge after 1 year. If challenge is negative continue with milk and milk products. The management of food allergy is simple, to stop the inciting food. Milk and milk products should be withdrawn from the diet. Soya milk is a very good substitute in India though extensively hydrolyzed formula (EHF) is recommended. Some issues with soya have been raised in the literature but are minor. In case of allergy to soy protein, it should be stopped. Special formulae like EHF are not available in India. In this situation rice gruel is preferred for infants with adequate protein and calories to maintain the health. Supplementation of adequate minerals and vitamins is mandatory. IgE mediated CMPA infants can have problems with EHF and need elemental amino acid formula (AAF). Mother milk should be encouraged. Very rarely cow milk protein through breastmilk may cause problem in the infant, this requires stoppage of intake of cow milk and milk product by the mother while breastfeeding. Infants with late onset reactions outgrow earlier as compared to IgE mediated reactors. More than 90% outgrow from this problem by 2–4 years of age.

Food Protein Induced Enterocolitis Syndrome

It is a rare and T-cell mediated GI food hypersensitivity characterized by intractable diarrhea with blood in the stool, vomiting, anemia, hypotonia, dehydration and hypovolemic shock. In absence of fever presence of eosinophils cells in the stool and negative stool culture help to differentiate from infective colitis. Severe UC should be excluded.

Soya Protein Allergy

Soya protein allergy is uncommon in our country. Isolated allergy is very rare. It has been reported in 10% of cases along with CMPA. The clinical manifestations are similar to CMPA. Diagnosis is by temporal relationship and diagnostic approach is same as in CMPA. Treatment is stoppage of soya based products. Usually infants outgrow and start tolerating after 1 year.

Celiac Disease

This is now defined as an autoimmune disorder that occurs in a genetically predisposed individual who gets sensitized to gliadin a protein moiety of wheat and on withdrawal of wheat there is clinical improvement. The other cereals like barley and rye, cross react to gliadin and produce symptoms of celiac disease. This is the most common cause of chronic malabsorptive diarrhea in children. The classical manifestations are diarrhea, FTT and anemia (**Fig. 9**). The atypical presentations are short stature, constipation, pain abdomen, iron deficiency anemia, diabetes, and dermatitis herpetiformis. Diagnosis is based on the high index of suspicion. The investigations include complete hemogram, type of anemia, D-xylose test, endoscopic duodenal biopsy and serological tests like, anti tissue transglutaminase, endomysial antibodies and deamidated gliadin peptide (DGP) antibodies. On endoscopy there are classical well defined endoscopic markers of celiac disease like grooving, scalloping, nodularity, loss of folds and mosaic pattern (**Fig. 10**). Duodenal biopsy shows varying degree of villus atrophy (Marsh classification). Narrow band imaging shows loss of villi. HLA DQ2 and DQ8 are positive in 98% of celiac patients. Diagnosis and treatment have been detailed in the chapter on celiac disease in the previous Section on gastrointestinal disorders.

Figure 9 Case of celiac disease showing multiple micronutrient deficiencies, stunted growth and pedal edema

Figure 10 Endoscopic view of duodenum showing atrophic folds with grooving, scalloping and mosaic pattern in celiac disease

Intestinal Lymphangiectasia

There is a defect in the lymphatic drainage of small bowel and may be associated with lymphedema of upper or lower limbs. Patients presents with diarrhea, generalized edema, tetany but no anemia. The hypoproteinemia is responsible for edema and occurs due to loss of protein by the rupture of dilated lacteals in the small intestine. The diagnosis is made by upper gastrointestinal (UGI) endoscopy showing pearl like lesions/vesicles in the mucosa and the endoscopic biopsy of the small intestine. This requires withdrawal of triglycerides other than medium chain triglycerides (MCT), hence MCT rich diet is recommended. MCT gets absorbed directly by the enterocytes and go into portal circulation rather than going into lymphatic. The edema and diarrhea disappear, but compliance is a problem.

Abetalipoproteinemia

This is an autosomal recessive disorder due to defective synthesis of apolipoprotein B, making the intestinal enterocyte unable to

couple triglycerides into chylomicrons for systemic transport, leading varied manifestations. Acanthocytes in blood smear is a great clue. Fatty diarrhea is one of the major manifestations apart from deficiencies of other fat soluble vitamins. Treatment includes replacement of triglycerides containing long chain fatty acids with MCT and dietary supplements with tocopherol. In the same group the other disorders which present with fat malabsorption are familial hypobetalipoproteinemia, Anderson's disease, chylomicron retention disease and Wolman disease.

Pancreatic Disorders

Most important pancreatic disorders like chronic pancreatitis, cystic fibrosis and hypoplasia of pancreas are responsible for fatty diarrhea. There are syndromes like Shwachman-Diamond syndrome, Johanson-Blizzard syndrome, isolated pancreatic enzyme deficiency, Pearson syndrome, etc. which are also associated with fat malabsorption. Chronic pancreatitis is characterized by pain abdomen and usually long history and fatty diarrhea develops, when more than 90% of pancreatic tissue is destroyed. Various pancreatic tests described earlier including imaging studies and ERCP confirm the diagnosis. The description of the stools is greasy/oily stools difficult to clean and fat droplets may be noted per-rectum or fat may get separated when stool is kept for some time. In cystic fibrosis, respiratory symptoms dominate; pancreatic insufficiency develops during second decade of life. Pancreatic hypoplasia manifests in early infancy and FTT along with steatorrhea are the main manifestations. Various syndromes manifest with other associated clinical picture. Careful enzyme replacement therapy is helpful to ameliorate the symptoms.

Bile Salt Diarrhea

Conjugated bile salts reach to duodenum for solubilization and micellization. The congenital absorption defect and resection of terminal ileum allow the excess of the bile salts in the colon and cause excess of secretion and watery diarrhea. At the same time lead to fat malabsorption due to decreased bile salt pool in the body. In case of SIBO the bacteria deconjugate the bile salts and these deconjugated bile salts are responsible for cathartic effect and diarrhea. Cholestyramine is effective to bind the bile salts and reduces watery diarrhea symptoms.

Short Gut (Bowel) Syndrome

It occurs when there is a significant decrease in the absorptive surface due to congenital and acquired causes. In children the length of the small and large intestine is 600 cm and 150 cm respectively. Children are mostly afflicted by various congenital malformations, e.g., malrotation leading to volvulus, gastroschisis and due to extensive gut resection in necrotizing enterocolitis and ischemic bowel injury. The exact clinical manifestations depend

upon the extent, site of resection and left over length of gut with or without ileocecal valve. The symptoms occur when small bowel length is less than 170 cm and no colon or small intestine less than 70 cm with intact colon. Limited ileal resection has better clinical outcome. However, the loss of ileocecal valve predisposes to SIBO and its complications. Short gut syndrome can lead to liver disease, renal stones, d-lactate acidosis and gallstones due to prolonged requirement of TPN. Treatment of this condition is supportive care, maintenance of nutrition by enteral or parenteral route. Small bowel transplantation is required when there is extensive resection of the small bowel and nutritional support is inadequate.

Endocrinopathies

Diabetes mellitus (DM), congenital hypoparathyroidism, Di-George syndrome; multiple endocrine neoplasia, Addison disease, mucocutaneous candidiasis, hyperthyroidism, secretory tumors: gastrinoma (Zollinger-Ellison syndrome), somatostatinoma (somatostatin), VIPoma (ganglioneuroma and ganglioblastoma: VIP) and carcinoid: 5-hydroxytryptamine can cause chronic diarrhea. Diarrhea in DM is due to altered bowel motility, SIBO and bile salt malabsorption and celiac disease (10%). It is worth mentioning that all above-mentioned conditions are associated with chronic diarrhea. The diagnosis of underlying conditions depends on diligent search and treatment is disease specific. The tumors need surgical resection.

Cystic Fibrosis

Around 90% of children suffering from CF develop exocrine pancreatic insufficiency and results in malabsorption of nutrients. The condition is discussed in detail in the Section on respiratory disorders. Malabsorption of fat, carbohydrate and proteins is due to loss of exocrine function and involvement of biliary tract. There is deficiency of lipases, amylases and proteases. Maldigestion results in steatorrhea and fecal fat excretion is usually more than 14 g per day. Thick secretions and SIBO also contribute to malabsorption. This is responsible for oily/greasy stools. Oil droplets or separate oil can be seen in stools. Fecal elastase and chymotrypsin levels are very low. Neonate may be born with microcolon or thick secretion/pellets in small and large bowel. Sweat chloride and cystic fibrosis transmembrane regulator (CFTR) gene studies confirm the diagnosis. Treatment is replacement of pancreatic enzymes.

Inflammatory Bowel Diseases

This covers ulcerative colitis, Crohn's disease, and indeterminate colitis and has been discussed in the previous Section on gastrointestinal disorders. Ulcerative colitis involves only the colon. Endoscopic picture is classical and biopsy shows involvement of colonic mucosa (**Fig. 11**). Crohn's disease is more severe, involves whole of the GI tract from oral cavity to rectum. This is a transmural

Figure 11 Colonoscopic picture showing acute (ulceration, bleeding, edema, loss of vascular pattern) and chronic (pseudopolyps) lesions in ulcerative colitis

disease involving all layers of gut gives rise to deep linear ulcers and punched ulcer and cobblestone appearance of mucosa and hence leads to perforation and fistula formation (**Fig. 12**). Indeterminate colitis is defined when the condition neither fits with UC nor with Crohn's disease.

Microscopic Colitis

This is an unusual entity recently described as cause of chronic diarrhea in children. Exact etiology is unknown, even though various pathophysiological mechanisms have been postulated. It presents as chronic profuse watery diarrhea with cramping abdominal pain. On colonoscopy the mucosa is absolutely normal; however the histology of biopsy reveals the changes in the form of subepithelial collagenous band in case of collagenous colitis (CC) (**Fig. 13A**) and increased in number of intraepithelial lymphocytes in lymphocytic colitis (LC) (**Fig. 13B**). Biopsy shows inflammatory infiltrates in the mucosa and submucosa. Lymphocytes outnumber the plasma cells in lamina propria. Lymphocytes infiltrate the mucosa and account for 10–25% of all mucosal cells. Treatment includes budesonide, mesalamine and probiotics.

Hirschprung Disease

Chronic diarrhea in Hirschprung disease (HD) during neonatal period and early infancy is a result of enterocolitis due to bacterial stasis in the lumen. Thirty percent of HD during early

infancy develop diarrhea. Infants present with fever, explosive diarrhea, abdominal distension, bleeding per-rectum and perianal excoriation. Diagnosis is suspected by delayed passage of meconium (> 24 hours) after birth that is present in 94% of HD infants. Per-rectal examination is very classical: rectum is empty and on withdrawal of finger there is gush of stool. In older children there is no fecal soiling and withholding maneuver as seen in functional constipation. Barium enema, manometry and rectal biopsy have classical features of HD seen in older children. The treatment of enterocolitis is supportive care and antibiotics. Later on surgical treatment is required.

CHRONIC DIARRHEA WITHOUT FAILURE TO THRIVE

Chronic Nonspecific Diarrhea of Childhood

Chronic nonspecific diarrhea of childhood (CNSD) is the very common form of chronic diarrhea in the preschool years without failure to thrive. This is also called toddler's diarrhea. The typical time of onset may range from 1 year to 3 years of age and can start from infancy until age 5 years. The consistency and the frequency of the stools are different from that of other children. Affected children may pass multiple bowel movements usually 4–10 times per day. Specific to CNSD is the pattern that these patients pass stools only during waking hours, typically beginning with a large formed or

Figure 12 Perianal fistula, colonoscopic picture showing deep fissured and punched out ulcers with cobblestone appearance in case of Crohn's colitis

Figure 13A Histopathological picture of colon showing subepithelial thick collagenous band suggestive of collagenous colitis

Figure 13B Histopathological picture of colon showing increased intraepithelial lymphocytes in lymphocytic colitis

semi formed stool after awakening. As the day progresses, stools become more watery and smaller in volume. Transit time of enteral contents may be especially short, and parents frequently describe undigested food remnants in the stool. Although some affected children describe mild abdominal discomfort, most typically appear healthy and maintain a normal appetite and activity level. Potential pathophysiology mechanisms for CNSD include increased intestinal motility and osmotic effects of intraluminal solutes (e.g., carbohydrates). The toddlers have great affection for fruit juices and cold beverages. Therefore excessive intake of fruit juices, particularly those containing sorbitol or fructose (e.g., apple, pear, cherry, and prune juices), may contribute to the stool osmotic load, thus causing or worsening diarrhea. Reassurance is the cornerstone of therapy for CNSD. Parents should be assured that their child is growing well and is healthy. Dietary modification, including the avoidance of sucrose and fructose is the main stay of treatment. Beyond the restriction of fruit juices, possible helpful changes may be to liberalize fat to encourage normal caloric intake and to slow intestinal transit time, not to restrict fiber, and to assure adequate but not overhydration. Try to rule out organic causes as far as possible.

Irritable Bowel Syndrome

This is a most common functional disorder of GI tract in older children. This is characterized by pain abdomen followed by act of defecation that relieves the pain. Three types of IBS are associated with diarrhea, constipation or combination of both. The genesis of pain involves complex genetic, psychological and somatic factors. Majority of the times children are suffering from other psychological or functional disorders. Usually the symptomatology is of chronic nature. According to ROME III diagnostic criteria there has to be pain abdomen for 2 months plus 2 or more of the following at least 25% of the time: (1) improvement with defecation, (2) onset associated with change in the frequency of stools, (3) onset associated with change in the form of stool and (4) no evidence of IBD or neoplasia. Elaborate investigations are not needed in this condition. The family history of functional GI disorders is positive in 50–70% of one or both of the parents. The symptoms of diarrhea respond to reassurance and *isabgol* (*Psyllium* seed, *Ispaghula*,

or *Psyllium* spogel) husk. The role of drugs in children is not well defined.

Functional Diarrhea

This is an uncommon but does occur in older children. The factors responsible are similar to those of CNSD. In addition psychological factors and stressors may be there. Try to rule out organic causes. Treatment is reassurance, *isabgol* husk and the measures described under CNSD.

Factitious Diarrhea

It is also known as laxative abuse or Munchausen syndrome by proxy. High index of suspicion to be observed while evaluating the patient for chronic diarrhea and this is one of the condition that is liable to be missed. Patients with other psychiatric conditions like anorexia and bulimia nervosa are more prone than general population. Subtle clues can be identified in investigations such as hypokalemia, which suggests ingestion of stimulants, pseudomelanosis coli in chronic anthracene laxatives such as *senna* or *cascara*. Presence of a large fecal osmotic gap suggests magnesium ingestion. If the suspicion is high, sample should be subjected to laxative analysis in form of spectrophotometer, etc. Treatment is mainly the behavioral therapy and avoidance of laxative.

PREVENTION

Postinfectious chronic diarrhea can be prevented by giving adequate nutrition during an episode of acute diarrhea. Breast-feeding during infancy is protective against GI infections. Avoiding early introduction of animal milk can prevent CMPA. Supplementation of zinc and other micronutrients is also important to prevent prolongation of diarrheal duration and recurrence. Rotavirus vaccine is available to prevent the rotavirus infection in infants and children less than 5 years of age. In developing countries raising the standards of living, hygiene and sanitation are equally important steps to prevent infectious diarrhea. HIV infection can be prevented by following universal precautions. Antenatal diagnosis of some of the congenital conditions is possible. However, noninfectious causes of chronic

diarrhea are difficult to prevent but early recognition, diagnosis and appropriate intervention can avoid complications and ensure better outcome.

PROGNOSIS AND OUTCOME

Prognosis of chronic diarrhea depends upon the underlying etiology. The outcome of persistent diarrhea is determined by the underlying nutritional status and the age of the child. With dietary modification the outcome is good. Severe malnutrition and intractable diarrhea of infancy are associated with high morbidity and mortality. Earlier mortality used to be 40–50% but now with the better understanding of enteral and parenteral nutrition the mortality has significantly come down to 5%. The mortality due to immune deficient states and pancreatic disorders is still very high. The replacement therapy in pancreatic exocrine insufficiency is very difficult to maintain due to high cost of enzyme therapy. Overall prognosis of chronic diarrhea has changed due to better understanding of pathophysiology, etiopathogenesis and newer treatment modalities. The follow-up, monitoring of treatment, assessment of anthropometry and dietary modifications and supplementation of nutrients at regular intervals have a key role to play for better outcome.

IN A NUTSHELL

1. Type of chronic diarrhea should be well-defined based upon clinical features and the investigations.
2. Common causes of chronic diarrhea are celiac disease, persistent diarrhea, cow milk protein allergy, and giardiasis.
3. Meticulous approach is important to categorize the type of chronic diarrhea (small or large bowel on the basis of characteristics of the stool).
4. Neonatal diarrhea, congenital or acquired is a challenge to manage.
5. Protracted or intractable diarrhea of infancy is different from chronic diarrhea in older children. There is a great impact on the nutrition and growth of infant.
6. Supportive care in form of appropriate, age specific dietary modification and supplementation of vitamins/minerals is mandatory.
7. Etiology of chronic diarrhea must be ascertained before specific therapy.
8. Nonspecific chronic diarrhea in preschool children, functional diarrhea, factitious diarrhea and irritable bowel syndrome should be recognized.
9. The prognosis and outcome depend upon the underlying etiology, complication and effective therapy.
10. Early recognition of etiology of chronic diarrhea and timely intervention can avoid long-term complications.

Chapter 36.6

Antibiotic Associated Diarrhea

Seema Alam, Vikrant Sood

A universal consensus on the definition of antibiotic associated diarrhea (AAD) is still elusive but commonly it is described as frequent, watery stools that occur in response to use of antibiotics to treat infections. Early onset of AAD occurs within 2–7 days, while delayed onset may occur within 2–8 weeks after the antibiotic are discontinued. The definition requires exclusion of other common causes of diarrhea including intercurrent infection such as viral gastroenteritis or bacterial infection, laxative use, or diarrhea from other causes.

EPIDEMIOLOGY

There is scarcity of data on the prevalence of AAD in children worldwide with no Indian studies (**Table 1**). Available data suggest that the prevalence of AAD is 13–29 % in majority of the studies. High prevalence of 59–80% seen in some studies can be explained by their small sample. The only data from Asia is from two studies done in Chinese children revealing a prevalence of 16.8% and 19.4% and a study among 225 Thai children, where 6.2% had AAD when amoxicillin and cloxacillin combination was the most common antibiotic prescribed. There was a trend towards a higher

incidence of AAD in the amoxicillin/clavulanate group (16.7%) compared to amoxicillin (6.9%) and erythromycin (11.1%) groups. Almost all these studies have been done in the developed countries with no comparable data from the developing world.

ETIOLOGY

Mild AAD would present with only watery stools, occur sporadically and resolve on withdrawal of the antibiotic. They are usually *C. difficile* (CD) toxin negative and do not need any further treatment. The most common organism found associated with AAD is CD, though a large majority remains undiagnosed. Other less commonly involved organisms include *Staphylococcus aureus*, *Clostridium perfringens*, *Klebsiella oxytoca* and *Candida*.

Relevance of *Clostridium difficile*

Clostridium difficile is a gram-positive, spore-forming obligate anaerobe, ubiquitous in the environment, and widely distributed in healthcare settings. Spores are ingested via contact with contaminated surfaces and, under favorable conditions (in susceptible hosts), will germinate to a vegetative state that produces toxins. Antibiotic-mediated suppression of normal human gut microbiota is strongly associated with colonization and proliferation of CD. It is the most common cause of AAD with incidence varying from 10% to 20% of all cases of AAD, and almost all cases of colitis associated with antibiotic therapy. Initial data suggested increase in CD infection paralleling the widespread epidemic of irrational antibiotic use. As seen in the **Table 2**, at least three studies

Table 1 Prevalence of antibiotic associated diarrhea (AAD) in children

Author	Place	Study type	Prevalence of AAD (%)	Age group	All or particular antibiotics	Outpatient or hospitalized patients
Mitchell 1996	USA	Prevalence	22/76 (28.9%)	12–47 months	Amox/clav	Outpatient
Vanderhoof 1999	USA	RCT	25/95 (26%)	6 months–10 years	All	Outpatients

Table 2 Incidence of *Clostridium difficile* associated diarrhea (CDAD)

Study	Subjects (n)	Age	Time period	Incidence of CDAD
Kim et al.	4,895	< 18 years	2001–2006	4.4–6.5 per 10,000 patient-days
Nylund et al.	21,274	1–18 years	1997–2006	3,565–7,779
Zilberberg et al.	-	< 18 years	1997–2006	7.24–12.80/10,000 hospitalizations
Schwartz et al.	299	1–17 years	2008–2012	8.3/10,000 patient days*

*Yearly incidence static over study time period.

have found an increase in the incidence of *Clostridium difficile* associated diarrhea (CDAD) in the children in the last decade. But a cohort of 299 hospitalized children (1–17 years of age) with CD infection at a large tertiary care center, the incidence rate of CD infection (8.3 cases per 10,000 patient days) did not change significantly over the 4 year study period.

Adult data from Indian population reports a prevalence varying from 7% to 17% in hospitalized diarrheal cases (**Table 3**). In contradiction to Western data, a retrospective chart review at an Indian tertiary care hospital reported 524 cases over a 5-year period of which 7.1% specimens were positive for CD toxin with decreasing yearly incidence throughout the stay (11.2% in 2001, 9.4% in 2002, 8.6% in 2003, 5% in 2004 and 4% in 2005). This may be due to stringent surveillance and an improved antibiotic policy followed at the tertiary care hospital. Indian pediatric data on CD infection presents a similar picture.

Table 3 Prevalence of *Clostridium difficile* associated diarrhea (CDAD) in Indian population

Author Year	Number of Subjects	Prevalence of CDAD (%)	Out/Inpatient
Niyogi 1991	341 diarrheal cases 172 controls	11.1 3	Inpatient
Bhattacharya 1991	233	7.3	Inpatient
Dhawan 1999	210	15	Inpatient
Chaudhry 2008	524	7.1	Inpatient
Joshya 2009	214	12.1	Inpatient
Ingle 2011	99	17	Inpatient
Kaneria 2012	50 diarrheal cases 50 controls	10 6	Inpatient

The incidence of CD increased significantly in the outpatient setting, particularly in the emergency department (1.18 cases vs. 2.47 cases per 1,000 visits). The incidence among inpatients decreased during the study period (1.024 cases vs. 0.680 cases per 1,000 patient-days). These studies suggest that the incidence of community acquired CD infection is also increasing in the pediatric population. Some cases of CD infection can be expected to occur in the weeks or even months following discharge. In addition, the increased circulation of CD within hospitals will increase the rate of asymptomatic CD carriers within the population. Contact with such cases will in the end lead to some cases of community acquired CD infection. Furthermore, it has been suggested that an animal reservoir may play a role in the emergence of community-acquired CD infection. The pediatricians need to keep this in mind while treating difficult diarrhea in the hospital and the community. Comparable Indian data is not available.

RISK FACTORS FOR ANTIBIOTIC ASSOCIATED DIARRHEA

Type of Antibiotic Used

The antibiotics with which AAD is associated are: penicillin G and V (3%), penicillin A and M (11%), amoxicillin-clavulanate (23%), cephalosporins (9%), macrolides (8%), trimethoprim-sulfamethoxazole (6%) and erythromycin (16%). Statistically significant difference is seen between the rates of onset of AAD with amoxicillin/clavulanate compared with all other antibiotics combined. Higher prevalence was found in those where amoxy-

clavulanate was the only antibiotic used. The relative risk (RR) of diarrhea was between 3 and 5 for penicillin V, amoxicillin, and nystatin; 6.5 for a first-generation cephalosporin; and 10.2 for cloxacillin has been reported by Kramer et al., although the author did not define AAD. The rate of AAD associated with parenterally administered antibiotics especially those with enterohepatic circulation was similar to rates associated with oral antibiotics.

Age

In some studies the younger children of less than 2 years were more often associated with AAD. The highest incidence (18%) of AAD was in the 2 months to 2 years age group. Among adults, it is elderly who are more likely to have AAD. So the extremes of age have a higher risk of developing AAD. The RR of onset of an episode of diarrhea in a child receiving amoxicillin/clavulanate was 2.43 (range, 1.4–4.21) and 3.5 (1.89–6.46) when the child was aged less than 2 years.

Hospitalization

Lower rates of AAD in outpatients compared to hospitalized ones is based on their better health status and lack of exposure to highly virulent nosocomial pathogens.

Comorbidity

Incidence of AAD varies widely being influenced by underlying comorbid illnesses, use of acid suppressing medications, duration of hospitalization, prolonged nasogastric tube insertion, gastrostomy and jejunostomy tubes, underlying bowel disease, gastrointestinal tract surgery, and impaired humoral immunity.

Risk Factors for *Clostridium difficile*-associated Diarrhea

Antibiotic usage, though not the only prerequisite, remains the most important risk factor for occurrence of CDAD, which is highly modifiable. Most commonly implicated ones include ampicillin (or amoxicillin), clindamycin, cephalosporins (in particular the third generation cephalosporins such as cefotaxime, ceftriaxone and ceftazidime) and quinolones, though all antibiotics, even vancomycin and metronidazole on rare occasion, have been reported to cause CDAD. Change from cefotaxime to ceftriaxone for initial treatment of severe sepsis or pneumonia in medical patients led to the average number of patients with CD toxin-positive stools per quarter to increase from 16 to 39 but further shift to levofloxacin helped in bringing it down to five cases a year later in an Irish hospital. The delay in the decline of CDAD after virtual withdrawal of cephalosporins may reflect a slowly diminishing environmental reservoir. Decrease in intravenous (IV) cephalosporins usage from 210 to 28 defined daily doses with corresponding increase in piperacillin-tazobactam and moxifloxacin ($p < 0.001$) led to significant decrease in the relative risk (RR 3.24, 95%CI 1.07–9.84, $p = 0.03$) of developing *Clostridium difficile* infection.

Use of rectal thermometers and polyvinyl gloves and environmental contamination are the other risk factors for CDAD.

PATHOGENESIS

Commensal microbes resist colonization of pathogens via various mechanisms including competition for nutrients, production of pathogen inhibiting substances and competitive inhibition of pathogen binding/toxin receptor sites. Disruption of normal enteric flora caused by the antibiotic usage may lead to overgrowth of pathogens secondary to decrease in colonization resistance. Functional disturbances of the intestinal carbohydrates (secondary

to lack of colonic digestion of complex carbohydrates and absence of absorption promoting short chain fatty acids) and bile acids metabolism results in osmotic diarrhea. Also, use of other drugs might affect the intestinal mucosa and the motility. Erythromycin accelerates the rate of gastric emptying; amoxicillin-clavulanate stimulates small bowel motility.

CLINICAL PRESENTATION

More than two-thirds of the children develop AAD during the antibiotic therapy and 15% in the week following after stopping antibiotic. 17% present during antibiotic treatment and continue after stopping the antibiotic. AAD was seen to begin 5.3 ± 3.5 days after start of antibiotic and the mean duration was 4 ± 3 days with none requiring hospitalization. In some studies the younger children of less than 2 years were more often associated with AAD. High prevalence of AAD was seen in the studies not using the standard definition of AAD. Most of them have reported mild illness.

Symptomatology in CDAD ranges from asymptomatic colonization (37% for infants 0–1 month of age, 30% between 1 month and 6 months of age, 14% between 6 months and 12 months of age, and adult rate of 0–3% by 3 years of age) or minor symptoms as acute gastroenteritis (in younger children) to more profound diseased states like pseudomembranous colitis. Pseudomembranous colitis usually presents with abdominal cramps, fever, leukocytosis, fecal leukocytes, hypoalbuminemia, colonic thickening on computed tomography (CT) scan and widely spread punctate yellow plaques on endoscopic examination. This form of colitis follows administration of clindamycin, cephalosporins and penicillin, occurring as an epidemic or endemic in a hospital with usually no previous history of antibiotic intolerance. Most of these cases are CD toxin positive. These may result in increased morbidity and mortality as evident by a 2–3-fold increase in length of hospital stay, a 6-fold increase in the risk of mortality, and the need for colectomy (approximately 2%). Children may have a better outcome with CDAD as depicted in a recent study by Schwartz et al. In this study, 90% of children with CDAD experienced resolution of symptoms by 30 days after disease onset and only 2% experienced a severe outcome. CDAD have a symptomatic recurrence of 15–35%. This is a serious problem since they increase length and overall cost of hospitalization. The longer hospitalization is also responsible for reinfection due to a different strain from the hospital environment.

DIAGNOSIS

Differential diagnosis of AAD includes acute infective diarrhea—viral or bacterial pathogens; mucosal diseases—inflammatory bowel diseases, short bowel syndrome etc.; food allergy, and other medications associated diarrhea. Severe diarrhea, liquid stool with mucus and blood, fecal leukocytes more than 5/high power field, altered flora and presence of gram-positive bacilli with oval subterminal spores are sensitive predictors for diagnosis of CD infection. The cytotoxin assay that uses tissue culture is the gold standard for diagnosis. It is very sensitive test detecting as little as 10 pg of toxin B.

The enzyme-linked immunosorbent assay (ELISA) available for detection of CD has a false negative rate of 10–20% since about 100–1,000 pg of the toxin A and B are needed for the test to be positive. Few of the strains just produce toxin B so the test which detect both toxin A and B should be preferred. ELISA is more easily available, results are available within hours and the cost is about \$40 per test. Therefore, detection of toxin A and B by ELISA and detection of toxin B by tissue culture form the mainstay in the diagnosis of CD.

Stool culture is not easily available but has high sensitivity with low specificity. CD was isolated on culture from stool specimen of 16/80 (20%) patients, while 23 (28.8%) stool specimens were positive for CD toxin. CD has been isolated in 7.2% by culture whereas the overall positivity was 18% by ELISA. Diagnosis of CD by culture is difficult and time consuming because of strict anaerobic nature of organism. Moreover, mere isolation of CD on culture is not sufficient to establish the pathogenic role of these isolates. ELISA for the detection of toxin A and B is recommended to ensure rapid diagnosis of CD. A two-step algorithm evaluated in 1,468 stool specimens first screened the specimens by an immunoassay for CD glutamate dehydrogenase antigen (C.DIFF CHEK-60). Later screen-positive specimens underwent toxin testing by a rapid toxin A/B assay (TOX A/B QUIK CHEK); toxin-negative specimens were subjected to stool culture. This algorithm allowed final results for 92% of specimens with a turnaround time of 4 hours.

TREATMENT

The management options for AAD include discontinuation of implicated antibiotics and use of supportive management with fluid and electrolytes if required. Avoidance of usage of any antiperistaltic drug (may precipitate toxic megacolon) and control of infection in the patient with other antibiotics are also important. In some of cases of CDAD, withdrawal of the inciting agent will lead to resolution of clinical signs in three days. Oral metronidazole or oral vancomycin (for a duration of 10 days) are the drugs of choice for CDAD with more than 90% cure rates for both. Using metronidazole allows the treatment cost to be low and also prevents the development of vancomycin-resistant enterococci. Vancomycin should be reserved for those with severe illness, or intolerance or failure to metronidazole. Treatment regimens may also include probiotics, bile-acid sequestrants and IV immunoglobulin (IVIG). Most recurrences also respond to this line of management. A prolonged treatment with low dose vancomycin is preferred for the repeated recurrences. Metronidazole, in view of low cost and established efficacy, is the drug of choice for the initial treatment with mild to moderate disease while reserving oral vancomycin with or without IV metronidazole for patients with severe disease and for patients who do not respond to oral metronidazole. To reduce the costs, use of IV formulation compounded by pharmacy into oral solution can be used to the best advantage.

Use of gloves with symptomatic patients, washing of hands with soap and water, and environmental decontamination are key control measures. Latest treatment modalities include newer antibiotics (rifaximin, nitazoxanide and fidaxomicin), fecal microbiota transplantation, and various experimental options (rifalazil, ramaplanin, tolevamer, monoclonal antibodies).

PREVENTION

Handwashing, isolation and environmental decontamination are the factors which can prevent recurrences and reinfection. Avoidance of usage of rectal thermometers, usage of vinyl gloves and hospital antibiotic policies are other factors which can help.

Role of Probiotics

Probiotics are living microorganisms, which when administered in adequate amounts that confer a health benefit to the host. Antibiotics disrupt the natural microbial flora of the intestine leading to overgrowth of pathogens while decreasing the colonization resistance. Probiotics, thereby acting as surrogate normal flora, act to protect the intestine until the normal microbiota can recover. Other potential mechanisms of action

include production of bacteriocins, stimulation of the immune response, production of toxin-destroying proteases, attachment site interference, etc.

Saccharomyces boulardii and *Lactobacillus spp.* (e.g., *Lactobacillus rhamnosus GG*) are the most popular species used as probiotics with documented benefit in various trials. *S. boulardii* has been shown to prevent the binding of toxin A to inactivate toxins A and B by proteolytic digestion, inhibition of CD adhesion, cellular protection from histologic damage and inhibition of proinflammatory cytokine gene expression.

A recent Cochrane analysis (23 trials, 4,213 participants) to assess the efficacy and safety of probiotics for preventing CDAD or CD infection in adults and children, suggested that probiotics significantly reduce this risk by 64%. The incidence of CDAD was 2.0% in the probiotic group compared to 5.5% in the placebo or no treatment control group (RR 0.36; 95% CI 0.26–0.51). The incidence of CD infection was 12.6% in the probiotics group compared to 12.7% in the placebo or no treatment control group. In another meta-analysis to assess the efficacy and safety of probiotics for preventing pediatric AAD (22 trials, 23 treatment arms and 4,155 participants) and CD infections (5 trials, 1,211 participants), probiotics (all strains combined) significantly reduced the incidence of pediatric AAD (pooled RR = 0.42, 95% CI: 0.33–0.53) and significantly reduced pediatric CD infection (pooled RR = 0.35, 95% CI: 0.13–0.92). Both *Saccharomyces boulardii lyo* and *Lactobacillus rhamnosus GG* significantly reduced pediatric AAD. There was no significant effect by type of antibiotic, or by duration or dose of probiotic. No adverse events were found relating to the use of probiotics. Thus, it concluded that probiotics significantly prevented pediatric antibiotic associated diarrhea and pediatric CD infection.

Risk benefit ratio needs to be carefully balanced while using probiotics (especially *S. boulardii*) in select group of patients. These include those with intravascular catheters and critically ill debilitated immunocompromised patients. The risks include increased chances of fungemia with probiotics as a probable source. It is important to note here that we need to now concentrate on specific probiotics individually when assessing their role in AAD or in other disorders, because clubbing together the effective strains with ineffective ones might actually be diluting the effect of the former. These meta-analyses raise the issue of how cost-effective is the addition of probiotics to antibiotics in the developing world. Probiotics may have a potential role to play in the prevention of AAD but the cost benefit ratio should be carefully assessed. Since the prevalence of AAD is low and the addition of probiotics is going to prevent only 1 in 7–10 cases of AAD, it may not be very cost-effective to routinely add probiotics to antibiotics in children.

IN A NUTSHELL

1. Prevalence of antibiotic associated diarrhea (AAD) is around 11% in children receiving antibiotics.
2. Children younger than 2 years and type of antibiotics are the two risk factors identified for AAD.
3. The most common organism found associated with AAD is *Clostridium difficile*; other less commonly involved organisms include *Staphylococcus aureus*, *Clostridium perfringens*, *Klebsiella oxytoca* and *Candida*.
4. The incidence of community acquired *Clostridium difficile* is increasing in the pediatric population.
5. Detection of toxin A and B by ELISA and detection of toxin B by tissue culture form the mainstay in the diagnosis of *C. difficile*. There should be a two-step method to detect CD infection.
6. Most of the AAD would respond to only discontinuation or change of the antibiotic. Oral metronidazole or oral vancomycin are drugs of choice for *Clostridium difficile*.
7. Probiotics reduce the risk of AAD in children, when given to 7–10 patients along with antibiotics would prevent AAD in one child.
8. Cochrane analysis confirms the efficacy (reduce this risk by 64%) and safety of probiotics for preventing CDAD or CD infection in adults and children.

Section 37 HEPATOBILIARY DISEASES

Section Editor Surender Kumar Yachha

Chapter 37.1

Applied Anatomy and Physiology of Liver and Biliary Tract

Vishnu Biradar

It is important to have basic knowledge of anatomy, physiology and histology of the liver to understand its diseases and their complications. This chapter discusses in a brief about development of the liver followed by normal anatomy and histology of the liver and lastly physiologic functions of liver.

DEVELOPMENT OF LIVER

Liver is developed in fetus in the 3rd–4th week of gestation from two primordial buds. Hepatic outgrowth from foregut endoderm develops into the parenchyma and septum transversum develops into the connective tissue elements of the hepatic stroma and capsule. Septum transversum is invaded by cranial part of diverticulum. Furthermore, cranial part of diverticulum forms the prehepatocytes or hepatoblasts inside the septum transversum, and is organized in cords around developing sinusoids derived from branches of the vitelline veins that penetrate the septum transversum. The caudal part of the hepatic diverticulum forms the extrahepatic biliary tree and ventral pancreatic anlage. The extrahepatic biliary tree is recognizable in 4-week-old embryo. Rest of the biliary tract structures such as gallbladder, cystic duct, hepatic ducts, common bile ducts and pancreatic duct are visible by end of 5 weeks. By 16th week, biliary duct system is fully formed.

Secretion of factors such as bone morphogenic protein (BMP) by the mesenchymal cells of the septum transversum and of fibroblast growth factors (FGF) by the precardiac mesoderm appear to play an important role in the induction of hepatogenesis. The development of the liver is also associated with changes in the vitelline veins and in the umbilical veins. Venous system is recognizable in 7-week-old embryo. The development of the intrahepatic biliary tree begins between the 5th and 9th week postfertilization. Biliary epithelium is believed to arise from precursor bipotential hepatoblasts that can differentiate into either hepatocytes or biliary epithelial cells. *HNF-1 β* and *HNF-6* genes or gene products regularize this process. The Notch pathway is also involved in bile duct development; the Jagged1/Notch2 interaction may be critical for induction of biliary differentiation and repression of hepatocytic differentiations. The liver becomes the site of hematopoiesis between 6 and 7 weeks. As the fetus enters the third trimester, hematopoiesis diminishes and becomes focal. Little hematopoiesis is seen in portal tract after 32 weeks of gestation.

Embryological changes in liver development are outlined in

Table 1 Hepatic development

Developmental age	Characteristic
Week 3–4	Hepatic diverticulum appears as an evagination of the foregut
Week 5	Umbilical veins connect with the developing hepatic sinusoids. Ductal plate begins to form hematopoiesis
Week 6	Hematopoiesis begins
Week 7	Definitive venous pattern established within the liver
Week 9	Liver accounts for 10% of fetal weight
Week 12	Remodeling of the ductal plate. Bile formation begins
Week 16	Major bile ducts formed at porta hepatis
Week 36	Hematopoiesis reduced to small widely spaced islands

ANATOMY

Liver is the largest solid organ in our body, situated just below the right diaphragm and divided by falciform ligament anteriorly into right and left lobes. Parietal peritoneum covers the liver except for the bare area, where the liver remains in direct contact with the diaphragm and is suspended by fibrous tissue and the hepatic veins. It is attached to diaphragm by the superior and inferior coronary ligaments and the right and left triangular ligaments. Inferiorly, there are two distinct lobes: (1) caudate and (2) quadrate lobes. The caudate lobe has boundaries of the inferior vena cava groove, porta hepatis and ligamentum venosum fissure. On the inferior surface, the quadrate lobe is defined by the gallbladder fossa, porta hepatis and ligamentum teres hepatis. The true right and left lobes of the liver are roughly equal size and are not divided by the falciform ligament, but by a plane passing through the bed of gallbladder and the notch of the inferior vena cava. *Liver is divided into eight segments by Claude Couinaud on basis of distribution of portal and hepatic veins.* Couinaud lobes were numbered in clockwise fashion from 1 to 8 starting from caudate lobe being segment 1. Segments 1 to 4 form left lobe and segments 5–8 form the right lobe.

Approximately 70% of blood is supplied to liver from the portal vein and rest 30% from the hepatic artery. The portal vein is formed behind the neck of pancreas by the superior mesenteric vein and the splenic vein. At the hilum, the portal vein divides into right and left branches. The hepatic artery commonly arises from the celiac trunk. Within the hilum, portal vein is posterior to the hepatic artery and hepatic artery is on the right side of the bile duct. In the liver parenchyma, the arteries, portal veins, and bile ducts are surrounded by a fibrous sheath, the Glissonian sheath, whereas the hepatic veins lack this structure. Majority of the venous drainage of the liver is accomplished by three major hepatic veins: (1) right, (2) middle and (3) left drains into the inferior vena cava, except that the caudate lobe drains into inferior vena cava directly.

Table 1.

Each lobe is drained by right and left hepatic ducts, which joins to form the common bile duct. The cystic duct usually drains into the lateral aspect of the common hepatic duct. The caudate lobe drains into the left hepatic ducts. The liver is innervated by both sympathetic and parasympathetic nerve fibres. Lymphatic drainage of liver surface occurs to the nearest lymph nodes.

FUNCTIONAL UNITS AND HISTOLOGY

Under the low power (10 X) microscope, normal liver consists of a regular structure based on portal tracts and efferent veins. A typical *portal tract* contains portal venules, hepatic arterioles and small interlobular bile ducts (**Fig. 1**). Blood from both venules and arterioles pass through the sinusoidal system to reach efferent hepatic venules. From these, the blood drains into successively larger veins to reach the inferior vena cava. Bile is secreted into bile canaliculi, which flows towards canals of Hering and to the bile ductules and hence to interlobular bile ducts, further from the smallest ducts into larger ducts, to reach the small intestine by the way of common bile duct.

The functional relationship between these various structures has been the subject of much debate. The most widely used models are the Kiernan's classic lobule and Rappaport's acinus. The Kiernan's classic lobule has an efferent venule at its center and portal tracts at its periphery, hexagonal unit (**Fig. 2**). The Rappaport's acinus is 3D structure, based on a terminal portal tract, with blood passing from this, through successively less well-oxygenated parenchymal zones 1, 2 and 3, to efferent venules. It is worth emphasizing that both lobules and acini are concepts rather than fixed anatomical structures. Both these concepts have their merits in different situations. For example, the sinusoidal congestion of venous outflow obstruction is often more easily understood on the basis of the lobule, with maximum intensity at its center. Bridging hepatic necrosis, however, is difficult to understand in terms of the lobule and has been explained as death of hepatocytes in acinar zone 3, the zones in which oxygen saturation is relatively low.

The hepatocytes are arranged in plates separated by the sinusoidal labyrinth. The layer of hepatocytes next to a small portal tract is known as the limiting plate, which is one celled. In children, limiting plate may be two cells thick. Hepatocytes are polygonal cells with well-defined cell borders. Most cells contain one diploid nucleus. Nucleoli are often visible, with rare mitotic figures. Polyploidy and variation in nuclear size is therefore normal

characteristics of human liver. A few nuclei may appear vacuolated because of glycogen accumulation, especially in children and adolescents. Hepatocyte cytoplasm is normally rich in glycogen. Many different proteins such as albumin can be demonstrated in or on the hepatocytes, in keeping with the several metabolic functions of liver. Between the hepatocytes, their walls formed by two or three cells, are the bile canaliculi. Lipofuscin is a normal constituent of adult liver, increasing in amount with age, but also sometimes found in children.

Sinusoidal endothelial cells form a continuous lining which is fenestrated, allowing passage of macromolecules between sinusoids and the space of Disse, which separates the hepatocytes and the space of Disse. Perisinusoidal cells, or cells of Ito, are stellate-shaped fat-storing cells lying between hepatocytes and the space of Disse. They store vitamin A and appear to play a significant role in fibrogenesis. Kupffer cells lie on the sinusoidal surface. They are part of the reticuloendothelial system, and their main function is phagocytosis.

BIOPSY OF THE NORMAL LIVER

Percutaneous liver biopsies are necessarily taken through the liver capsule, which may be seen at one of the core or as a separate piece. Minimum 6 g of liver tissue is considered as adequate and must contain at least six portal tracts. For enzyme analysis, 30 g tissue is required. For copper estimation, 1–2 g of liver tissue is sufficient. Transjugular biopsy specimen may be small and fragmented, especially in patients with cirrhosis, but are usually adequate for histological diagnosis.

Surgical biopsies taken from the inferior margin of the liver are in the form of wedges covered on two aspects by capsule. The structure of the immediately subcapsular zone differs somewhat from the deeper tissue, but there is good correlation between the volume fraction if nonparenchymal components in subcapsular and deeper zone. The appearances mimicking cirrhosis do not usually extend beyond 2 mm into the liver, and confusion is unlikely except with very small samples. In surgical biopsies taken some time after the beginning of an operation, neutrophil leukocytes accumulate under the capsule and in portal tracts, around terminal venules and focally within the parenchyma. Here, there is focal loss of hepatocytes. Similar parenchymal changes have been reported after heavy sedation without full anesthesia. They may also found in patients infected with cytomegalovirus.

Normal Appearances in Childhood

Hematopoiesis in liver is active during the fetal period and continues until a few weeks after birth. Hematopoietic cells are present in portal tracts and sinusoids. Hepatocyte plates are mainly two cells thick until the age of 5 or 6, when the adult pattern of single cell plates is established. Hepatocytes and their nuclei may vary in size. Glycogen vacuolation of nuclei is common in adolescents. Lipofuscin pigment is absent or scanty in the first two decades of life.

LIVER PHYSIOLOGY AND METABOLISM

There are numerous pathways for metabolism of carbohydrate, protein, fat and other substances present in hepatocytes. They are regulated by various hormones secreted by endocrine tissues. Metabolic changes occurring during development of liver are listed in **Box 1**.

BOX 1 Metabolic changes during liver development

- Accumulation of glycogen in fetal liver (to levels two- to three-fold higher than in the adult by term)
- Low rates of gluconeogenesis by fetal liver
- Low rates of glucose use by fetal liver
- Amino acids an important energy source for fetal liver (extensive transamination and oxidative degradation)
- High capacity of fetal liver for fatty acid synthesis
- Rapid induction of ability to oxidize fatty acids during first day of life
- Fatty acid oxidation critical to support of hepatic gluconeogenesis
- Rapid increase in hepatic ketogenesis after birth.

Bile Metabolism

Hemoglobin from senescent red blood cells (RBCs) is broken down to heme and protein. Heme is then converted into bilirubin, which is unconjugated and in insoluble form. One gram of hemoglobin produces 34 mg of bilirubin. This unconjugated bilirubin binds to albumin by noncovalent bond and is then transported to liver. Albumin bound unconjugated bilirubin gets dissociated, just before uptake by hepatocytes. Unconjugated bilirubin, insoluble form, is taken up by hepatocytes, gets converted by enzyme uridine-5'-diphosphate (UDP) glucuronyl transferase enzyme to soluble form, bilirubin mono- or diglucuronide conjugates which is excreted into canaliculi by canalicular protein multiple drug resistant protein 2 (MRP 2) against concentration gradient (energy dependent). From canaliculi, conjugated bilirubin is excreted into intestine via bile duct system. In intestine, bilirubin is broken down to stercobilirubin which is excreted into feces and urobilinogen which is reabsorbed by intestine. This reabsorbed urobilinogen either gets excreted into urine or recycled by the liver.

Carbohydrate Metabolism

Glucose is required as an energy source, especially for the brain, RBCs, muscle and kidney. Glucose homeostasis is monitored by gut-brain-liver axis. Glucose levels are maintained mainly by the liver. Glucose when in excess gets stored as glycogen in hepatocytes and glycogen gets degraded to glucose during fasting stage. Gluconeogenesis also play important role in forming glucose during fasting. In prolonged fasting, brain utilizes ketones as an energy store. During this, glucose is synthesized by anaerobic glycolysis, i.e., Embden-Meyerhof pathway which forms pyruvate and lactate predominantly by RBCs and from amino acid precursors such as alanine from muscle. Lactose and galactose present abundantly in diet gets absorbed in intestine and enters into metabolic pathway to form either glucose or fat depending on need.

In fetal life, glycogen synthesis starts around 9 weeks of gestation, which increases before birth. After birth, this glycogen is metabolized to glucose preventing hypoglycemia in full term neonate.

Protein Metabolism

Liver synthesizes albumin and other secretory serum proteins. Albumin production starts in utero around 8 weeks of gestation and reaches adult levels in second part of infancy. Liver also produces fibrinogen, transferrin and apolipoproteins and clotting factors.

Fat Metabolism

Fat metabolism occurs by fatty acid oxidation where it produces free fatty acids (FFAs). Fatty acid oxidation occurs in mitochondria and peroxisomes. FFA utilized for gluconeogenesis for energy production when needed. During prolonged fasting, ketones are produced by beta oxidation of fatty acids in mitochondria present in hepatocytes which is utilized by brain for energy. As was mentioned earlier, excess glucose gets converted to glycogen in liver and fat in peripheral tissue, which is deposited in adipose tissue and as a triglyceride in hepatocytes.

Drug Metabolism

Hepatocytes contains various microsomal enzymes like CYP 450 or UDP-glucuronosyltransferase, sulfotransferases, GSTs (dimeric enzymes conjugating glutathione), etc. Newborn liver has low activities of certain enzymes which make it vulnerable to drug toxicity. It is also due to less concentration of antioxidants. Microsomal activities increase in next 1 year after birth, irrespective of gestation of newborn at the time of birth.

IN A NUTSHELL

1. Liver is the largest solid organ, situated below right diaphragm subdivided into eight segments by Couinaud. It is supplied majorly by portal vein blood 70% and by hepatic veins 30%.
2. Liver develops from foregut endoderm with the interplay of factors such as *BMP*, *FGF*, *HNF-1 β* and *HNF-6* genes or gene products, the Jagged1/Notch2 interaction pathway, etc.
3. Functional unit is Rappaport acinus and Kremer's classic lobule which are concepts rather than fixed anatomical structure.
4. Liver biopsy in early infancy may show active hematopoiesis, glycogen vacuolation of nuclei, high content of glycogen, two cell thick hepatocytes plates and absence of lipofuscin which is contrary to adult.
5. Bile acid synthesis and bile excretion is unique feature of liver along with many metabolic pathways of carbohydrate, protein and fat which work simultaneously to meet metabolic demands of body and also drug metabolism.

Chapter 37.2

Liver Function Tests

Neelam Mohan, Sakshi Karkra

Liver is a unique organ which performs synthetic, biochemical and excretory functions, so no single biochemical test can detect the global functions of liver. The title *liver function tests* is, however, somewhat of a misnomer as only the bilirubin and albumin offer information regarding the functional capacity of the liver. Though they lack sensitivity and specificity a good interpretation of these assays do give a lot of information in association with the clinical history, physical examination, radiological imaging and liver biopsy. Advantages and limitations of liver function tests are listed in **Box 1**. Liver functions tests are classified in four categories: i.e., test for (1) Transport of organic anions and metabolism of drugs; (2) Injury to hepatocytes (serum enzyme tests); (3) Biosynthetic capacity; and (4) Clearance of substance from plasma by the liver.

BOX 1 Advantages and limitations of liver function tests

Advantages

- Sensitive screening modality for liver dysfunction
- Useful to recognize the pattern of liver disease, like in differentiating acute viral hepatitis, chronic liver disease (CLD) and various cholestatic disorders
- To assess the severity of liver disease and predict outcome
- For follow-up of patients and in evaluating response to therapy of certain liver diseases like autoimmune liver disease, postliver transplant, etc.

Limitations

- Lack sensitivity and they may be normal in certain liver diseases like congenital hepatic fibrosis, noncirrhotic portal fibrosis and rarely in cirrhosis
- They lack specificity for any particular disease
- Serum albumin may be decreased in CLD but they may be also abnormal in malabsorption, malnutrition, or renal disorders like nephrotic syndrome
- Aminotransferases though done for screening of liver diseases; may be raised in cardiac and muscular diseases
- Liver function tests except for serum bile acids are not specific for liver diseases

TESTS FOR TRANSPORT AND DRUG METABOLISM

Serum Bilirubin

Bilirubin is derived from hemoglobin degradation. Original van D Bergh's method of measuring bilirubin classified bilirubin into direct and indirect. Measurements of bilirubin can be altered by exposure to light, therefore, samples must be kept in dark.

Total bilirubin Normal range is 0.2–0.9 mg/dL (2–15 μ mol/L). It is slightly lower in females as compared to males (by 3–4 μ mol/L).

Direct bilirubin This is the water-soluble fraction of the total bilirubin. Normal range is 0.3 mg/dL (5.1 μ mol/L).

Indirect bilirubin This is a measure of unconjugated fraction of bilirubin and is calculated by the difference of the total and direct bilirubin (**Flow chart 1**).

Urine Bilirubin

Unconjugated bilirubin is tightly bound to albumin and not filtered by the glomerulus and thus not present in urine while conjugated bilirubin is water soluble and may be found in urine. In early

Flow chart 1 Types of hyperbilirubinemia

hepatobiliary disease like in acute hepatitis, urine bilirubin may be positive (tests strips impregnated with diazo reagent can detect as little as 0.1–0.2 mg/dL of bilirubin) while the patient may not appear clinically icteric.

Urobilinogen

When the bilirubin glucuronides are secreted into the upper small intestine they are hydrolyzed to unconjugated bilirubin. This is further reduced by the anaerobic intestinal microbial flora to form three colorless tetrapyrroles called urobilinogen. The urobilinogen oxidizes spontaneously to produce the major color pigments of stool in the lower intestinal tract. Around 20% of the urobilinogen produced daily undergo enterohepatic recirculation, majority being taken up by the liver and then re-excreted into bile with a small fraction being excreted in the urine. In biliary obstruction, urine as well as stool urobilinogen excretion decrease to very low concentrations because very small amount of bilirubin reaches the intestinal tract. In patients with hepatocellular dysfunction like viral hepatitis or well-compensated cirrhosis in children, more urobilinogen escapes hepatic uptake and thus appears in the urine.

TESTS FOR HEPATOCYTE INJURY

Enzymes that Detect Hepatocellular Necrosis:

Aminotransferases

The aminotransferases or transaminases are the most frequently utilized and specific indicators of hepatocellular damage. These enzymes—aspartate aminotransferase [AST, or serum glutamate oxaloacetic transaminase (SGOT)] and alanine aminotransferase [ALT, or serum glutamate pyruvate transaminase (SGPT)] catalyze the transfer of the amino acids of aspartate and alanine to the keto group of ketoglutaric acid. ALT is primarily located in liver while AST is present in tissues like liver, skeletal muscle, kidney, heart, muscle, brain, pancreas, lung, leukocytes and red blood cells.

AST is present in both the mitochondria and cytosol of hepatocytes (isoenzymes), while ALT is a cytosolic enzyme with the highest concentrations in the liver. Elevation of the enzyme occurs due to destruction or change in cell membrane permeability of tissues rich in the aminotransferases allowing AST and/or ALT to leak from damaged cells into serum. Whether serum AST level elevation is of hepatic origin should be confirmed by obtaining a serum ALT level. About 80% of AST activity in human liver is contributed by the mitochondrial isoenzyme, whereas most of the circulating AST activity in normal people is derived from the cytosolic isoenzyme. Large increases in mitochondrial AST occur in serum after extensive tissue necrosis. Causes of deranged aminotransferases (AST and ALT) are listed in **Table 1**.

Aspartate aminotransferase:Alanine aminotransferase ratio (De Ritis ratio) This ratio may assist in differentiating the site of biliary obstruction. In a cholestatic picture, an AST:ALT ratio of less than 1.5 is suggestive of an obstruction outside liver. In such conditions the ALT titer is considerably higher than AST. An AST:ALT ratio of greater than 1.5 indicates intrahepatic (mechanical or medical)

Table 1 Causes of deranged aminotransferases (AST and ALT)

Mild elevation of AST and ALT (1–3 times)	Moderate elevation of AST and ALT (3–20 times)	Marked AST and ALT elevations (> 20 times, 1,000 U/L)	Isolated raised AST	Falsely low AST, ALT
<ul style="list-style-type: none"> Neonatal hepatitis EHBA Fatty liver Nonalcoholic steatohepatitis (NASH) Drug toxicity 	<ul style="list-style-type: none"> Wilson disease Autoimmune hepatitis Typhoid Malaria Celiac disease Medications Acute viral hepatitis Chronic hepatitis B and C 	<ul style="list-style-type: none"> Acute viral hepatitis Ischemic hepatitis Drugs Autoimmune hepatitis Acute Budd-Chiari syndrome 	<ul style="list-style-type: none"> Hemolysis Myopathy Thyroid disease Exercise Myocardial infarction 	<ul style="list-style-type: none"> Hemodialysis Pyridoxine deficiency Uremia

Abbreviations: AST, aspartate transaminase; ALT, alanine aminotransferase; EHBA, extrahepatic biliary atresia.

cholestasis. The ratio invariably rises to more than one as cirrhosis develops because of decreased plasma clearance of AST secondary to impaired function of sinusoidal cells and the lack of ALT rise is probably due to pyridoxine deficiency. Causes of abnormal AST:ALT ratio are listed in **Table 2**.

Wilson disease presenting as acute liver failure can be diagnosed with 100% sensitivity and specificity using the combination of an ALP:bilirubin ratio less than 4, along with an AST:ALT ratio of greater than 2.2. Also the AST:platelet ratio index (APRI) is an useful indicator but has poor sensitivity where an APRI greater than 1.5 signifies moderate to severe fibrosis.

Other enzymes that are deranged in hepatocellular necrosis are isocitrate dehydrogenase, glutamate dehydrogenase, lactate dehydrogenase and sorbitol dehydrogenase but none of these tests have proved to be useful in practice.

Enzymes that Detect Cholestasis

Alkaline phosphatase These are zinc metalloenzymes with a serine at center. These are present in nearly all tissues such as liver, kidney, bone, etc., with most circulating alkaline phosphatase originating from liver or bone in healthy people. It is found in the microvilli of bile canaliculi and on the sinusoidal surface of hepatocytes. Alkaline phosphatase from intestine and placenta are derived from different genes while that from liver, bone and kidney are thought to be from the same gene. Average values of alkaline phosphatase are relatively high in childhood, puberty and in old age while lower in middle age with males having higher values in comparison to females. Alkaline phosphatase reaches the circulation probably by leakage from the bile canaliculi into hepatic sinusoids. In drug-induced cholestasis there is preferential rise in ALP, rather than gamma-glutamyl transpeptidase (GGT) and an ALT:ALP ratio is less than 2. Causes of deranged alkaline phosphatase are listed in **Table 3**.

Glutamyl transpeptidase Gamma glutamyl transpeptidase is a membrane bound glycoprotein with gene on chromosome 22 which catalyzes the transfer of glutamyl group to other peptides, amino acids and water. The kidneys, pancreas, liver, intestine and prostate contain large amounts with men having higher values.

Table 2 Causes of abnormal AST:ALT ratio

*Tumor specific isoenzymes are Regan, Nagao and Kasahara isoenzymes.

**Wilson disease complicated by hemolysis and fulminant hepatic failure (FHF) usually have low levels of alkaline phosphatase leading to low ratio of alkaline phosphatase and bilirubin in fulminant Wilson disease. Copper replaces cofactor zinc and might result in subsequent inactivation of alkaline phosphatase. This low ratio of alkaline phosphatase to bilirubin is associated with a poor prognosis.

Range varies from less than 385 U/L in less than 1 month, less than 225 U/L at 1–2 months and less than 135 U/L in 2–4 months age group with serum values similar to adults in children more than 4-year-old (0–30 IU/L). As it is not found in bone, so bone disease can be excluded if elevated GGT levels are found. Phenobarbitone and phenytoin lead to high GGT levels as they are enzyme inducers, on the contrary, valproic acid does not induce serum GGT levels, except in cases of true hepatotoxicity so this is good test for monitoring liver injury during valproate therapy. **Table 4** enlists important causes of deranged GGT.

5'-Nucleotidase 5'-Nucleotidase (5-NT) catalyzes the hydrolysis of adenosine-5-phosphate or inosine-5-phosphate. Though it is found in liver, intestines, brain, heart, blood vessels, and endocrine pancreas, its marked elevations are seen only with underlying liver disease. 5-NT is located in both sinusoidal and canalicular membranes in liver. Their levels are lower in children, increase gradually with adolescence and reach a plateau after 50 years of age. The abnormal 5-NT values usually mimic that of serum AP levels, as both enzymes have similar locations within the hepatocyte but 5-NT levels do not increase in the presence of bone disease, unlike alkaline phosphatase.

Leucine aminopeptidase These are zinc-dependent exopeptidases by which processing, catabolism and degradation of intracellular proteins occurs. This enzyme is normally found in cells of the liver and small intestine. Levels are raised in cholestasis, cirrhosis, hepatitis, ischemia (reduced blood flow to the liver), necrosis and tumor.

TESTS OF THE BIOSYNTHETIC CAPACITY

Serum Proteins

Most of the serum proteins are synthesized in liver. Albumin, most of the α - and β -globulins, fibrinogen and other coagulation factors are produced in the parenchymal cells.

Albumin Albumin is a useful indicator of hepatic function. Its half life is around 20 days, so in acute liver disease, its level are not reliable indicator. The serum albumin levels tend to be normal in acute viral hepatitis, drug-induced hepatotoxicity and obstructive jaundice. Its levels are increased by corticosteroids and thyroid hormone while lower levels are seen in chronic liver disease (CLD) like cirrhosis. Normal serum values are 3.5–4.5 g/dL. Hypoalbuminemia is not specific for liver disease but may occur in chronic protein losing enteropathies, protein malnutrition and nephrotic syndrome.

Prealbumin The serum prealbumin level is 20–30 mg/dL. Its levels are reduced in liver disease probably due to decreased synthesis. Reduction in its level may precede alteration in serum albumin because of its short half life so its determination is useful in drug-induced hepatotoxicity where early fall may predict hepatotoxicity.

Serum ceruloplasmin It is an acute phase protein synthesized in the liver. Normal plasma levels are 20–40 mg/dL. The levels rise in infections, rheumatoid arthritis, non-Wilson liver disease, obstructive jaundice and in pregnant females. The plasma level is usually low in Wilson disease, neonates, protein losing enteropathy, copper deficiency, aceruloplasminemia, kwashiorkor, marasmus and Menkes disease.

Procollagen III peptide The serum concentration of this peptide increase with hepatic fibrosis, inflammation and necrosis. Serial measurement of procollagen III may be helpful in the follow-up of CLD.

Alpha-1 antitrypsin Alpha-1 antitrypsin, a glycoprotein, synthesized by liver is an acute phase protein and is an inhibitor of serine proteinases, especially elastase. Its normal concentration is 100–160 mg/dL. Its level increases with inflammatory disorders in children and in pregnancy and after oral contraceptive pills (OCP) in adults. The alleles are M, F, S, Z and null forms. Neonatal hepatitis is associated with PiZZ homozygotes. While in adults ZZ, MZ, SZ and FZ phenotypes are associated with cirrhosis. Its deficiency should be confirmed by quantitative measurement.

Alpha fetoprotein It is the principal protein in fetal plasma in early gestation and is subsequently present at very low levels. More

than 90% of patients with hepatocellular carcinoma (HCC) have raised levels except when HCC arises in noncirrhotic liver. Serial determination with rise in the values should raise the suspicion of HCC in cirrhotic patients. Raised values are also found in other liver diseases like in regeneration phase of acute hepatitis, chronic hepatitis, adenomas associated with tyrosinemia and in hepatic metastasis. Normal range is less than 10 mg/dL in children more than 6-month-old.

Prothrombin time (PT) Eleven blood coagulation factors like fibrinogen, prothrombin, labile factor, stable factor, Christmas factor, Stuart-prower factor, prekallikrein and high-molecular-weight kininogen are produced in liver. The extrinsic coagulation pathway is assessed by one stage PT which is expressed in seconds or as a ratio of the patient's PT to control PT. Normal control usually is 9–11s and a prolongation of more than 2s is considered abnormal. The prolonged PT is not specific for liver diseases and is seen in various deficiencies of coagulation factors, disseminated intravascular coagulation (DIC), and ingestion of certain drugs. If the PT returns to normal or improves by at least 30% within 24 hours of a single parenteral injection of vitamin K1 (5–10 mg), it indicates good liver parenchymal function while in parenchymal disease only minimal or no improvement is seen. Most patients with extrahepatic obstruction like extrahepatic biliary atresia (EHBA) would respond promptly to a single injection of vitamin K1 unlike some inherited metabolic diseases in the newborn, such as tyrosinemia in which the profound prolongations of both PT and partial thromboplastin time (PTT) may appear out of proportion to other parameters of liver dysfunction. It is important to perform PT/partial thromboplastin time activated with kaolin (PTTK) before invasive procedures like liver biopsy and kidney biopsy. The PT test is not a sensitive index of CLD but has high prognostic value for patients with acute hepatocellular disease. A persistently abnormal PT in a previously well child can be the single laboratory test that can predict the possibility of the development of acute liver failure. Many of the clotting factors, including the vitamin K-dependent factors II, VII, IX, and X, are less than 70% of adult levels in both full-term and preterm newborns. The hemostatic system of the neonate is dynamic and evolves toward that of normal adult. Normal values at various ages in postnatal period need to be considered. Normal values of PT and activated PTT are given in **Table 5**.

Fibrinogen Low levels of fibrinogen are seen in liver disease accompanied by DIC when there is consumption of fibrinogen and other clotting factors. Conversely, high levels may be seen in patients with hepatic diseases because fibrinogen is an acute phase reactant or because of elevations described specifically in cholestatic disease. Some patients with liver disease develop a dysfibrinogenemia with an abnormal fibrin monomer aggregate, which is manifested by a normal measured fibrinogen level.

Lipids and Lipoproteins

The liver plays a central role in production and degradation of lipoproteins. The cholesterol is transported in the blood in lipoprotein X, a lipoprotein specific to cholestasis. However, in noncholestatic liver diseases, declining lipoprotein cholesterol

Table 5 Reference values for prothrombin time (PT) and activated partial thromboplastin time (aPTT) in infants

Postnatal age	PT, Seconds	Activated PTT, Seconds
1 month	11.8 (10.0–13.6)	44.7 (26.9–62.5)
3 months	12.3 (10.0–14.6)	39.5 (28.3–50.7)
6 months	12.5 (10.0–15.0)	37.5 (21.7–53.3)

Source: Andrew M, Paes B, Milner R, et al. Development of the coagulation system in the healthy preterm infant. *Blood*. 1988;72:165–7.

may reflect deteriorating liver function and may be an indicator of prognosis. In acute hepatocellular injury there is mild hypertriglyceridemia secondary to decrease in levels of hepatic enzymes such as lecithin-cholesterol acyltransferase (LCAT) and triglyceride lipase (TGL).

Bile Acid Tests

Bile acids are a class of endogenous organic anions synthesized from cholesterol exclusively in the hepatocytes, conjugated to glycine or taurine and then secreted into bile. Measuring serum bile acids may not be as useful a test in children because of the presence of a relative physiologic cholestasis in neonates, which results in baseline elevations of serum levels even in healthy babies. These baseline elevations decrease within the 1st year of life, indicating a maturation of the bile acid transport processes. Serum bile acids are disproportionately elevated in primary sclerosing cholangitis and progressive familial intrahepatic cholestasis (PFIC) syndromes (subtypes 1, 2 and 3) even when the serum bilirubin is normal. The development of the technique of fast atom bombardment mass spectrometry has allowed the rapid screening of urine samples from infants and older children with suspected bile acid synthetic disorders using microliter amounts of sample directly.

TESTS BASED ON SUBSTANCES CLEARED FROM PLASMA BY THE LIVER

Ammonia

The concentration of ammonia in the blood is regulated by the balance of its production and clearance. Production is mainly in the large intestine by the action of bacterial urease on dietary protein and amino acids. Clearance of ammonia occurs mainly in the liver via transformation of ammonia into urea via the urea cycle and into glutamine by transamination of α -ketoglutarate to glutamate and then to glutamine. The liver ordinarily removes 80% of the portal venous ammonia in a single pass. In CLDs, disturbed urea cycle function caused by parenchymal liver cell destruction and portosystemic shunts permit large amounts of ammonia to bypass the liver and exert their effects on the central nervous system. Some ammonia is also made by the kidney and small intestine, a fact that becomes important when a patient is taking certain drugs like valproic acid, which can cause an increase in serum ammonia independent of any hepatotoxicity because of the drug-induced ammonia production by the kidney.

Exogenous Substances Used in Tests to Assess Quantitative Liver Function

The tests for quantitative liver function or true dynamic liver function are based on uptake, metabolism and excretion of a determinate substance. The ideal test would be inexpensive, easy to perform and analyze, safe, have a single pharmacokinetic profile with minimal drug interactions, high predictive value and with quick results. Dynamic function tests can be either those using elimination of a substrate for testing (e.g., indocyanine green clearance, caffeine clearance and galactose elimination) or those that detect metabolites of the substance administered [e.g., aminopyrine breath test, monoethylglycinexylidide (MEGX) test, and para-aminobenzoic acid (PABA) test]. MEGX testing is important in evaluating liver function to determine the suitability of the donor liver for transplant and to measure graft function post transplantation. PABA is a nontoxic, inexpensive and orally administered probe drug that is readily absorbed from the gastrointestinal tract and undergoes biotransformation to three metabolites independent of phase I cytochrome P450 biotransformation reactions which are lost in patients with

extensive hepatocellular damage. Through phase II conjugation reactions, PABA combines with either glycine [to form para-aminohippuric acid (PAHA)]; acetyl-coenzyme A (CoA) [to form para-acetamidobenzoic acid (PAABA)]; or both glycine and acetyl CoA [to form para-acetamidohippuric acid (PAAHA)]. The use of PABA to quantify hepatic function has been reported to be a promising prognostic test for children with both CLD and fulminant liver failure with a sensitivity of 92% and negative predictive value of 92% compared with a sensitivity of 54% and a negative predictive value of 63% with King's College criteria.

OTHER LABORATORY TESTS TO ASSESS FOR LIVER DISEASE

Serum Globulins

The serum globulin level can be quickly determined by subtracting the albumin concentration from the total protein level. Serum globulins can be further separated by using serum protein electrophoresis into α_1 , α_2 , β , and γ fractions. The α_1 fraction is composed principally of α_1 -antitrypsin, ceruloplasmin and orosomucoid, all of which are acute-phase reactants and increase in response to liver disease and many inflammatory disorders. Haptoglobin makes up a large part of the α_2 fraction. Transferrin and β -lipoprotein make up a major portion of the β fraction. The principal constituents of the γ fraction are the immunoglobulins (Ig), particularly IgG, IgA and IgM. Abnormalities may occur in the serum protein electrophoresis profile in various liver diseases, such as hypergammaglobulinemia seen in autoimmune hepatitis and low α_1 peak in α_1 -antitrypsin deficiency.

Plasma and Urine Amino Acids

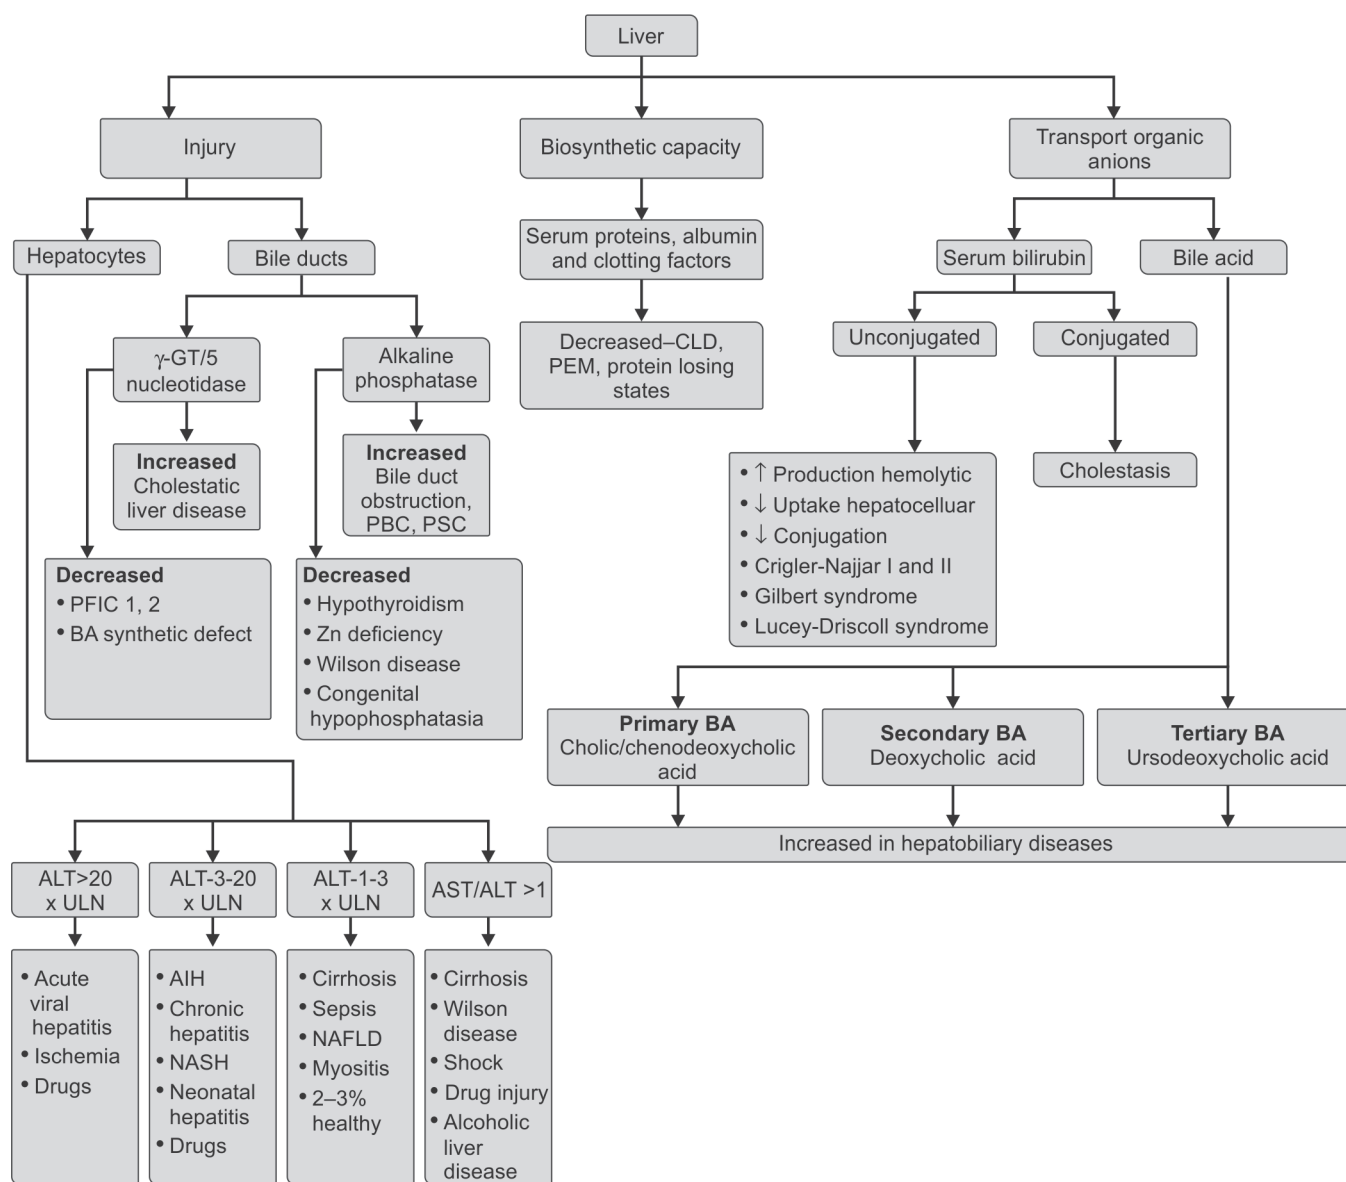

Amino acids in the blood and urine may help to support the diagnosis of an inborn error of intermediary metabolism, such as hereditary tyrosinemia, methylmalonic acidemia and defects of urea cycle defects.

An approach to liver functions tests is summarized in **Flow chart 2**.

IN A NUTSHELL

1. Liver enzymes are commonly used in the evaluation of patients with a range of liver diseases, but they lack sensitivity and the specificity.
2. Alanine transaminase is a very specific marker of hepatocellular injury with relatively low concentration in other tissues.
3. Aspartate transaminase occurs in two isoenzymes which are the mitochondrial isoenzyme more specific to liver and cytosolic isoenzyme which is present in skeletal muscle, heart muscle and kidney tissue.
4. Aspartate transaminase usually rises in conjunction with ALT to indicate a hepatitis picture. An AST:ALT ratio of less than 1 is seen in viral hepatitis, autoimmune hepatitis, nonalcoholic steatohepatitis (NASH), toxic and cholestatic hepatitis while AST:ALT ratio of greater than 2 suggests cirrhosis, ischemia, Wilson disease, or alcoholic liver disease.
5. Elevation of GGT with high ALP is suggestive of biliary tract obstruction.
6. Synthetic function of liver is assessed by albumin and PT.
7. Low alkaline phosphatase is commonly seen in Wilson's disease, hypothyroidism and zinc deficiency.
8. Prothrombin time has a better prognostic value for patients with acute hepatocellular disease.
9. In a setting of underlying liver disease, worsening of PT is suggestive of decompensation of liver.

Flow chart 2 Approach to liver function tests

Abbreviations: AST, aspartate transaminase; ALT, alanine aminotransferase; PSC, primary sclerosing cholangitis; PBC, primary biliary cirrhosis; CLD, cholestatic liver disease; PEM, protein-energy malnutrition; NASH, nonalcoholic steatohepatitis; PFIC, progressive familial intrahepatic cholestasis; NAFLD, nonalcoholic fatty liver disease; ULN, upper limit of normal.

Chapter 37.3

Neonatal Cholestasis

Surender Kumar Yachha, Moinak Sen Sarma

Neonatal cholestasis is defined as impaired canalicular biliary flow in a neonate resulting in accumulation of bilirubin, bile acids and cholesterol in blood and extrahepatic tissues. Though some of the disorders may be clinically evident after the first month of life, anytime later in the infancy, these diseases are still classified as neonatal cholestasis as the etiology is believed to be since birth. Conjugated hyperbilirubinemia is defined as direct bilirubin level greater than 1 mg/dL when total bilirubin is less than 5 mg/dL or greater than 20% of total bilirubin if greater than 5 mg/dL.

Table 1 elaborates the common causes of neonatal cholestasis in India. Out of all the causes, the thrust is early diagnosis and management of potentially treatable conditions by pediatricians. Biliary atresia has a time bound progression and needs early intervention. Metabolic disorders like galactosemia, neonatal hemochromatosis and tyrosinemia are sick neonates who deteriorate rapidly.

Reasons for Delay in Referral

- Misdiagnosed as physiological jaundice or breastmilk jaundice
- Babies may look well, feed well, develop normal social smile giving a false impression of well-being to parents
- Lack of awareness at primary and secondary levels of care to prioritize referral
- Lack of clarity in clinical approach to promptly diagnose the underlying cause.

Hence, it is imperative for every pediatrician to ask for diaper staining of urine and look for organomegaly in any neonate with jaundice suggesting conjugated jaundice. Any infant beyond 2 weeks of life with cholestasis should be immediately evaluated. However, there are disorders that may present in first 2 weeks of life particularly metabolic diseases and infection like herpes simplex virus (HSV).

Stool Color in Neonatal Cholestasis

Pale stools can be present in extrahepatic or intrahepatic causes as shown in **Figure 1**. Pigmented stools point toward an intrahepatic etiology. However, the color may often be ambiguous causing confusion in interpretation. It is important for the pediatrician to see for himself 3–4 consecutive stools samples in a transparent container against a well-lit contrast background to decide on the color. Pale stool documentation indicates a very high possibility of nonflow of bile into small intestine thus warranting an early referral and urgency to diagnose biliary atresia.

Coagulopathy in Neonatal Cholestasis

During the course of the disease, child may have overt coagulopathy features such as spontaneous skin bleeds, muscle hematoma during immunizations or intracranial bleed. Coagulopathy is correctable with vitamin K particularly in extrahepatic causes.

Who is a Sick Neonate?

Other than lethargy, poor feeding, and seizures in a cholestatic neonate there are features that must always alarm the pediatrician

Figure 1 Pale stools in neonatal cholestasis

Table 1 Etiology of 1,008 cases of neonatal cholestasis (combined data of 8 medical centers in India)

Disease groups	Causes in each subgroup
A. Hepatocellular 53% (n = 533)	
Neonatal hepatitis 47% (n = 468)	<ul style="list-style-type: none"> • Idiopathic giant cell hepatitis 64%. • TORCH infections 22% (CMV, 58%; toxoplasmosis, 23%; hepatitis, 10%; rubella, 4.5%; syphilis, 4%; and herpes 1%). • Sepsis, 8%. • Other causes like malaria, UTI, etc., 6%.
Metabolic 4% (n = 43)	Galactosemia, 35%; AIAT deficiency, 33% (suspected);* TPN related, 19%; tyrosinemia, 7%; storage disorders, 4%; hemochromatosis, 2%.
Other causes 2% (n = 22)	Inspissated bile plug syndrome (n = 9), recurrent intrahepatic cholestasis (n = 2), progressive familial intrahepatic cholestasis (n = 1), hypothyroidism (n = 4), associated Down's syndrome (n = 3); and one case each of polycystic disease, postintestinal surgery and immunodeficiency.
B. Obstructive 38% (n = 383)	Biliary atresia, 34%; Choledochal cyst, 4%.
C. Ductal Paucity 3% (n = 29)	Syndromic variety, 17%; nonsyndromic variety, [†] 83%.
D. Unknown 6% (n = 63)	

*Recent studies using confirmatory test of isoelectric focusing reported 57/58 children of liver disease having normal PiMM phenotype.

[†]Mostly now considered secondary to other causes and not as a primary defect.

warranting early workup. These are uncorrectable coagulopathy, hypoglycemia, ascites, family history of early infantile sib deaths, maternal history of stillbirths, abortions, associated fever, anemia or respiratory distress.

Tables 2 and 3 enlist the common causes of neonatal cholestasis with their presentation and the clinical evaluation of intrahepatic causes of neonatal cholestasis.

BILIARY ATRESIA

Biliary atresia is an idiopathic inflammatory process involving the bile ducts resulting in obstruction of biliary tract, chronic cholestasis and progressive fibrosis that eventually causes biliary

cirrhosis and end-stage liver disease. Etiopathogenesis is unclear. Viruses, autoimmunity and genetic susceptibility have been proposed, but there is no convincing disease-causal relationship. There are no racial or familial predispositions. Incidence is 1:15,000 in Asia. Biliary atresia may exist in isolation (90%) or as a part of a larger syndrome (10%). Biliary atresia may be associated with polysplenia, situs inversus, malrotation of gut and cardiac anomalies (biliary atresia splenic malformation). This condition has a worse outcome in view of the comorbidities. **Figures 2A to F** elaborates the three anatomical types of biliary atresia. Cystic dilatations may be seen in 6–22% of cases (**Figs 3 and 4**), mostly extrahepatic and should not be confused with choledochal cyst on imaging. Biliary atresia presents as normal birthweight, apparently healthy baby with persistently pale stools. As age advances in an unoperated child, features of decompensation appear in the form of deepening of jaundice and presence of ascites (**Fig. 5**).

Management

Liver functions in biliary atresia are not discriminatory with regard to other intrahepatic causes except that it might show high gamma-glutamyl transpeptidase. Ultrasonography, liver biopsy and hepatobiliary scintigraphy features are shown in **Table 4** and **Figures 6 to 8**. Due to procedural technical difficulties and poor diagnostic accuracy, endoscopic retrograde cholangiopancreatography and magnetic resonance cholangiopancreatography are not popular in the work-up algorithm. In developing countries, liver biopsy should be done to decrease the frequency of negative laparotomy and to achieve cost-benefit with reduced morbidity. Laparotomy and per-operative cholangiography (gold standard) is performed wherever possible to have final confirmation of biliary atresia (**Figs 9 and 10**).

The most common form of biliary atresia is type III which requires Kasai portoenterostomy (**Fig. 11**). Hepaticojejunostomy is done for types I and II. Success of the surgery is based on the anatomical findings, age at surgery and the experience of the surgeon. Best option is to perform surgery between day 28 and day 60 of life. Outcome progressively decreases as the age

Table 2 Common causes of neonatal cholestasis and their presentation

	Extrahepatic	Intrahepatic
Nonsick	Biliary atresia Choledochal cyst (CC)	Progressive familial intrahepatic cholestasis (PFIC) Paucity of interlobular bile ducts (PILBD) (syndromic or nonsyndromic) Idiopathic neonatal hepatitis Niemann–Pick disease (type C)

Abbreviations: PFIC, progressive familial intrahepatic cholestasis; NH, neonatal hepatitis; HSV, herpes simplex virus; MH, mitochondrial hepatopathies; HLH, hemophagocytic lymphohistiocytosis; FAOD, fatty acid oxidation defects.

Figures 2A to F Anatomical types of biliary atresia: (A) Normal biliary tract; (B) Type I (5%): common bile duct (CBD) obliterated with patent proximal system. Good sized noncontractile gallbladder; (C) Type I with cyst. A cyst may appear anywhere in the biliary system just proximal to site of obstruction (seen with all three types); (D) Type II (3%): Obliterated CBD and common hepatic duct (CHD) but patent right and left hepatic ducts. Absent or rudimentary gallbladder; (E) Type III (>90%): Entire biliary tract obliterated with fibrous mass at porta. Absent or rudimentary gallbladder; (F) A variant of type III where ducts at porta are obliterated but distal CBD is patent. Good sized non-contractile gallbladder

Figure 4 Biliary atresia with cyst seen at surgery

advances. The success of surgery is shown by the excretion of bile and improvement of jaundice. Ascending cholangitis occurs in 30–60% of cases following Kasai surgery, mostly due to gram-negative rods. Portal hypertension develops if the disease takes a progressive course. Approximately 75% develop variceal bleeds by the age of 2 years. After surgery, the survival rate with native liver is 32–60% after 5 years and between 22% and 53% after 10 years. On long-term follow-up, children with successful portoenterostomy by adolescence require liver transplantation in 85% cases and 15% have symptom-free survival with native liver. Despite this outcome, portoenterostomy remains the first-line treatment of biliary atresia as it allows children to escape immunosuppressive drug treatment due to liver transplantation for a long period of time and a proportion can still survive without transplantation.

Figure 3 Biliary atresia with cyst. Paucity of contrast in intrahepatic ducts seen in peroperative cholangiogram

Figure 5 Decompensated biliary atresia at advanced age

GALACTOSEMIA

It is an autosomal recessive disorder of galactose metabolism, caused by a deficiency of the enzyme galactose-1-phosphate uridylyltransferase (GAL-1-PUT). In the absence of this enzyme, galactose is converted to a toxic byproduct, galactitol, that affects the liver, brain, kidneys, and eyes by its osmotic property. Lactose, a disaccharide is broken down to glucose and galactose by brush border enzymes in the small bowel. Therefore, lactose is a rich source of exogenous galactose. Clinical manifestations may appear soon after ingestion of galactose (breastmilk/formula feeds). These include jaundice, hepatosplenomegaly, liver dysfunction, coagulopathy, hypoglycemic seizures, renal tubular dysfunction, cataract (bilateral), *Escherichia coli* sepsis (common), and rarely

Figure 11 Kasai portoenterostomy: wide dissection at portal plate followed by attachment of roux-en-Y isoperistaltic jejunal loop at porta

hemolysis. If untreated, rapid downhill course may result in progressive liver disease, cirrhosis, and death. Activity of enzyme GAL-1-PUT activity in red blood cells is low or absent. Therapy

is supportive. Lactose-free diet is the mainstay of treatment. Stop breastmilk, animal or formula feeds in the neonate, and change over to nonlactose formula feeds. Soy-based feeds, though not

recommended in neonates are the only option presently in India as lactose-free formulations are not available (compulsion). Restriction of milk or milk products is lifelong. Restriction of galactose-containing fruit and vegetables is not currently recommended. Long-term liver outcome is good on galactose restricted diet. However, a subset (25–50%) in the long run have speech apraxia, language impairment and lower intelligence quotient due to endogenous production of galactose.

PROGRESSIVE FAMILIAL INTRAHEPATIC CHOLESTASIS

Progressive familial intrahepatic cholestasis (PFIC) is a group of genetic disorders that show progressive intrahepatic cholestasis with autosomal recessive inheritance. PFIC1 (original Byler disease) is caused by mutations of the *FIC1* gene located on chromosome 18q21-22, which encodes a P-type ATPase protein involved in aminophospholipid transport. The defect is in the intestine as well. PFIC2 is due to mutations of the *SPGP* (sister of P-glycoprotein) gene encoding the ATP-dependent canalicular bile acid transporter (also called BSEP, bile salt export pump) located on chromosome 2q24. PFIC3 is due to mutations of the *MDR3* (multidrug resistance 3) gene encoding the biliary phospholipid transporter and is located on chromosome 7q21. Clinical features, investigations and treatment of each subtype are listed in **Table 4**.

ALAGILLE SYNDROME

This autosomal dominant disorder is a syndrome of *paucity of interlobular bile ducts*. Mutations in human *JAG-1* gene (on chromosome 20p) or *Notch-2* gene are responsible. Diagnostic criteria are listed in **Box 1**. Associated anomalies include those of kidneys (small kidneys, ureteropelvic obstruction, renal tubular acidosis), or arteries (aneurysms or stenoses of intracranial, internal carotid or renal arteries).

Problems can occur in childhood and later in life. These include intractable pruritus due to cholestasis, disfiguring xanthomas (**Fig. 14**) due to hyperlipidemia, bony fractures due to vitamin D deficiency, and poor quality of life particularly due to pruritus. Almost 20% progress to cirrhosis. Major cause of mortality is related to cardiac disease and vascular events.

Treatment consists of (1) management of pruritus, (2) supplementation of multivitamins, vitamin D and calcium, and (3) biliary diversion in those with refractory pruritus and disfiguring xanthomas. Liver transplant is required for those with poor quality of life, progressive liver disease, and cirrhosis.

BOX 1 Criteria for diagnosis of Alagille syndrome

Paucity of interlobular bile ducts (PILBD) on liver biopsy + any three of five features below:

1. Chronic cholestasis (80% begin in neonatal period)
2. Characteristic facies (broad forehead, small chins and saddle nose with bulbous tip and hypertelorism (**Fig. 12**))
3. Skeletal abnormalities: Butterfly vertebrae T6-T9 (**Fig. 13**), curved phalanges and short ulna
4. Cardiac anomalies (peripheral pulmonary artery stenoses, tetralogy of Fallot)
5. Ocular anomalies:
 - Posterior embryotoxon (prominent white ring of Schwalbe at corneo-ueveal junction) on slit-lamp examination,
 - Optic nerve drusen (globules of calcified mucoproteins) on funduscopy

Note:

In the absence of liver biopsy finding, any four of five criteria.

No clinical criteria is required if suspicion is high and *JAG-1* or *NOTCH-2* mutation is detected.

NEONATAL HEMOCHROMATOSIS

This is an alloimmune gestational disease causing abnormal iron handling in utero by neonate and/or mother. The disorder presents as neonatal liver failure, ascites and hypoalbuminemia. A subgroup has shrunken nodular liver at birth as cirrhosis begins

Figure 12 Characteristic facies in Alagille syndrome

Table 4 Investigations for biliary atresia

Investigations	Findings	Comments
Ultrasound	One of the following <ul style="list-style-type: none"> • Absent GB • Rudimentary GB (length <15 mm with irregular mucosal lining and contour) • Good sized, noncontractile GB (size > 20 mm but prefeed-postfeed contractility < 50%) ± • Triangular cord sign (echogenic area > 4 mm in size anterior to right branch of portal vein)	Diagnostic accuracy 75–95%
Liver biopsy	• Bile ductular proliferation, fibrosis and widening of portal tracts (not before 4 weeks of age)	Diagnostic accuracy 88–97%
Scintigraphy	<ul style="list-style-type: none"> • Priming: ursodeoxycholic acid (30 mg/kg/day in 2–3 divided doses) for three days • Radioactivity in duodenum indicates patent biliary system that rules out biliary atresia • No excretion does not confirm biliary atresia • To be performed when stools are ambiguous in color • Not useful when stools are pale 	Adjunct in diagnosis

Figure 13 Butterfly vertebra

Figure 14 Xanthelasma in Alagille syndrome

in utero. Another presentation could be extrahepatic siderosis (pancreas, salivary glands, myocardium, thyroid), with sparing of reticuloendothelial system. There is history of recurrent sib deaths, oligoamnios and megaplacenta.

Investigations reveal (1) low or normal transaminases; (2) high serum ferritin: median 2,448 (range: 415–100,000) $\mu\text{g/L}$, low serum transferrin, and high transferrin saturation; confirmation is by lip biopsy: salivary gland biopsy shows iron deposition on staining (best for Indian situations) or MRI pancreas with low signal intensity on T2 imaging confirms the diagnosis.

Treatment

- Antenatal intravenous immunoglobulin (IVIG) infusion (1 g/kg) weekly to the mother from 18th week to term for at-risk pregnancies (70% neonates survive without transplant). This is offered where there is history of earlier sib death due to neonatal hemochromatosis.
- IVIG \pm exchange transfusion for symptomatic neonates (survival 75%).
- Liver transplantation is the only definitive treatment if medical treatment fails. Chelation and antioxidants are no longer used.

TYROSINEMIA TYPE 1

This is an autosomal recessive disorder causal due to deficiency of fumarylacetoacetate hydrolase in tyrosine metabolism. The

child may present with one or more of the following features: neonatal liver failure; acute liver failure in first 2 years of life (the most common presentation); chronic liver disease in childhood (ascites, coagulopathy); boiled cabbage odor of urine; renal tubular dysfunction; hypophosphatemic rickets; neurologic crises (peripheral neuropathy); and hepatocellular carcinoma (HCC) by 1st or 2nd decade.

Investigations reveal mildly raised bilirubin and transaminases. Serum alpha-fetoprotein is high (average: 160,000 $\mu\text{g/mL}$; normal full-term neonates: 84,000 $\mu\text{g/mL}$). Mass spectrometry reveals increased succinylacetone in urine and blood.

Treatment

- Dietary restriction of phenylalanine and tyrosine (formulation not marketed in India).
- Nitisinone is a potent inhibitor of 4-hydroxyphenylpyruvate dioxygenase and has been shown to efficiently prevent tyrosine degradation, and production of succinylacetone. Survival without liver transplant is 85% if started early at dose of 1–2 mg/kg/day (not marketed in India).
- Liver transplantation in failed nitisinone therapy, end-stage liver disease.

TORCH INFECTIONS

Contrary to the popular belief that TORCH is a major cause of neonatal cholestasis. It is now clear that positive TORCH titers are a *red herring* in the workup of a neonate with cholestasis. Except for acquired HSV infection which has rapid deterioration, the rest of the TORCH infections rarely cause jaundice. Acquired cytomegalovirus (CMV) is very rare and affects 1–2.5% newborns in first 90 days of life. Neonatal hepatitis is self-resolving and requires only supportive therapy. Suspicion of CMV hepatitis is raised when there are other stigmata: microcephaly, cataract, chorioretinitis or periventricular calcification. Serum IgM CMV positivity does not mean active liver replication. It is mandatory to demonstrate CMV DNA by the polymerase chain reaction (PCR) or culture in liver tissue \pm histological changes (inclusion bodies in vascular endothelium). CMV associated with biliary atresia is a highly doubtful entity, and it often delays referral. It should not be treated or pursued.

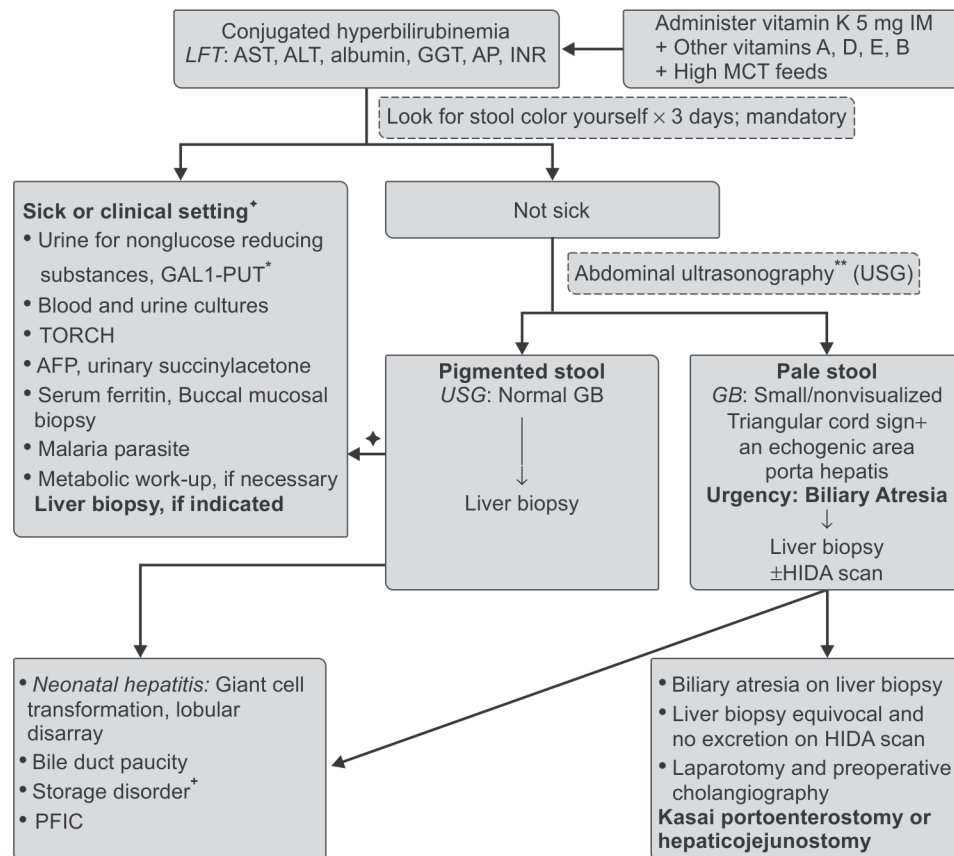

Herpes simplex virus infection is acquired in utero, perinatal period (85%), or postnatal period. No history is available in 60–80% of mothers. The child may present with poor feeding, lethargy, vesicles, seizures, renal failure, and ascites. Mortality is high if not treated on time. Suspect HSV infection in a sick neonate presenting in first week of life especially if bacterial cultures are sterile. Positive HSV cultures from vesicles, oropharynx, conjunctiva, blood, or cerebrospinal fluid (CSF) are diagnostic. Treatment consists of high dose acyclovir 60 mg/kg/day for 21 days, but is often continued till PCR for HSV is negative. It is essential to document negative CSF PCR at the end of therapy.

IDIOPATHIC NEONATAL HEPATITIS

It is a diagnosis of exclusion, usually seen in low birthweight or preterm babies. The infants are otherwise well and thriving. Stools are pigmented or pale. Resolution is spontaneous. Organomegaly disappears in 4–6 months. Liver function test normalizes in 4–12 months (average: 9 months). Liver biopsy reveals lobular disarray, hepatocyte ballooning, giant cell transformation, and extramedullary hematopoiesis. Therapy is supportive. Follow-up is necessary to document and finally label as idiopathic neonatal hepatitis, when the liver dysfunction has normalized.

MANAGEMENT OF NEONATAL CHOLESTASIS

Refer to **Flow chart 1** and **Tables 5** and **6**.

Flow chart 1 Approach to a case of neonatal cholestasis

Abbreviations: GB, gallbladder; MCT, medium chain triglycerides; AST, aspartate aminotransferase; ALT, alanine aminotransferase; AP, alkaline phosphatase; GGT, gamma-glutamyl transpeptidase; INR, international normalized ratio.

*Individualize investigations; *Stop milk feeds till galactosemia is ruled out; **Surgery, if choledochal cyst on USG, small gallbladder may also occur in bile duct paucity; *May need bone marrow testing.

IN A NUTSHELL

1. Neonatal cholestasis is defined as impaired canalicular biliary flow in a neonate resulting in accumulation of bilirubin, bile acids and cholesterol in blood, and extrahepatic tissues.
2. Common causes of neonatal cholestasis in India are hepatocellular causes (53%), and obstructive reasons (38%). Neonatal hepatitis and biliary atresia are the most frequent causes of hepatocellular and obstructive cholestasis, respectively.
3. Biliary atresia presents as normal birthweight, apparently healthy baby with persistently pale stools. As age advances in an unoperated child, features of decompensation appear in the form of deepening of jaundice and presence of ascites.
4. The most common form of biliary atresia is type III which requires Kasai portoenterostomy. Hepaticojejunostomy is done for types I and II.
5. Supportive therapy with fat and water-soluble vitamins is mandatory for management in neonatal cholestasis. In PFIC and Alagille syndrome, pruritus must be managed medically or surgically.

Table 5 Clinical features, investigations, treatment and outcome of children with progressive familial intrahepatic cholestasis

Clinical parameters	PFIC1	PFIC2	PFIC3
Onset*	Infancy	Neonatal age	Adolescence Rarely infantile period
Rate of progression	Moderate	Fast	Slow
Cirrhosis	By 1st decade of life	By 1st year of life	Young adults
Extrahepatic [†] manifestations	Present	None	None
GGT	Normal or low	Normal or low	High
Serum cholesterol	Normal	Normal	Normal or elevated
Serum primary bile acids	Very high	Very high	High
Bile composition	Low primary bile acid (3–8 mM)	Very low primary bile acid (<1 mM)	Low phospholipid 1–15% total (N = 19–24%)
EM of bile	Coarse granular bile (Byler's bile)	Amorphous bile	-
Liver histology	Bland cholestasis	Giant cell hepatitis	Ductular proliferation
Immunostaining	Nonspecific	BSEP immunostaining absent	MDR3 protein immunostaining absent
Gene protein	ATP8B1 (FIC1)	ABCB11 (BSEP)	ABCB4 (MDR3)
Treatment [@]	Supportive Biliary diversion	Supportive Biliary diversion LT	Supportive LT

Abbreviations: GGT, gamma-glutamyl transpeptidase; EM, electron microscopy; LT, liver transplant; PFIC, progressive familial intrahepatic cholestasis.

*Pruritus, the dominant presentation in PFIC manifests after 4 months of age as the child does not develop hand motor coordination till then. Generalized irritability and constant rubbing against mother's clothes are early signs of the same. Initially child learns itching around ears and face and then in the rest of the body as the child grows up. Jaundice and nutritional deficiencies (fat and fat soluble) are other manifestations.

[†]Diarrhea, pancreatitis, sensorineural deafness and wheeze are the extrahepatic. manifestations.

@Treatment of PFIC:

- Supportive: Ursodeoxycholic acid (UDCA), and management of pruritus.
- Biliary diversion procedures are done in intractable pruritus with poor quality of life before the development of cirrhosis. It has 75% clinical and biochemical response.
- Diversion procedures are: partial external (jejunal conduit draining gallbladder to external surface of abdominal wall), partial internal (gallbladder to colon) and ileal bypass.
- LT is offered in end-stage liver disease. In PFIC1, LT is discouraged as diarrhea persists even after LT due to the receptor defect in intestine.

Table 6 Supportive management of neonatal cholestasis

Nutrition: 85% of fat must be given as medium chain triglycerides in a total requirement of 120–140 kcal/kg/day		
Drug	Dose	Side effects
Vitamin K	2.5–5 mg on alternate day (available as oral or parenteral)	None
Vitamin D (cholecalciferol, 25-OH cholecalciferol)	2,500–5,000 IU/day 3–5 µg/kg/day	Hypercalcemia Nephrocalcinosis
Vitamin A	Aquasol A: 2,500–5,000 IU/day or Injectable: 30,000 IU IM at diagnosis and then 10,000 IU monthly till cholestasis resolves	Hepatotoxicity Pseudotumor cerebri Hypercalcemia
Vitamin E	Aquasol E: 50–400 IU/day	Diarrhea
Water-soluble vitamins	Twice the recommended daily allowances	None
Pruritus		
UDCA	10–20 mg/kg/day	Diarrhea
Rifampicin	10 mg/kg/day	Hepatotoxicity
Cholestyramine	0.25–0.5 g/kg/day	Steatorrhea, constipation

Chapter 37.4

Portal Hypertension

Surender Kumar Yachha, Moinak Sen Sarma

The superior mesenteric vein (SMV) and splenic vein (SV) join to form the portal vein which constitutes 80% of blood supply to the liver, rich with nutrient and hormones from the gut. Very low resistance in the portal bed results in low baseline pressure. Portal hypertension (PHT) is defined as an elevation of portal blood pressure above 5 mm Hg. It is one of the major causes of morbidity and mortality in pediatric liver diseases.

NORMAL PORTOSYSTEMIC ANASTOMOSES

The portal system begins as capillaries which originate in the mesentery of the intestines and spleen and end in the hepatic sinusoids. SMV drains venous blood from entire small bowel and mid-transverse colon. Inferior mesenteric vein (IMV) drains blood from mid-transverse colon to rectum. IMV joins SV proximal to its junction with SMV. Splenic vein joins the SMV to form portal vein, which enters the liver and gives off right and left branches.

Short gastric veins and posterior gastric vein drain fundus of stomach into SV. Left gastroepiploic vein drain the anterior and posterior surfaces body of stomach along the greater curvature to drain into SV. Right gastroepiploic vein drains the distal part of stomach and antrum along greater curvature into the SMV. Left gastric vein (coronary vein) drains upper part of body along lesser curvature, fundus and lower part of esophagus to join the portal vein just before it gives off its intrahepatic branches. Right gastric vein drains the lower part of body along lesser curvature and pylorus to drain into the portal vein also.

PATHOPHYSIOLOGY

Portal hypertension occurs due to two main reasons: extrahepatic portal venous obstruction (EHPVO) and cirrhosis. PHT is the result of a combination of increased portal resistance and/or increased portal blood flow. The mechanism of the increased portal resistance depends on the site and cause of PHT. Pressure is directly proportional to both blood flow through the portal system and resistance to the blood flow (Ohm's Law). Resistance in turn is inversely related to the radius of the lumen raised to the fourth power (Poiseuille's law). Hence, small changes in the vasculature may result in large changes in pressure. Blood viscosity and vessel length also can influence resistance. In cirrhosis, in an attempt to nourish the compromised hepatic parenchyma there is an increase in portal venous flow by vasodilatation in the splanchnic circulation that is mediated by increased nitric oxide (NO) production.

In EHPVO, the event of an acute portal venous thrombosis (PVT) is usually unrecognized and may have occurred due to a known or unknown etiology. The child may have had a preceding febrile illness, intra-abdominal infection or dehydrating illness followed by subtle abdominal pain or transient ascites which may have been forgotten or undetected. In retrospect, a search into the child's past history is often unyielding and perplexing for the physician. Following this event of PVT, the thrombus begins to organize. In order to bypass the obstruction, multiple hepatopetal collaterals form in 6–20 days to compensate for the high volume blood flow from the splanchnic system draining into the liver. A well-established portal cavernoma forms in 3 weeks. Portal cavernoma is a radiological term that denotes the replacement of the portal vein with a bunch of collaterals having blood flow toward the liver.

In order to decompress the portal system, collaterals and spontaneous shunts form that connects the high-pressure portal venous system with lower-pressure systemic veins. Collaterals develop by dilatation of existing dormant collateral vessels, as well as development of new blood vessels and sprouts (angiogenesis) mediated by increased NO and endothelin-1. Unfortunately, this process of angiogenesis and collateralization is insufficient for normalizing portal pressure and actually causes complications of PHT, such as varices and hemorrhoids. Chronic back pressure from the portal system causes congestion and enlargement of spleen.

Anatomical Changes in Portal Hypertension

- To bypass the obstruction, there is dilatation of portal venous tributaries and reversal of blood flow in these veins that anastomose with the systemic veins.
 - Valves of the perforators connecting the portal to systemic circulation become incompetent and dilated submucosal plexus develops which are known as varices. *See details below.*
 - There are also embryonic channels that are normally obliterated and open up in PHT. A typical example of the same is paraumbilical veins that exist normally between left branch of PV and coronary vein.
 - Formation of new collaterals in abdomen. *See details below.*
- Portosystemic circulation and its changes in PHT are shown in **Figure 1** and **Table 1**.

Varices

Varices are abnormally tortuous vessels in the venous system most commonly seen in esophagus and stomach. Hepatic venous pressure gradient (HVP) an indirect marker of the portal pressure is calculated by difference between the wedged hepatic venous pressure (WHVP) and free hepatic vein pressure (FHVP). Varices usually form and rupture when HVP is greater than 10 mm Hg and greater than 12 mm Hg respectively. They rupture when the intravariceal pressure increases and exceeds the variceal wall strength. High blood flow and lack of natural mechanisms for tamponade may result in life-threatening hemorrhage. Rarely, varices may bleed at ectopic locations (duodenum, small bowel, colonic) or be present around the extrahepatic biliary tract leading to complications.

Collateral Flow

In intrahepatic PHT, the reopened paraumbilical vein communicates with the left branch of the portal vein to the anterior abdominal walls (superior and inferior epigastric veins) which finally drain into the IVC through iliac veins bypassing the liver. The direction of flow of the veins above and below the umbilicus is away from the same towards the periphery. Caput medusa (radiating tortuous vessels from the umbilicus appearing as a bunch of snakes) is an exaggerated form of this exuberant portosystemic collateralization. An audible venous hum, the Cruveilhier-Baumgarten murmur, may occasionally be appreciated through these vessels. Both these features are rare in children.

In extrahepatic PHT, the main portal vein and invariably its left branch are occluded, so dilated veins do not appear on anterior abdominal wall.

In Budd-Chiari syndrome associated with an inferior vena cava block, the collateral venous circulation is established via the lumbar veins that connect the superior epigastric, inferior epigastric and circumflex iliac to the drain through tributaries of azygos and hemiazygos vein which finally drains into the superior vena cava. The direction of flow of anterior abdominal wall veins is cephalad both above and below umbilicus. Flank veins and tortuous back veins are essential of this entity.

Figure 1 Schematic representation of portosystemic circulation

Abbreviations: RPV, Right branch of portal vein; LPV, left branch of portal vein; EV, esophageal varices; GV, gastric varices; SGV, short gastric veins; PGV, posterior gastric vein; LGV (coronary vein), left gastric vein; RGV, right gastric vein; LGEV, left gastroepiploic vein; RGEV, right gastroepiploic vein; GR-SRV, gastrosplenic vein; IMV, inferior mesenteric vein; SMV, superior mesenteric vein; RP-PV, retroperitoneal-paravertebral venous plexus; SCAV, subcutaneous anterior abdominal wall veins; PUV, paraumbilical vein; MRV, middle rectal vein; PDV, pudendal vein; InHP, internal hemorrhoidal plexus; SRV, superior rectal vein; RIIV, right internal iliac vein; LIIV, left internal iliac vein. Red arrows indicate the direction of normal blood flow. NB: The normal flow is reversed in the gastrosplenic circuit.

Table 1 Effects of portal and systemic venous communication in portal hypertension

Communication with portal circulation	Communication with systemic circulation	Effects
Left gastric and lower esophageal veins	Lower branches of esophageal veins that drain into azygos and hemiazygos veins	Esophageal and gastric varices*
Superior rectal veins	Middle and inferior rectal veins drain into internal iliac and pudendal veins	Rectal varices
Persistent tributaries of left branch of PV	Periumbilical branches of superior and inferior epigastric veins	Caput medusae
Intraparenchymal branches of right branch of PV in bare area	Retroperitoneal veins that drain into lumbar, azygos and hemiazygos	Retroperitoneal plexus (at risk during intervention procedures and surgeries)
Omental and colonic veins in the region of hepatic and splenic flexure	Retroperitoneal veins that drain into lumbar vein	Rarely retroperitoneal plexus forms in these regions

*Gastric varices are formed by another pathway. Due to reversal of blood flow in the splenic vein, afferents from short and posterior gastric veins draining the fundus will enlarge into a varix in the fundus. This will drain through gastrosplenic shunt into the left renal vein.

HOW TO CLINICALLY SUSPECT PORTAL HYPERTENSION?

Extrahepatic Portal Hypertension

- Splenomegaly with upper gastrointestinal (UGI) bleeding
Or
- Moderate to large splenomegaly (without bleeding).

Intrahepatic Portal Hypertension

Splenomegaly ± UGI bleeding with one or more of the following:

- Presence of ascites
- Abdominal veins
- Any other evidence of liver disease (jaundice, encephalopathy, stigmata of cirrhosis or abnormal LFT).

Figure 2 Common causes of portal hypertension in children

Common causes, investigations and complications of PHT are shown in **Figure 2**, **Box 1**, and **Table 2**.

BOX 1 Mandatory tests in portal hypertension

- Hemogram for hypersplenism
- Liver function tests including prothrombin time
- Doppler-ultrasound:
 - Portal cavernoma and patency of SV, SMV, IMV and left renal vein
 - Portal vein diameter
 - Hepatic veins and IVC patency
 - Changes of cirrhosis in liver
 - Changes in biliary tract (extrahepatic and intrahepatic biliary dilatation)
- UGI endoscopy for varices
- Specific investigations of underlying etiology

EXTRAHEPATIC PORTAL VENOUS OBSTRUCTION

This disorder predominantly occurs in children with its onset occurring and manifesting sometime during childhood followed by its persistence throughout adolescence and into adulthood. Major bulk of PHT in Indian children is due to EHPVO in contrast to cirrhosis in the West. EHPVO is the consequence of PVT just outside the liver. It may have variable extension proximally into the intrahepatic radicles, distally into its confluence, tributaries (SV and SMV) or entire splanchnic system. Isolated involvement of the splenic, superior mesenteric or IMV is not included under the definition of EHPVO. For the working definition of EHPVO, it is mandatory to document a portal cavernoma on imaging.

Etiopathogenesis

What exactly causes PVT is not clearly known. Intra-abdominal infections produce endotoxemia that result in portal vein

Table 2 Complications of portal hypertension

Effects	Comments
Hypersplenism	Sequestration from long-standing splenomegaly. Usually asymptomatic clinically. Decrease of ≥ 2 cell lines (total leukocyte $< 4,000/\text{mm}^3$ and platelet counts $< 50,000/\text{mm}^3$). Anemia may be confounding (recent or chronic bleeding).
Portal hypertensive gastropathy (PHG) and duodenopathy (Fig. 3A)	Mucosal changes in stomach and duodenum due to chronic congestion. Milder forms of PHG appear as snake skin-like changes on endoscopy. Severe forms of PHG have red spots over the same which uncommonly bleed. Watermelon-like appearance in the antrum is known as gastric antral vascular ectasia (GAVE).
Portal colopathy (Fig. 3B)	Seen in long-standing portal hypertension. Asymptomatic in majority. Present infrequently as painless rectal bleed. Large anorectal varices and/or mucosal changes (hyperemia, ectasias, superficial ulcers) are demonstrated on colonoscopy.
Portal biliopathy (Fig. 3C)	Formation of varices around the bile duct (epicholedochal and paracholedochal) and gallbladder. Seen in long-standing portal hypertension. Compression or ischemia of bile duct by varices and bile flow stasis lead to stricture and stone formation in biliary tract. Usually asymptomatic in the majority. Symptomatic in 10–20% of adolescents and adults as cholestatic jaundice with episodes of cholangitis. Diagnosed on cholangiography and/or endoscopic ultrasound.
<i>Additional complications in patients with cirrhosis</i>	
Ascites	Pathophysiology and management detailed in Section 35, Chapter 35.20.
Hepatic encephalopathy	Refer to Chapter 37.10 for details.
Hepatopulmonary syndrome (HPS)	Portosystemic shunting causes decreased vasodilator (NO and endothelin) clearance in the liver which further leads to right-to-left shunting and ventilation-perfusion mismatch in the alveoli. Manifests as insidious onset dyspnea (orthopnea), cyanosis and clubbing.
Hepatorenal syndrome	PHT leads to activation of renin-angiotensin-aldosterone system, renal vasoconstriction and impaired renal function. Manifests as prerenal failure (anuria and azotemia nonresponsive to diuretics or albumin). Often precipitated by spontaneous bacterial peritonitis, large volume paracentesis or GI bleed in a cirrhotic. Rarely observed in children.

Figures 3A to C (A) Portal hypertensive gastropathy; (B) Anorectal varices (portal colopathy); (C) Narrowing of common bile duct with upstream biliary dilatation, narrowing of right hepatic duct and irregular dilation of left hepatic duct suggestive of portal biliopathy

phlebosclerosis is one of the postulations. Various studies have shown that intra-abdominal sepsis, umbilical sepsis, umbilical catheterization and *Bacteroides* bacteremia are the causative agents of portal phlebitis. Studies have failed to show any pre-

existing hypercoagulable states in children. Rarely, congenital anomalies of portal vein and iatrogenic trauma during surgery have been reported.

Clinical Presentation

Almost 85% of children present with upper gastrointestinal bleeding due to variceal hemorrhage (most commonly esophageal varices). The rest 15% may present as nonbleeders with only splenomegaly (**Figs 4A and B**). The duration from the development of PHT to clinical manifestations is highly variable. Bleeders may manifest from anytime in infancy to adulthood. Mean age of presentation is 6.3–9.3 years with a mean number of 1.8–3.1 bleeding episodes per child.

Preceding variceal bleeds, there is often a history of febrile illness and concomitant use of nonsteroidal anti-inflammatory drugs (NSAIDs) inducing erosions superimposed on pre-existing portal hypertensive gastropathy changes precipitating bleeding. Abdominal pressure from coughing in respiratory tract infection coupled with high cardiac output in fever make them prone for hemorrhage. Variceal bleeds in EHPVO are large volume well-tolerated bleeds necessitating the requirement of packed cell transfusion. Presence of gastrointestinal (GI) bleeding and absence of jaundice are 97.5% accurate in predicting the diagnosis of EHPVO. Clinical examination reveals splenomegaly with no evidence of chronic liver disease. The size of the spleen may decrease acutely just after a massive bleeding to compensate for the volume loss. Dragging sensation and left upper quadrant pain may occur due to large size of spleen. Splenic infarction is a complication in long-standing EHPVO children with massive splenomegaly (**Fig. 4C**).

Rarely, after a massive bleed, there may be transient transudative ascites that quickly resolves with diuretics (in contrast to a cirrhotic with recurrent history of ascites with or without antecedent bleed followed by aggressive, prolonged diuretic therapy). There are a few situations in which jaundice may be present in EHPVO particularly due to portal biliopathy. Mild icterus and biochemically unconjugated hyperbilirubinemia may be seen due to increased hemolysis in the enlarged spleen. Unscreened blood transfusion in the past may cause chronic hepatitis B or C infection manifesting later with conjugated jaundice. Most importantly jaundice is a manifestation of portal biliopathy-related changes as detailed in the chapter.

Growth Retardation and Quality of Life

Duration of PHT determines the growth of the child. Growth retardation (stunting and wasting) occurs in up to 54% children. The theories proposed for the same are: (1) malabsorption due to portal enteropathy; (2) deprivation of hepatotropic factors due to poor portal supply to liver; (3) chronic anemia; and (4) growth hormone resistance and low insulin like growth factor (IGF). Chronic dragging sensation and apprehensions of rupture of a massive spleen may preclude them from contact sports. Children with EHPVO have a poor quality of life (QOL) in physical, emotional, social and school functioning health domains. Increasing size of spleen, presence of hypersplenism and growth retardation significantly affects the QOL. A trend in improvement of QOL is seen after shunt surgery.

Investigations

Doppler ultrasonography is the best noninvasive investigation for diagnosis of EHPVO. Portal cavernoma on ultrasound confirms EHPVO. Portal vein block is seen in 92% cases and other 8% may have total splenoportal axis block. The Doppler ultrasonography is sensitive (94–100%) and specific (96%) to diagnose EHPVO.

Figures 4A to D (A) Massive splenomegaly in a boy with EHPVO; (B) Congested large spleen seen at surgery; (C) CT scan showing splenic infarct; (D) Portal cavernoma seen on MR portovenogram

Doppler also gives additional information about the degree of splenomegaly, size of SV and left renal vein, patency of SMV and IMV, presence of ascites and portosystemic shunts particularly for surgical intervention. CT angiography or MR portovenogram is indicated in cases where Doppler has been inconclusive and as a definitive road-map before contemplating shunt surgery in select cases (**Fig. 4D**).

The liver function tests in EHPVO are essentially normal. Hypoalbuminemia may occur during bleeding episodes. Blood counts may reveal hypersplenism. At initial evaluation serological tests for hepatitis B and C infections should be done in patients who have received blood transfusion before the start of endoscopic therapy. All patients of EHPVO, negative for hepatitis B infection should be immunized.

CIRRHOSIS IN CHILDREN

Presentation of cirrhosis is variable ranging from asymptomatic to decompensated disease. As cirrhosis advances, eventually the clinical picture evolves into jaundice and PHT. Decompensation

is heralded with the development of edema and ascites due to hypoalbuminemia, encephalopathy due to hyperammonemia and/or bleeding (variceal or coagulopathy). **Table 3** lists the common causes of cirrhosis (sinusoidal PHT) in children.

Clinical Manifestations

History of recurrent or persistent jaundice, ascites, coagulopathy or encephalopathy (one or more) favors the diagnosis of an underlying chronic liver disease. However, this history may be absent in majority as cirrhotic children usually have an insidious presentation with a smouldering course and overt features. In contrast to EHPVO, cirrhotics bleed less often. However, when they bleed, the hemorrhage is not well tolerated. It often worsens the child's condition further and results in decompensation that manifests as ascites and/or encephalopathy soon after the bleed. Cirrhosis may also be caused by extrahepatic biliary disease. Pruritus and cholangitis may be the manifestation. Examination of a cirrhotic child is summarized in **Table 4**. Investigations specific to cirrhosis are listed in **Table 5**.

MANAGEMENT OF PORTAL HYPERTENSION

Variceal Bleed

Flow charts 1 to 3 show the algorithms to manage variceal bleeding.

Most often, acute variceal bleeding occurs due to rupture of large esophageal varices. Gastric variceal bleeding is less frequent. Ongoing bleed is assessed by tachycardia, fall in blood pressure or postural drop (decrease in systolic blood pressure ≥ 20 mm Hg or a decrease in diastolic blood pressure ≥ 10 mm Hg within

Table 3 Common causes of cirrhosis (sinusoidal portal hypertension)

Infants and younger children (< 5 years of age)	Older children (> 5 years of age) and adolescents
Biliary atresia	Autoimmune liver disease
Choledochal cyst	Wilson disease
Progressive familial intrahepatic cholestasis I and II	Hepatitis B virus
Alagille syndrome*	Sclerosing cholangitis [#]
Galactosemia	Tyrosinemia type I
Tyrosinemia type I	Alagille syndrome*
Indian childhood cirrhosis	Progressive familial intrahepatic cholestasis III*
Glycogen storage disease IV	Niemann-Pick disease type C*
	Glycogen storage disease III*
	Nonalcoholic fatty liver disease (NAFLD)
	Choledochal cyst

*These are diseases beginning in the neonatal period or early infancy but have a slow progression. Cirrhosis and portal hypertension mostly manifest after the first decade.

[#]Sclerosing cholangitis may be intrahepatic, extrahepatic or both. Secondary causes (e.g., Langerhan's cell histiocytosis) are more common than primary (idiopathic) sclerosing cholangitis.

Hepatitis C-related cirrhosis develops in 5–20% of those infected and it takes 15–20 years for cirrhosis to develop. Hence, it is a rare cause of cirrhosis in children.

Table 4A General physical examination in a cirrhotic child

Features	Causes
Pallor	Bleed (GI, skin, intracranial), hemolysis (Wilson disease)
Icterus	Icteric tinge: early cirrhosis. Deep icterus: terminal disease, superimposed hemolysis or renal failure
Cyanosis	Hepatopulmonary syndrome (HPS)
Clubbing	HPS or intrapulmonary shunting
Edema	Pedal, facial, anasarca: feature of decompensation
Fat soluble vitamin deficiencies	Bitot spots, follicular keratosis (vitamin A), phrynoderma (essential fatty acids), rickets (vitamin D)
Skin changes	Paper-money skin (cirrhosis), pruritus scratch marks, vitiligo and psoriasis (autoimmune liver disease), acanthosis nigricans (NAFLD), xanthomas and xanthelasma (Alagille syndrome)
Ecchymoses	Vitamin K deficiency
Abnormal facies	Alagille facies: prominent forehead, deep-set eyes with moderate hypertelorism, pointed chin, and saddle or straight nose with a bulbous tip
Kayser-Fleischer ring	Wilson disease. (Mostly detected by slit-lamp examination. Rarely seen in naked eye examination)
Cataract	Galactosemia, Wilson disease
Vertical gaze palsy	Niemann-Pick disease

Table 4B Stigmata of chronic liver diseases (cirrhotics)

Features	Comments
Spider nevi	Small, raised, dark lesions with radially distributed convoluted vascular branches. Elicited by compression of the lesion in the center with a blunt end of a paper-pin. These are drained by the superior vena cava and are located in upper abdomen, axilla, neck and upper part of back. Cause: Increased estradiol in the circulation.
Palmar erythema	Physiological erythema may be normally seen up to 2 years of age. Relevant thereafter. Cause: Increased cardiac output or altered sex hormone metabolism (Fig. 5A).
Nail changes	Horizontal white bands (Muehrcke's nails) or leuconychia (Fig. 5B). Cause: Chronic malnutrition (hypoalbuminemia) in liver disease.
Sexual characteristics	Testicular atrophy in males, breast atrophy in females, loss of axillary or pubic hair. Rarely seen in adolescents. Cause: Altered sex hormone metabolism and reduced testosterone synthesis in liver.
Gynecomastia (males)	Usually bilateral. Unilateral gynecomastia occurs normally at puberty onset and may also occur due to spironolactone usage.

Paper-money skin and clubbing can also be accepted as stigmata of cirrhosis. Dupuytren's contracture and parotid enlargement are not usually seen in children and are specific for alcoholic cirrhosis in adults.

Table 4C Abdominal examination specific for cirrhosis

Features	Characteristics
Liver margins	Sharp and irregular (<i>Leafy</i> in Indian childhood cirrhosis).
Liver surface	Nodular, e.g., tyrosinemia, hepatitis B (postnecrotic macronodular cirrhosis).
Liver consistency	Firm is not specific for cirrhosis. Hard in congenital hepatic fibrosis.
Liver span	Shrunk specific for cirrhosis. Enlarged in cirrhosis due to secondary biliary causes, cholestatic diseases in infancy, storage disorders.
Differential enlargement	Left lobe larger than right lobe.
Splenomegaly	Mild-to-moderate. Massive in storage diseases.
Dilated tortuous veins	Sites: anterior abdominal wall, flank, back (Fig. 5C).
Ascites	Minimal: Puddle sign Moderate: shifting dullness Massive, tense: fluid thrill (shifting dullness absent)

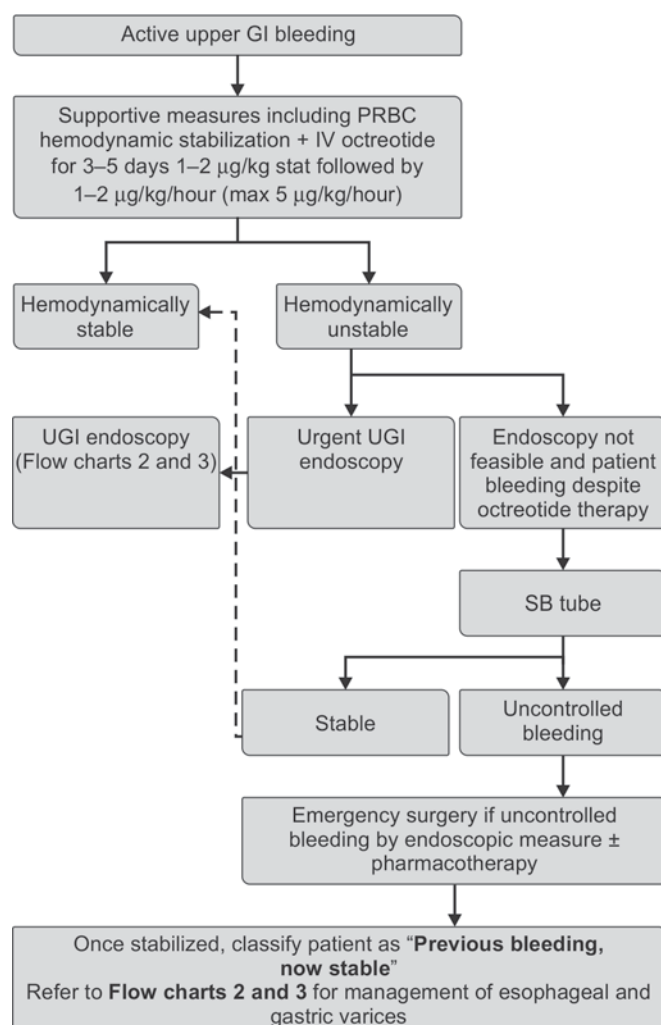

Figures 5A to D (A) Palmar erythema in a 10-year-old girl with autoimmune liver disease; (B) Leukonychia in an 8-year-old boy with Wilson disease; (C) Dilated anterior abdominal wall veins in a 2-year-old child with biliary atresia (failed portoenterostomy); (D) *Reticulin stain*: Bands of fibrosis forming nodules

Table 5 Investigations specific to cirrhosis

Investigations	Special features in cirrhosis
Liver function tests and prothrombin time	Hypoalbuminemia (< 3.5 g/dL) and coagulopathy (INR >1.5) indicate poor synthetic functions
Ultrasound Doppler	Liver margin irregularity and surface nodularity Caudate lobe hypertrophy Dilated PV with hepatofugal flow* Hepatic vein and inferior vena cava block in BCS Intrahepatic collaterals <i>Coarse parenchyma is not a definite evidence of cirrhosis</i>
Transient elastography (fibroscan)	Noninvasive measurement of degree of fibrosis Not required in all cases
Liver biopsy	Method: Percutaneous needle biopsy or transjugular (in select cases with persistent coagulopathy ± thrombocytopenia and necessary for histologic diagnosis) Loss of architecture, bands of fibrosis with nodule formation Masson's trichome or reticulin stain outlines the fibrosis (Fig. 5D) <i>Special features specific to underlying condition</i>

*Normal PV diameters (mm): Birth: 3–5, 1 year: 4–8, 5 years: 6–8, 10 years: 6–9, 15 years: 7–11.

In adults, PV diameter >13 mm is suggestive of intrahepatic PHT.

Flow chart 1 Management algorithm for active upper GI bleeding

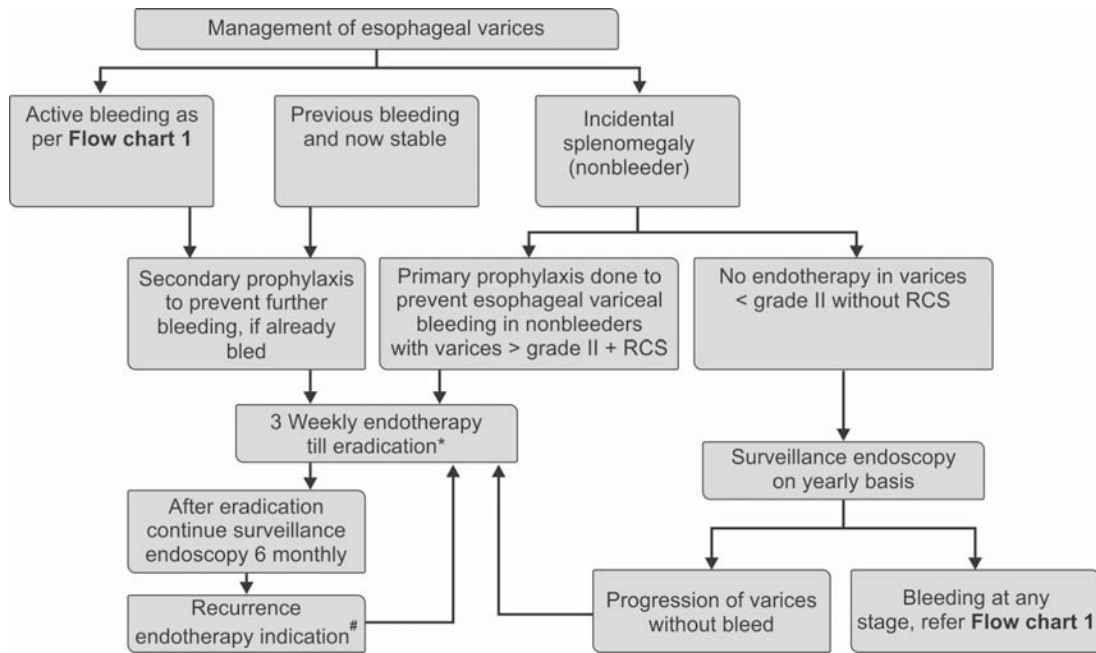

3 minutes of standing from supine position) and saline lavages. A wide bore nasogastric tube should be inserted and multiple cold saline lavages (250–500 mL each cycle) should be done till the effluent is clear. Lavages help to assess the ongoing bleed, reduce entry of blood (prevent hyperammonemia and encephalopathy in a cirrhotic) and help in clearance for visualization during UGI endoscopy. Hemodynamic resuscitation with packed cell transfusion and octreotide is to be followed by endoscopic therapy. Packed red cell transfusion should target to maintain hemoglobin at 8 mg/dL. Hypertransfusion may increase portal pressure and aggravate further bleeding from varices. In select settings pediatric Sengstaken-Blackmore tube is useful.

Octreotide is a somatostatin analog that decreases the splanchnic and azygos blood flow, thus reducing the pressure in the varices and also reduces the gastric secretion. Overall this therapy is well tolerated, with mild side effects like hyperglycemia, abdominal discomfort, nausea and diarrhea which often resolve spontaneously. Limited studies in children have shown control of bleeding in 64–71% children. Pediatric Sengstaken-Blakemore tube, a triple lumen tube has a limited role in the present era of effective endoscopic and pharmacotherapy.

Endoscopic Therapy

The goal of endoscopic management in bleeders is to find the cause, localize the site of bleeding and control acute variceal bleeding. Further, endoscopic procedures are done at intervals of 2–3 weeks. Eradication of esophageal varices to prevent rebleeding is called *secondary prophylaxis*. During endoscopy, one should look for the presence of esophageal varices, gastric varices, ectopic varices, portal hypertensive gastropathy and for any other cause of bleeding like duodenal or gastric ulcers. Prophylaxis to prevent the first episode of variceal bleed is called *primary prophylaxis*.

Grading of varices on endoscopy is given in **Box 2**. Various other classifications and grading systems are also available. Red-colored signs are markings on the surface of varices that make them at risk of bleed usually seen in esophageal varices greater than or equal to grade II. For secondary prophylaxis of esophageal varices, options are sclerotherapy alone or band ligation followed

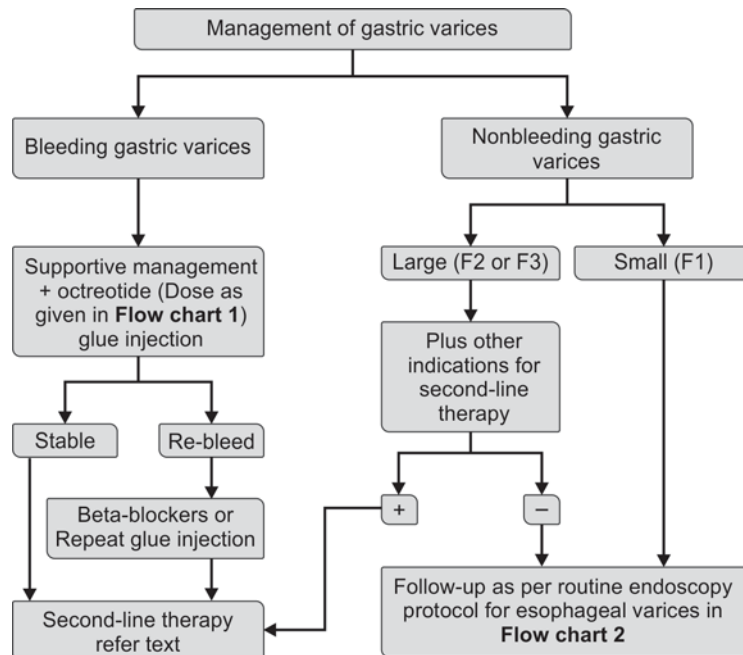

Flow chart 2 Management algorithm for esophageal varices

*EVL: Patient > 3 years of age; EST: Patients < 3 years of age or if bands are not affordable.

Initially, endotherapy is done with EVL for large varices followed by EST for smaller varices (not amenable to EVL) till they are eradicated.

#Endotherapy indication (EST/EVL): Only in esophageal varices grade II with RCS, Grade III or IV.

No endotherapy in varices < Grade II without RCS. Observe for progression, if there is recurrence but varices are small in size.

Flow chart 3 Management algorithm for gastric varices

by sclerotherapy till eradication. Options for primary prophylaxis, options are nonselective beta-blockers (NSBBs) or band ligation for varices greater than or equal to grade II (**Fig. 6A**) with red color signs. Small varices which are not at risk of bleeding may either be

observed or followed up with repeat endoscopies every 1–2 years and intervened when large. Bleeding gastric varices (IGV1, IGV2, GOV1, GOV2) are usually large (F2 or F3) (**Fig. 6B**) and are treated with glue injection followed by second-line therapy.

BOX 2 Grading of varices on endoscopy**Grade of esophageal varices (Paquet's classification)**

- I: Small varices without luminal prolapse
- II: Moderate sized varices showing luminal prolapse with minimal obscuring of gastroesophageal junction
- III: Large varices showing luminal prolapse substantially obscuring the gastroesophageal junction
- IV: Very large varices completely obscuring the gastroesophageal junction

Red color signs

Red wale marks: Dilated venules arranged longitudinally on the varices
Cherry red spots: Small red spots about 2 mm in diameter on the surface of the varices

Hemocystic spots: Round dark red blood blisters about 4 mm large in diameter

Diffuse redness: A diffuse red discoloration of the variceal surface

Location of gastric varices (Sarin's classification)

GOV1: Varices extending along the lesser curvature (continuing with esophageal varices),

GOV2: Varices extending along greater curvature (continuing with esophageal varices),

IGV1: Isolated varices in fundus (not continuing with esophageal varices),

IGV2: Isolated varices other than in fundus (elsewhere in stomach)

Size of gastric varices (Hashizume's classification)

F1: tortuous: F2: nodular: F3: tumorous

When classifying gastric varices both location and size should be taken into consideration

First-line Therapy for Variceal Bleeding

Endoscopic variceal ligation (EVL) is presently performed with a device called *multiple band ligator* (**Fig. 6C**). Varices are ligated sequentially in a spiral fashion which occludes them. Subsequently, superficial ulcers develop over the banded variceal site while the rubber band and necrotic ligated tissue sloughs off. Due to the size of the ligators, EVL can only be performed in children > 3 years of age and it is helpful to give sedation/general anesthesia so as to minimize the risk and increase the ease of performing the procedure.

When varices are large, EVL will rapidly downgrade the varices with fewer complications. Once the varices are smaller, endoscopic sclerotherapy (EST) is used to further downgrade the varices with advantages of blocking the perforators and paraesophageal collaterals to prevent recurrence.

Sclerotherapy

Two to three milliliter of 1% ethoxysclerol is injected into the engorged vessel at various sites beginning 2–3 cm above the gastroesophageal junction. Endoscopic sclerotherapy (EST) is effective in more than 90% of cases in controlling esophageal variceal bleeding. Both the superficial varices as well as perforators are sclerosed. Transient fever and retrosternal discomfort are the commonest complaints postsclerotherapy and is observed in nearly a third of subjects. Major complications include esophageal ulceration (18–30%), perforation (1–1.4%), and later esophageal stricture (6–16%).

Following emergency EST or banding, the varices are then sclerosed at intervals of 2–3 weeks until all varices are obliterated (no varices) as shown in **Figure 6D**.

Glue Injection

The gastric varices are known to bleed more severely than esophageal varices, though the incidence of bleeding is much less. Endoscopic injection of the tissue adhesive (glue) N-butyl 2-cyanoacrylate or isobutyl 2-cyanoacrylate is used for gastric

Figures 6A to C (A) Large (grade IV) esophageal varices; (B) Large (F3) gastric varices; (C) Band ligation of esophageal varices

varices (**Fig. 6E**). These two agents are tissue adhesives that harden within 20 seconds of contact with blood, and result in more rapid control of active bleeding. Frequent glue injections are not advisable in children with EHPVO as it tracks into the tributaries and makes the anatomy nonshuntable in the future. After controlling acute gastric variceal bleed, it is advisable to do shunt surgery in EHPVO. However, in cirrhotic PHT shunt surgery is not indicated as it produces encephalopathy.

Figures 6D and E (D) Eradicated esophageal varices; (E) Glue injection of gastric varices

Beta-blockers

Beta-2 blockers cause blockade of the splanchnic bed, leaving unopposed α -adrenergic stimulation and thus decreased splanchnic and portal perfusion. Since β_1 -blockade lowers the cardiac output and portal perfusion, therapeutic doses (propranolol 0.5–2.0 mg/kg/day, maximum 8 mg/kg) should decrease the pulse rate by at least 25%, thereby reducing the HVPG less than 12 mm Hg. The major adverse effects associated with the use of propranolol are heart block, exacerbation of asthma. Long-term use may lead to impotence in 5%. In patients with diabetes mellitus, β -blockers should be avoided.

Second-line Therapy for Intractable Bleeding from Large Varices

Transjugular intrahepatic portosystemic shunt (TIPS) It is an emergency procedure where a catheter that introduced through the jugular into a hepatic vein. A needle tract through the hepatic parenchyma is created between the portal vein and hepatic vein and a stent is deployed. Thus, an *artificial portosystemic shunt* is created. In a cirrhotic, TIPS serves as a bridge to liver transplantation while on waiting list. Encephalopathy is particularly a problem with TIPS as the liver is bypassed and unfiltered toxins and ammonia from the gut reach the brain.

Balloon-occluded retrograde transvenous obliteration (BRTO) It is an emergency technique to embolize and give balloon tamponade to a bleeding gastric varix via a naturally available gastroduodenal

Table 6 Indications for shunt surgery in portal hypertension

Emergency	Elective
Acutely bleeding varices, failure of all conservative measures: <ul style="list-style-type: none"> • Pharmacotherapy (octreotide) • Sengstaken-Blackmore tube (rarely required in current era) and endoscopic management 	Complications of portal hypertension* <ul style="list-style-type: none"> • Large gastric varices (previously bled) • Portal colopathy • Portal biliopathy • Bleeding ectopic varices • Splenic infarction • Massive splenomegaly affecting quality of life • Symptomatic hypersplenism

*One or more of the complications. Each case needs to be individualized.

Figure 7 Central end-to-side splenorenal shunt surgery

shunt. The procedure can be done via transjugular or transfemoral routes. Limited procedures have been done in children so far.

Surgery In the pre-endoscopy era when EHPVO had high mortality, shunt surgery was the only treatment modality available. With the successful emergence of endoscopic procedures, shunt surgery are now a second-line therapy. Select indications in India are listed in **Table 6**. Shunt surgeries are mostly done for PHT in EHPVO common being central end-to-side splenorenal with splenectomy (**Fig. 7**), side-to-side splenorenal with spleen preserving and end-to-side mesocaval. However, shunt blocks may occur in 10% cases. Mesoportal Rex bypass (MPRB) is an example of a physiological (ideal) shunt where a graft is placed between the SMV and a patent left branch of PV through the Rex venous recessus, thereby restoring normal hepatopetal blood flow. This procedure is technically demanding.

Gastric devascularization for treatment of bleeding gastric varices is performed in a cirrhotic or in EHPVO having no suitable shuntable veins.

BUDD-CHIARI SYNDROME

Budd-Chiari syndrome (BCS) is a condition of hepatic venous outflow tract obstruction in the absence of cardiac and pericardial diseases.

Etiopathogenesis

Budd-Chiari syndrome (BCS) may be primary (idiopathic) or secondary (tumors and abscesses). Pathologically, there may be a thrombus in hepatic vein or inferior vena cava (IVC) or a membrane (web) in IVC. The site of block in children is predominantly hepatic vein (72–100%) followed by combined HV-IVC (24%)

and isolated IVC (4.3%). Prothrombotic states (factor V Leiden, proteins C or S deficiency, antiphospholipid antibody syndrome, myeloproliferative diseases) are significantly rare in children as compared to adults.

Clinical Presentation

Presentation ranges from complete absence of symptoms to fulminant hepatic failure, through acute (rapid) or chronic (progressive) development of symptoms over weeks to months before diagnosis is made. Hallmark of acute Budd-Chiari syndrome (20–30%) is tender hepatomegaly, and mild jaundice without significant encephalopathy. Chronic Budd-Chiari syndrome is most common (65%) manifesting as PHT with dilated venous collaterals. The ascites is tense and intractable that rapidly accumulates despite repeated large volume paracentesis and poorly controlled with diuretics. Often dilated tortuous veins with cephalad flow (above and below umbilicus) are seen in abdomen and flanks. Similar collaterals over back are the hallmark of an IVC obstruction. As chronic BCS is a *good cirrhotic*, there is usually absence of jaundice, near normal liver enzymes, low to normal albumin and absence of coagulopathy. GI bleed (35%) and pedal edema (22%) are relatively uncommon features. End-stage disease manifests just like any other cirrhotic with jaundice, shrunken liver, encephalopathy and coagulopathy.

Imaging

Color Doppler imaging and venography show thrombosis, narrowing of lumen or ostial block in the hepatic veins and/or IVC (**Fig. 8A**). Intrahepatic collateral and caudate lobe hypertrophy are the other features on Doppler ultrasound. Occasionally, a membrane may also be seen in IVC which is best demonstrated in combined antegrade and retrograde contrast cavography. Though liver biopsy is usually not required, the unique features are congestion and fibrosis in the centrilobular area.

Management

Table 7 summarizes the management of Budd-Chiari syndrome.

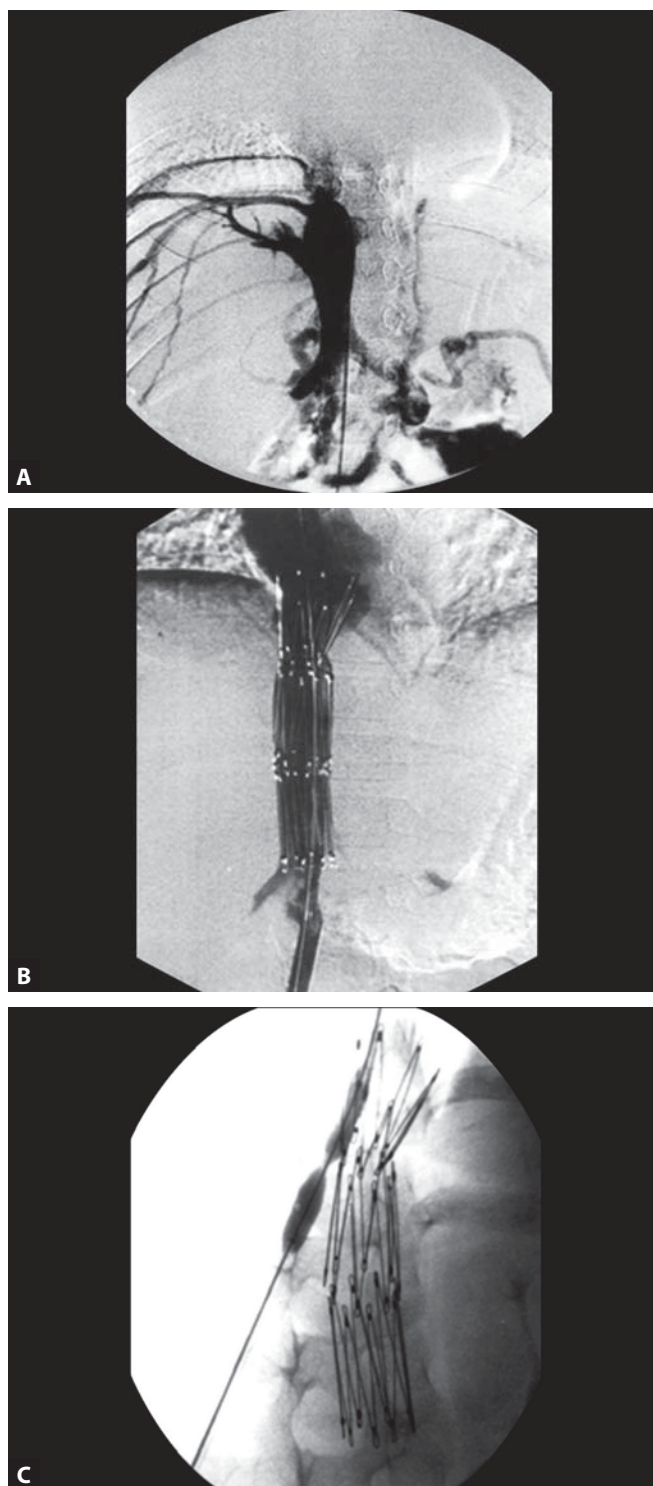

CONGENITAL HEPATIC FIBROSIS

During embryogenesis at 10th week, a double-layered structure known as *ductal plate* forms around the portal vein radicles, which proliferates to form the biliary tree. Ductal plate malformation (DPM) is the failed remodeling of the above that results in abnormally dilated biliary ductules. Congenital hepatic fibrosis refers to diffuse or segmental fibrosis of the liver due to DPM. In contrast to cirrhosis, liver architecture is preserved in congenital hepatic fibrosis.

Liver and extrahepatic involvement is summarized in **Table 8**. Majority (40–57%) present as well-tolerated variceal bleed with splenomegaly similar to EHPVO. In contrast, congenital hepatic fibrosis has a hard hepatomegaly with predominant left lobe. In a small proportion, recurrent episodes of jaundice occur during episodes of cholangitis due to biliary cystic disease that may progressively worsen the status of liver. Markedly elevated ALP or GGT (40–80%) with mildly raised or normal transaminases differentiates this condition from other causes of PHT. Hallmark of liver biopsy is DPM with broad bands of fibrosis and widening of portal tracts. Endoscopic eradication of varices, management of cholangitis and renal disease if present are the mainstay of therapy. Those without cholangitis or renal cysts are good candidates for shunt surgery and have a relatively favorable outcome.

NONCIRRHOTIC PORTAL FIBROSIS (HEPATOPORTAL SCLEROSIS OR IDIOPATHIC PORTAL HYPERTENSION)

This is a condition where there is neither cirrhosis nor extrahepatic portal obstruction but phlebosclerosis of the intrahepatic portal

Figures 8A to C (A) Blocked inferior vena cava seen on cavogram; (B) Stent placed in inferior vena cava; (C) Balloon angioplasty of right hepatic vein

radicles. Etiology is unclear but chronic exposure to vinyl chloride, copper sulfate or arsenic poisoning (West Bengal) has been postulated. The condition presents as massive splenomegaly in an adolescent or young adult with well-tolerated UGI bleed. The condition mimics EHPVO except that the portal vein is patent and dilated on imaging. Liver biopsy may be normal or shows obliterative portal venopathy. Nodularity of liver and ascites are rare features. Management is similar to EHPVO.

Table 7 Management of Budd-Chiari syndrome (BCS)

Control of ascites in all cases: Salt restriction, diuretics, large volume paracentesis		
Fulminant BCS	Acute BCS	Chronic BCS
Liver transplantation	Thrombolysis followed by radiological procedure See below	See below
Radiological intervention for ostial block/stenoses (preferably transjugular route than percutaneous transhepatic)		
<ul style="list-style-type: none"> Angioplasty ± stenting for short-length stenoses (< 5 cm length). Best is stenting if possible (Fig. 8B) TIPS for long segment stenoses (> 5 cm length) Long-term anticoagulation (warfarin) thereafter to prevent re-stenoses maintaining INR between 2.0 and 2.5 		
Membranous IVC		
<ul style="list-style-type: none"> Thin membranes: Intraluminal angioplasty by radiologic intervention (technically difficult) (Fig. 8C) Thicker membranes: Mesoatrial, cavoatrial or mesojugular shunts 		
Liver transplantation: Failure of all measures in acute or chronic BCS		

Table 8 Liver and extrahepatic involvement (including syndromes) in congenital hepatic fibrosis

Involvement	Condition
Liver involvement only	Isolated congenital hepatic fibrosis (most common) <i>Caroli's syndrome</i> : CHF + Caroli's disease (multiple cystic biliary dilatation)
Associated extrahepatic involvement	Autosomal recessive polycystic kidney disease (ARPKD) Nephronophthisis <i>Ivermark syndrome</i> : Pancreatic fibrosis <i>Joubert syndrome</i> : Dysgenesis of cerebellar vermis <i>Meckel-Gruber syndrome</i> : CNS and renal malformations <i>Bardet-Biedl syndrome</i> : Obesity, retinitis pigmentosa <i>Jeune syndrome</i> : Asphyxiating thoracic skeletal dystrophy <i>Congenital glycosylation disorder</i> : Protein losing enteropathy

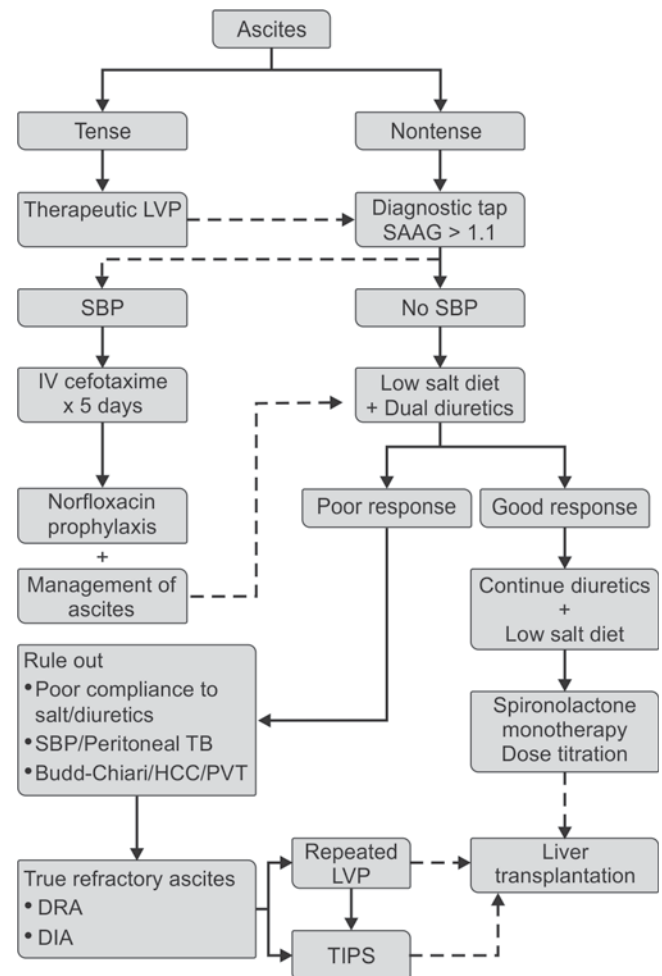

MANAGEMENT OF ASCITES

Ascites occurs in 44.1% and 12.8% children with cirrhosis and EHPVO respectively. Progressive deterioration of liver functions, PHT, splanchnic arterial vasodilatation and reduced plasma oncotic pressure due to low serum albumin all contribute to development of ascites. Inappropriate sequestration of fluid in splanchnic vascular bed leading to renin-angiotensin stimulation (underfilling theory) or primary inappropriate renal retention of sodium and water in the absence of volume depletion (overflow theory) are the other postulated mechanisms.

Management of ascites is detailed in a separate chapter in Section 35 on gastrointestinal disorders. **Flow chart 4** summarizes the approach for treating ascites.

Spontaneous Bacterial Peritonitis

Spontaneous bacterial peritonitis (SBP) is the most common complication of ascites occurring in 10–30% due to translocation of bacteria from the gut into peritoneal cavity. *E. coli*, *Klebsiella* and *S. aureus* are the most frequently isolated organisms. In a setting of ascites, presence of unexplained fever, abdominal pain, increased frequency of stools or worsening of encephalopathy in a cirrhotic should raise a suspicion for SBP. Frequently, SBP may be asymptomatic and incidentally detected on ascitic fluid analysis. Variants of SBP and their features are summarized in **Table 9**.

Flow chart 4 Management algorithm for ascites

Abbreviations: LVP, large volume paracentesis; SBP, spontaneous bacterial peritonitis; SAAG, serum ascites albumin gradient; dual diuretics (spironolactone and furosemide); HCC, hepatocellular carcinoma; PVT, portal vein thrombosis; TIPS, transjugular intrahepatic portosystemic shunt; DRA, diuretic resistant ascites (even after maximum dosage of both diuretics for at least 1 week); DIA, diuretic intractable ascites (side effects of diuretics appear before maximum doses can be tolerated).

Table 9 Description of spontaneous bacterial peritonitis and its variants

<i>Nomenclature</i>	<i>Ascitic fluid absolute neutrophil count/mm³</i>	<i>Ascitic fluid culture</i>	<i>Antibiotic treatment</i>
Spontaneous bacterial peritonitis (SBP) (monomicrobial neutrocytic)	> 250	Positive for single organism	Yes
Culture negative neutrocytic ascites (CNNA)	> 250	Negative	Yes
Monomicrobial nonneutrocytic bacterascites (MNB)	< 250	Positive	Yes if symptomatic No if asymptomatic

Table 10 Summary of portal hypertension: clinical features and investigations

	<i>Extrahepatic portal venous obstruction</i>	<i>Cirrhosis</i>	<i>Chronic Budd-Chiari syndrome</i>	<i>Congenital hepatic fibrosis</i>
GI bleed	Mostly (85%)	Rarely (20%)	± (35%)	± (40–50%)
Jaundice	Absent (unless complicated)	Recurrent or persistent (36%)	Absent (unless end stage)	Absent
Encephalopathy	Absent	± (30%) Recurrent	Absent (unless end stage)	Absent
Ascites	Absent (occasionally postbleed)	± (21%) Recurrent	Massive rapidly reaccumulating	Absent
Liver	Normal span	Shrunk or enlarged Irregular, nodular	Enlarged Irregular, nodular	Left lobe > right lobe Hard liver
Spleen	Enlarged	Enlarged	Enlarged	Enlarged
Dilated veins	None	Anterior abdominal wall Caput medusae	Abdominal wall Back veins in IVC block	±
LFT	Normal (unless complicated)	Abnormal	Near normal (unless end stage)	Normal except High ALP
Doppler USG	Portal cavernoma or block	Irregular liver outline Dilated PV	Hepatic veins ± IVC block	Irregular liver outline Left lobe enlarged
Collateral	Demonstration of varices in esophagus, and stomach by UGI	(seen in all three conditions, listed above)		

Treatment should be started empirically if SBP is suspected clinically, regardless of the availability of laboratory results. Antibiotic of choice is intravenous cefotaxime 50 mg/kg/dose every 8 hours for 5 days. This covers 95% of flora and is effective in 85% of cases. Risk factors for development of SBP are ascitic fluid protein concentration less than 1 g/dL, variceal hemorrhage and prior episode of SBP. Long-term administration of oral norfloxacin 5–7.5 mg/kg once a day in cirrhotic patients with ascitic fluid protein content of less than 1 g/dL or prior episode of SBP is recommended for prevention of SBP.

IN A NUTSHELL

1. A summary of portal hypertension (clinical features and investigations) is provided in **Table 10**.

Chapter 37.5

Gastrointestinal Bleeding

Nishant Wadhwa

Hemorrhage in gastrointestinal (GI) tract can occur from a variety of sites and the etiologies can be equally diverse. The disorders causing GI bleeding can range from minor problems to severe life-threatening conditions. The first task is to ascertain whether bleeding is from the upper GI (UGI) or lower GI (LGI) tract.

UPPER VERSUS LOWER GASTROINTESTINAL BLEEDING

Gastrointestinal bleeding in children can arise from the UGI or LGI tract. *Hematemesis* refers to the vomiting of fresh red blood or of coffee-ground material and is suggestive of UGI bleeding from lesions proximal to the ligament of Treitz. *Melena* refers to the passage per rectum of tarry stools and denotes bleeding from the UGI tract or the proximal small bowel. The tarry stools may be intermingled with maroon or red blood. *Hematochezia* is the passage of bright red blood per rectum and indicates a source of bleeding low in the GI tract, usually in the colon. However, since blood exerts a cathartic action, massive UGI bleeding may occasionally present as hematochezia.

In some instances, caregivers or children may report *blood* in their stool or emesis when blood is actually not present. Certain foods and medications can alter the color of stool or vomitus and result in unnecessary diagnostic testing. These include food coloring, colored gelatin or children's drinks, red candy, beets, tomato skins, antibiotic syrups or melena (bismuth or iron preparations, spinach, blueberries, grapes, licorice). The widely available guaiac test is the currently recommended qualitative method for confirming the presence of gross or occult blood in vomitus or stool.

UPPER GASTROINTESTINAL BLEEDING

The child typically presents with hematemesis and melena. It is relatively uncommon but not rare. One prospective intensive care unit (ICU) study reported an incidence of 6.4% (63 episodes in 984 patients). Only four (0.4%) episodes were considered life-threatening. Other studies reported an incidence of 25% among ICU patients not receiving prophylactic therapy for bleeding. In an Indian study done at Sanjay Gandhi Postgraduate Institute of Medical Sciences (SGPGIMS), Lucknow, 75 children out of 139 had UGI bleeding out of which 95% were variceal bleeding. In another study done at Kashmir, 31% were variceal and 26% due to duodenal ulcers. Hematemesis may result from swallowed blood, UGI mucosal lesions, variceal bleeding, or rarely, hemobilia (hemorrhage into the biliary tract). Swallowed blood may be seen in conditions like epistaxis, sore throat, or breastfeeding

on cracked nipples or may follow dental work or tonsillectomy. Common causes of UGI bleeding in children are summarized in **Box 1**.

Approach to Upper Gastrointestinal Bleeding

A detailed history and careful physical examination accompanied by limited laboratory studies may identify the underlying cause and predict the severity of GI hemorrhage. A nasogastric tube aspirate should be obtained early in the evaluation to confirm the presence of fresh blood and to assess the extent of active bleeding. In a child, age-adjusted tachycardia is the most sensitive indicator of acute, severe blood loss. Hypotension and delayed capillary refill are ominous signs of severe hypovolemia and shock. The nasopharynx should be carefully examined to exclude a non-GI source of bleeding. Skin findings may reveal evidence of a generalized vascular disorder. Skin findings, such as a caput medusa, spider angiomas and jaundice may indicate liver dysfunction. Hemangioma and telangiectasia may be indicative of lesions in the GI tract. Cutaneous palpable purpuras are suggestive of Henoch-Schönlein purpura. The abdominal examination may reveal signs suggestive of portal hypertension (splenomegaly). Laboratory studies which are essential in the initial evaluation include baseline blood and platelet counts, coagulation profile and liver function test. The etiology of UGI bleeding in children can be varied in different age groups of patients (**Table 1**).

Common Causes of Upper Gastrointestinal Bleeding

Esophagitis

Severe gastroesophageal reflux disease in children who are suffering from neuromuscular diseases, cerebral palsy or hiatal hernia can present with bleeding as a result of ulcerating or

BOX 1 Common causes of upper gastrointestinal bleeding

- Swallowed blood
- Epistaxis, sore throat, breastfeeding, dental work or tonsillectomy
- Vitamin K deficiency in neonate
- Erosive esophagitis
- Mallory-Weiss tear
- Hemorrhagic gastritis: trauma, surgery, burns or severe systemic stress (patients in intensive care units)
- Reactive gastritis: nonsteroidal anti-inflammatory drug (NSAID) gastropathy, ingestion of caustic substances, stress, mechanical trauma, viral infection, Crohn's disease, vasculitis (Henoch-Schönlein purpura), radiation, bile reflux, bezoar, hiatal hernia, prolapse of the gastroesophageal junction, or congestive gastropathy (associated with portal hypertension)
- Peptic ulcer
- Variceal bleeding: associated with portal hypertension
- Submucosal masses: lipoma, stromal tumors, duplication
- Vascular malformation: angiodysplasia, hemangioma, Dieulafoy's lesion
- Hemobilia

Table 1 Age-wise etiological profile of upper gastrointestinal bleeding in decreasing order of frequency

Newborn	Infant	Older child
Swallowed maternal blood	Stress gastritis or ulcer	Mallory-Weiss tear
Vitamin K deficiency	Acid-peptic disease	Acid-peptic disease
Stress gastritis or ulcer	Mallory-Weiss tear	Varices
Acid-peptic disease	Vascular anomaly	Caustic ingestion
Vascular anomaly	Gastrointestinal duplications	Vasculitis (Henoch-Schönlein purpura)
Coagulopathy	Gastric/esophageal varices	Crohn's disease
Cows' milk protein allergy	Bowel obstruction	Hemobilia, Dieulafoy's lesion

erosive esophagitis. Other causes of bleeding esophagitis include mechanical injury from a foreign body, chemical injury from a caustic ingestion or medication (*pill esophagitis*) and infection [*Candida albicans*, *Aspergillus*, herpes simplex virus and cytomegalovirus (CMV)].

Ulcer and Gastritis

Gastric/duodenal ulcers and gastritis can be a cause of UGI bleeding usually in patients older than 1 year. Ulcers can occur secondary to stress from surgery, burns, increased intracranial pressure, birthing, acute self-limited viral illness and multiorgan system disease, medications, infection, ischemia, mechanical trauma from foreign bodies or gastrostomy tubes, and tumor. Stress gastritis and ulceration with secondary UGI bleeding are well recognized in the critically ill infant. Gastric ulceration and erosions may be seen in children receiving nonsteroidal anti-inflammatory drugs (NSAIDs). *Helicobacter pylori* infection can cause gastroduodenal ulcer disease in children; however, diffuse nodular gastritis is the commoner pediatric lesion. The nodules represent polyclonal mucosal lymphoid aggregates. Rarely there can be ulcerating gastric tumors in children include leiomyosarcoma, teratoma and hemangiopericytoma.

Variceal Bleeding

Gastroesophageal variceal bleeding occurs in portal hypertension secondary to intrahepatic or extrahepatic causes. Cirrhosis underlies varices in most affected adults, whereas in many pediatric studies, a large proportion of patients have extrahepatic portal hypertension with normal liver function. A study done at SGPGIMS showed that 87% of UGI bleeding is secondary to extrahepatic portal vein obstruction (EHPVO). Other extrahepatic venous obstructions, such as splenic vein thrombosis and hepatic vein obstruction (Budd-Chiari syndrome) can also cause variceal bleeds.

Cirrhosis as a cause of variceal bleed should be considered in children with chronic biliary diseases (biliary atresia, cystic fibrosis, sclerosing cholangitis) and chronic hepatocellular diseases. Noncirrhotic causes of intrahepatic portal hypertension in children are less common and include congenital hepatic fibrosis, veno-occlusive disease, and schistosomiasis.

Biliary atresia is the leading cause of pediatric liver failure. Survival requires early surgical intervention with portoenterostomy. Varices may form during infancy and early childhood despite appropriate therapy as a result of ineffective biliary drainage, chronic cholangitis, and progressive cirrhosis. The onset of bleeding relates to the rate of disease progression and can occur within the first year of life.

Other Causes

Vascular anomalies are a rare cause of UGI bleeding in children. They may be focal lesions, such as an isolated gastric hemangioma, Dieulafoy's lesion or diffuse lesions, such as hereditary hemorrhagic telangiectasia. Rarely GI duplications can occur in the UGI tract and cause hemorrhage. Other miscellaneous reports in children have included vasculitis (Henoch-Schönlein purpura) and gastric polyps. UGI bleeding in a newborn has been discussed in the section on Neonatology.

Diagnosis

Endoscopy

Esophagogastroduodenoscopy (EGD) is the preferred method to evaluate the UGI tract for a source of bleeding. Hematemesis is considered a *red flag* sign and is an indication for early EGD. The purpose of endoscopic examination in the patient with GI bleeding is to establish the diagnosis and treat the bleeding site if possible.

EGD can determine the source of bleeding in 90% of the cases. EGD is particularly useful in the diagnosis of mucosal lesions, such as gastritis, varices, esophagitis, peptic ulcers and Mallory-Weiss tears. Whenever esophageal/gastric variceal bleeding is suspected, EGD in the first 12 hours is usually recommended.

The risk of rebleeding can be assessed using the Forest classification (**Table 2**).

Other Modalities

Scintigraphy is rarely used to evaluate UGI bleeding. Technetium-labeled bleeding scans and sulfur colloid scans are helpful in the diagnosis of obscure bleeding in the small bowel. Angiography can be helpful in cases of massive UGI bleeding. Bleeding must be at least 0.5 mL/min to be detected by angiography. Angiography can also be used selectively in children when bleeding is so massive that endoscopic evaluation and therapy are difficult and when vascular anomalies or hemobilia are suspected. Apart from diagnosis, angiography also provides a therapeutic approach, such as the placement of *coils* for embolization of the bleeding vessel.

Plain radiography has a limited role in the diagnosis of UGI bleeding. A plain X-ray film is useful in identifying unsuspected foreign bodies, with free air suggesting bowel perforation and bowel obstruction. Ultrasonography is the modality of choice when liver disease, portal hypertension or large vascular anomalies are suspected. Structural information and blood flow dynamics can be assessed noninvasively and without the need for sedation by Doppler ultrasound. Computed tomography (CT) and magnetic resonance (MR) imaging are valuable noninvasive modalities when mass lesions or vascular malformations are suspected.

Treatment

The initial goal in the treatment of any child with UGI bleeding is to provide hemodynamic stability, to provide adequate oxygen delivery, fluid and blood resuscitation, and correction of any coagulopathy or metabolic/electrolyte abnormality. After initial stabilization, medical and endoscopic treatment can proceed so as to ascertain the exact etiology and institute appropriate specific therapy.

Medical Therapy

It comprises administration of proton pump inhibitors (PPIs) to increase the gastric pH and vasoactive drugs to reduce the splanchnic circulation.

Acid suppression is recommended in children with UGI bleeding, although studies to establish a benefit in this age group have not been performed. The studies in adults have examined the effect of acid suppression given before or after endoscopy (with or without therapeutic intervention). In the setting of active UGI bleeding due to peptic ulcers, high-dose antisecretory therapy with an intravenous (IV) infusion of PPI significantly reduced the rate of rebleeding compared with standard treatment in patients with bleeding ulcers.

Table 2 Forest classification for risk of rebleeding from upper GI tract

Endoscopic finding	Class	Risk of rebleeding
Clean base	III	Low
Hematin-covered flat spot	IIc	Low
Adherent clot	IIb	High
Visible vessel	IIa	High
Oozing hemorrhage	Ib	High
Spurting hemorrhage	Ia	High

Vasopressin is an effective agent to decrease splanchnic blood flow and thereby decrease GI bleeding. It is also known to have significant side effects including bowel ischemia that have significantly limited its use. The long-acting somatostatin analog, octreotide is now the preferred agent over vasopressin owing to its better safety profile. Vasoactive medication may stop bleeding in 75–80% of cases of bleeding due to portal hypertension. The mechanism by which octreotide reduces splanchnic blood flow is not known. Doses for acute GI bleeding are typically in the range of an initial IV bolus of 1 $\mu\text{g}/\text{kg}$ up to 50 μg and then 1–5 $\mu\text{g}/\text{kg}/\text{h}$ as a continuous infusion. Usually the dose is gradually tapered after cessation of bleeding or endoscopic therapy rather than being abruptly stopped and octreotide may be readministered if rebleeding occurs. The role of octreotide is less clear in GI bleeding unrelated to portal hypertension.

Balloon Tamponade

In the child who continues to have uncontrollable variceal bleeding, balloon tamponade may be the only method that can stabilize the patient until a more definitive procedure can be undertaken. The Linton tube is used for small children or if bleeding gastric varices are present, and the Sengstaken-Blakemore tube is used for older children (**Figs 1A and B**). Both are highly effective and can stop esophageal and/or gastric variceal bleeding in up to 90% of patients. Risks associated with balloon tamponade include aspiration, esophageal rupture and ulcers, and airway obstruction.

Endoscopic Management

Among the mucosal lesions amenable to endoscopic therapy are ulcers with active bleeding, oozing from a clot overlying an ulcer, or an ulcer that has a visible vessel at its base. Endoscopic hemostasis of mucosal lesions includes injection, sclerotherapy, variceal banding and thermal methods.

Injection method Epinephrine 1:10,000 in normal saline is injected into and near the periphery of an oozing lesion. Injection therapy may slow or stop active bleeding, but it should be followed by contact thermal coagulation.

Contact thermal methods These procedures achieve hemostasis by local tamponade and coaptive coagulation, which involves fusing the walls of blood vessels up to 2 mm in size. Common contact thermal methods are heater probe, bipolar probes and bipolar circumactive probe (BICAP) cautery. The heater probe allows tamponade with firm direct pressure on a bleeding site, followed by delivery of two to four pulses of 15–30 J to coagulate the lesion. In adults, perforation has been reported in approximately 1% of

patients and rebleeding in 18% of patients after thermal methods. Endoscopic clip placement is a newer technique to capture and compress the tissue surrounding a bleeding vessel.

Sclerotherapy Sclerotherapy for children employs 25-gauge needles to inject volumes of sclerosant based on patient weight. The most common significant complication of injection sclerotherapy is esophageal ulceration leading to stricture formation, which occurs in 15% of all children treated. Details of the procedure have been provided in the previous chapter.

Band ligation Controlled studies in adults have shown that band ligation (**Figs 2A and B**) has a higher efficacy in preventing rebleeding and has fewer complications, lower costs and higher rates of survival. With the development of multiband ligation devices, which allow application of up to six bands per session, pediatric experience with this technique is encouraging. The inability to pass the band ligation apparatus in infants and small children is the only limiting factor.

When a child is bleeding and hemodynamically unstable, both sclerotherapy and band ligation can be technically difficult. In such cases, it is best to monitor the child in an ICU, protect the airway with an endotracheal tube, sedate the patient, and temporarily control the bleeding by passing a Sengstaken-Blakemore tube or Linton tube.

Angiography is employed when an additional therapeutic component is needed, such as placement of a transjugular portosystemic shunt, selective infusion of a vasoactive agent into a bleeding vessel, or embolization of a bleeding vessel with gelfoam or coils.

Surgical Management

Surgery is indicated in patients with a posterior duodenal ulcer with arterial bleeding, bowel perforation with bleeding, and gastroesophageal varices. Surgical intervention for gastroesophageal varices requires a portosystemic shunt procedure, such as a mesocaval shunt, distal splenorenal shunt, or central portocaval shunt. The esophageal transection and devascularization is potentially life-saving surgery for bleeding esophageal varices which is not amenable to other treatments.

LOWER GASTROINTESTINAL BLEEDING

Lower GI bleeding is defined as bleeding with an origin distal to the ligament of Treitz. The quantity of blood loss may range from stools positive for occult blood to a life-threatening hemorrhage presenting with profound shock. LGI bleeding can present as hematochezia, melena or occult bleeding.

Figures 1A and B (A) Sengstaken-Blakemore tube; (B) Linton tube

Figures 2A and B Band ligation of esophageal varices:
(A) Ligating the bleeder; (B) After the procedure

Epidemiology

In an Indian study done at SGPGIMS, Lucknow, causes of LGI bleeding were colitis (42%), colorectal polyps (41%), enteric fever (5%), solitary rectal ulcer (5%), portal hypertensive colopathy (3%), colonic arteriovenous malformation (1.5%) and internal hemorrhoids (1.5%).

In another study done at a tertiary care emergency department, rectal bleeding represented the chief complaint in 0.3% of all visits. Almost 50% of the children were younger than 1 year old. Allergic colitis was the commonest diagnosis, followed by anorectal fissure, in children younger than 1 year old. Infectious gastroenteritis and anorectal fissure were the commonest diagnoses between 1 year and 5 years and greater than 5 years age, respectively. Causes of LGI bleeding are listed in **Box 2**.

Approach to Lower Gastrointestinal Bleeding

The most important step is the rapid assessment of the degree of volume loss and the initiation of fluid resuscitation if needed. Tachycardia is a very sensitive initial indicator of severe blood loss, whereas slow capillary refill and hypotension are late signs of hypovolemia and shock. Symptoms of hemodynamic instability should prompt urgent placement of large-bore IV catheters and may lead to transferring the patient to the ICU.

History

A detailed family history is important, whether any first-degree relative has history of allergy, inflammatory bowel disease (IBD), familial adenomatous polyposis, hereditary hemorrhagic telangiectasia, Ehlers-Danlos syndrome or bleeding disorders. Any such history is strongly suggestive of the same disease in the presenting child. The occurrence of LGI bleeding soon after weaning and introduction of cow's milk formula in the diet strongly suggests the occurrence of cow's milk protein allergy. History of water source and history of recent travel and eating outside are important in cases of bacterial or viral GI infection, whereas recent travel to an endemic area is suggestive of amebiasis. Recent use of antibiotics is a risk factor for antibiotic-associated diarrhea and pseudomembranous colitis. Exposure to contaminated foods (chicken, eggs, unpasteurized milk) enhances the risk for outbreaks of bacterial GI infection. Age is a very important component of the history for finding the most common causes of LGI bleeding as the causes vary according to the age of the patient.

BOX 2 Causes of lower gastrointestinal bleeding

Presenting with hematochezia and/or melena

- *Intestinal ischemia*: Complicating intussusception, midgut volvulus, incarcerated hernia or mesenteric thrombosis
- *Meckel's diverticulum*
- *Upper GI source*: See hematemesis
- *Vasculitis*: Henoch-Schönlein purpura
- *Sloughed polyp*
- *Intestinal or colonic ulcer*: NSAID gastropathy, Crohn's disease, ulcerative colitis
- *Vascular malformation*

Rectal bleeding with signs of colitis (bloody diarrhea, tenesmus, night-time stooling)

- *Infectious colitis*: *Salmonella*, *Shigella*, *Yersinia enterocolitica*, *Campylobacter jejuni*, *Escherichia coli* O157:H7, *Aeromonas hydrophila*, *Klebsiella oxytoca*, *Clostridium difficile*, *Neisseria gonorrhoeae*, cytomegalovirus, *Entamoeba histolytica*, *Trichuris trichiura*
- *Inflammatory bowel disease*: Ulcerative colitis, Crohn's disease
- *Necrotizing enterocolitis*
- *Eosinophilic proctocolitis*
- *Hemolytic-uremic syndrome*

Rectal bleeding with normal stool pattern

- *Juvenile polyp*
- *Nodular lymphoid hyperplasia*
- *Eosinophilic colitis*
- *Inflammatory bowel disease*
- *Vascular malformation*

Bright red blood coating normal or hard stool

- *Anal fissure*
- *Beta-hemolytic streptococcal cryptitis*
- *Ulcerative proctitis*
- *Rectal prolapse*
- *Solitary rectal ulcer*
- *Internal hemorrhoids*

Occult gastrointestinal blood loss

- *Esophagitis*
- *Reactive gastritis*
- *Acid-peptic disease*
- *Eosinophilic gastroenteritis, colitis*
- *Celiac disease*
- *Inflammatory bowel disease*
- *Polyposis*
- *Meckel's diverticulum*
- *Vascular malformation*

Stool Characteristics

Bleeding which is limited to the outside of the stools or spots of red blood coating the stools or found in the diaper, on the toilet tissue, or in the toilet bowl imply bleeding from an anal or rectal origin.

Table 3 provides an approach to likely diagnosis based on the stool characteristics in a child with LGI bleed. Blood mixed through the stool suggests a colonic source for the bleeding located higher than the rectum, whereas hematochezia mixed with mucus and loose stools suggests colitis. Maroon-colored stools are suggestive of a hemorrhage arising from the distal small bowel. Currant jelly stools are potentially indicative of ischemic bowel lesions, such as those seen in cases of intussusception or midgut volvulus.

Physical Examination

A detailed examination of the anus, perineal area and rectum is essential. Fever suggests the presence of an infectious disease or inflammatory disorder. Failure to thrive may be suggestive of an underlying chronic disease like IBD. Extraintestinal manifestation of IBD, like episcleritis, pyoderma and erythema nodosum should not be missed. Jaundice and signs of chronic liver disease (CLD) should also be seen for evidence of portal hypertension and rectal varices.

Table 3 Etiological diagnosis of lower gastrointestinal bleed as per stool characteristics

Amount	Appearance	Character of stool	Pain	Possibilities
Small	Red	Hard	Yes	Fissure
Small to moderate	Red	Loose	Variable	Allergic, infectious
Small to moderate	Red	Normal coated with blood	No	Polyp
Moderate	Red to tarry	Normal	Yes	Henoch-Schönlein purpura
Moderate	Red to tarry to currant jelly	Normal	Yes	Intussusception
Moderate	Red to tarry	Loose	Yes	Hirschsprung with enterocolitis
Large	Red to tarry	Normal	No	Meckel's diverticulum, angiodysplasia

Common Causes of Lower Gastrointestinal Bleeding

Neonate and Early Infancy

The most important diagnosis to exclude in the neonate with rectal bleeding is necrotizing enterocolitis. The typical presentation is a preterm infant with small amounts of gross blood in the stool, feeding intolerance, and emerging signs of systemic instability. Enterocolitis in a neonate or infant with abdominal distention and impaired defecation may be due to Hirschsprung disease. Colitis in otherwise well-appearing infants is most often due to cow's milk protein allergy. Proctosigmoidoscopy in conjunction with the evaluation of multiple mucosal biopsy specimens may be helpful for diagnosis. Bowel obstruction with ischemic injury (intestinal volvulus, ileocolic intussusceptions) should be suspected in an infant or young child with vomiting, pain, and small amounts of blood in the stool. Doppler ultrasonography can also aid in the diagnosis of midgut volvulus by showing clockwise rotation of the superior mesenteric vein around the superior mesenteric artery (*whirlpool* sign).

Infectious Causes

Infectious enterocolitis can present with bloody stool at any age. Important bacterial pathogens include *Salmonella*, *Shigella*, *Campylobacter*, *Yersinia enterocolitica*, *Clostridium difficile*, and *Escherichia coli* (O157:H7). *Entamoeba histolytica* is the most important parasitic pathogen. CMV can cause enterocolitis in children with primary or secondary immunodeficiency and can present with massive life-threatening hemorrhage. Children with acquired immunodeficiency syndrome (AIDS) can suffer life-threatening GI bleeding from aphthous ulceration in the absence of a detectable infectious cause. Typhlitis, a polymicrobial inflammatory disease in the cecum of severely immunosuppressed patients, can present with massive GI bleeding.

Surgical Causes

Intussusception, Meckel's diverticulum, intestinal/rectal polyps, and other tumors and neoplasms are important causes of LGI bleed.

Intussusception usually occurs in patients 4–10 months of age, with 65% of cases occurring before 1 year and 80% by 2 years of age. The majority of cases occur in the region of the ileocecal valve, and no lead point can be precisely identified. In older children, a lead point, including polyp, Meckel's diverticulum, intestinal duplication, or neoplasm, is more likely to be found. Abdominal pain and vomiting, followed by passage of *currant jelly stool*, representing a mixture of blood, mucoid exudate, and stool, is characteristics of intussusceptions. On examination a palpable sausage-shaped abdominal mass can be palpated. Diagnosis is confirmed by abdominal ultrasonography.

Meckel's diverticulum is usually asymptomatic; however, it can present with LGI bleeding resulting from the ulceration of adjacent ileal mucosa by acid-secreting heterotopic gastric mucosa contained in the diverticulum. LGI bleeding is often brisk and

painless and may present as self-limited recurrent bleeding in an otherwise healthy child or life-threatening acute massive lower hemorrhage. Provided that gastric mucosa is present, the diagnosis of Meckel's diverticulum can be made with an 85–90% sensitivity by a radionuclide technetium 99 m pertechnetate scan showing the presence of heterotopic gastric mucosa in the right lower quadrant of the abdomen (**Fig. 3**). False-positive results of technetium 99 m pertechnetate scintigraphy have been reported in patients with intussusception, hydronephrosis, arteriovenous malformation and IBD. The treatment of choice is surgical excision.

Polyps and tumors Beyond infancy, juvenile polyps are the commonest source of significant rectal bleeding in childhood. Painless, intermittent bleeding is typical. Juvenile polyps are nonneoplastic polyps that contain dilated cystic spaces, infiltrating inflammatory cells, marked vascularity, and areas of eroded epithelium. They predominantly occur in the rectosigmoid but may occur throughout the colon. Children with multiple or recurrent juvenile polyps may have juvenile polyposis coli or juvenile polyposis syndrome, a genetic disorder that has an increased risk of adenomatous degeneration and malignancy. Bleeding from hamartomatous polyps (e.g., Peutz-Jeghers syndrome) is unusual unless accompanied by intussusception and bowel ischemia. Other tumors presenting with rectal bleeding in childhood are rare.

Hemorrhoids: Colonic and Anorectal Varices

Hemorrhoids are unusual in children and if present, portal hypertension should be suspected. One-third of the children with portal hypertension may have hemorrhoids or anorectal varices that are most often totally asymptomatic. Hemorrhoidal bleeding usually presents with bleeding on defecation. Treatment is advised only for symptomatic patients, and injection sclerotherapy is satisfactory for the majority.

Other Causes

Foreign body injury must be considered, including ingested glass, a broken glass rectal thermometer, or other sharp objects. Unexplained bleeding despite extensive evaluation should also raise suspicion of Munchausen's syndrome by proxy.

Investigations

Complete blood count, clotting studies, and routine chemistry are performed unless history taking and physical examination allow the cause of LGI bleeding in the patient to be determined without doubt. The presence of iron deficiency anemia suggests a history of chronic blood loss. Determination of erythrocyte sedimentation rate and/or C-reactive protein is useful when infectious colitis or an inflammatory disorder is being considered. Liver function tests are necessary when liver disease and portal hypertension are suspected to be responsible for LGI bleeding. In cases of invasive bloody diarrhea or suspicion of IBD, stool culture and stool examination for virus, ova and parasites, and *C. difficile* toxin are necessary.

Ultrasonography

Ultrasound examination of the abdomen is helpful in an acute abdominal disorder with obstruction and/or ischemia, or when an abdominal mass is present. It can help in diagnosis of intussusception, malrotation, hepatosplenomegaly, and CLD.

Colonoscopy

Colonoscopy is the preferred diagnostic modality for rectal bleeding. Limited inspection of the rectosigmoid is usually sufficient for infants with allergic colitis and may be adequate to establish an initial diagnosis of infectious, ischemic, or idiopathic colitis in older children. In other cases, complete colonoscopy is preferred to identify focal or multifocal lesions or assess the extent of colonic involvement. Unless ischemia or obstruction is suspected, a suitable bowel preparation should be administered to facilitate optimal visualization and potential intervention.

Bowel preparation is safely achieved in children using standard polyethylene glycol electrolyte. A small-diameter colonoscope (11 mm) can be used in most children beyond 2 years of age. A smaller-diameter gastroscope is required in infants.

Examination of the terminal ileum should be routinely attempted to detect active bleeding from the small bowel or Crohn's disease. Examination of the ileocolic junction is also required to detect the postoperative anastomotic ulceration. Superficial mucosal vascular lesions, such as telangiectasias, hemangioma, or venous malformation, are best visualized by colonoscopy.

Endosonography is comparatively more sensitive than endoscopy for detecting submucosal lesions and may be particularly useful in cases of vascular anomalies.

Radionuclide Scanning

Radionuclide scanning with technetium 99 m pertechnetate is done for suspected cases of Meckel's diverticulum or duplication. In this scan, technetium rapidly binds to the gastric mucosa, has been very useful in making the diagnosis of heterotopic gastric mucosa contained in Meckel's diverticulum or intestinal duplication in children, with an 85–90% sensitivity (**Fig. 3**).

Red blood cell (RBC) scan can also be performed to look for the site of bleeding. In this test, the patient's own red cells are labeled with technetium 99 m pertechnetate and reinjected into the bloodstream. The site of bleeding can be visualized, provided the bleeding rate is 0.5 mL/min or higher.

Angiography

An angiography can be done to evaluate for ongoing LGI bleeding in which esophagoastroduodenoscopy and colonoscopy are negative and bleeding rate is 0.5 mL/min or greater. Angiography can identify a potential bleeding site in 50% of children. Angiography also offers the benefit of selective arterial embolization in tertiary centers with the technical expertise to perform supraselective catheterization. It should be limited to the very few patients with active LGI bleeding and negative EGD and colonoscopy.

Capsule Endoscopy

Obscure GI bleeding, either occult or overt, is the most frequent indication for capsule endoscopy. Capsule endoscopy is a big step forward in the diagnosis of obscure GI bleeding of presumed small bowel origin. Capsule endoscopy is safe and well tolerated and the wireless capsule can make diagnoses beyond the reach of enteroscopes.

Treatment

Medical Therapy

It includes initial resuscitation measures and specific therapy for diseases. Bleeding from allergic colitis of infancy responds

Figure 3 Meckel's scan

promptly to dietary restriction and introduction of hydrolyzed protein formula. Ischemic colitis (necrotizing enterocolitis) is treated supportively with intravenous fluids, IV antibiotics and gut rest. Appropriate antibiotics are used to treat infectious colitis and immunosuppressive and anti-inflammatory agents are used for IBD. Rapidly proliferating hemangiomas have been successfully treated with corticosteroids and with interferon-alpha.

Endoscopic Therapy

Endoscopic therapy is primarily polypectomy for colorectal polyps. Juvenile polyps in children tend to be small to medium diameter (5–15 mm) and are often pedunculated, making resection with minisnares straightforward. Although malignancy is rare, an effort should be made to resect and retrieve all polyps for histopathologic examination to exclude the presence of adenomatous or cancerous epithelium. Hemostatic techniques, such as sclerotherapy, electrocoagulation, laser and elastic band ligation are used in children for vascular colonic anomalies.

Surgery

Surgery is most often indicated for bleeding resulting from nonreducible intussusception or a vascular anomaly. Over the past years, the rates of surgical intervention for intussusceptions have reduced because of the high level of success with pneumatic reduction. Meckel's diverticulum is treated by surgical resection. Patients with vascular anomalies may require excision of focal lesions or surgical resection or exclusion of a larger segment of involved bowel.

OCCULT GASTROINTESTINAL BLOOD LOSS

Occult blood in the stool is detected mostly while evaluating chronic GI symptoms, such as abdominal pain, vomiting, diarrhea, and constipation; unexplained systemic symptoms (weight loss, growth retardation, arthralgia, fever) or unexplained iron deficiency anemia. The most common causes are inflammatory disorders (including esophagitis), acid peptic disease, reactive gastritis, eosinophilic gastroenteritis, celiac disease, Henoch-Schönlein purpura, Crohn's disease, ulcerative colitis, polyps and Meckel's diverticulum. Rare causes of occult bleeding are vascular anomalies, infection and neoplasia. Infectious causes of occult GI blood loss include hookworm, ascariasis, amebic infection, *Strongyloides* infection and tuberculosis.

IN A NUTSHELL

1. Gastrointestinal bleeding in children can arise from the UGI or LGI tract. Hematemesis and melena are characteristic of UGI bleed.
2. Lower GI bleed can present with hematochezia, melena or occult bleed.
3. Most common causes of UGI bleed include stress gastritis, esophagitis and variceal bleeding. LGI bleed is usually because of enterocolitis, polyps, intussusceptions or a Meckel's diverticulum.
4. Upper GI endoscopy and colonoscopy are the preferred diagnostic modalities for diagnosis of bleeding from the UGI and LGI tract, respectively.
5. Treatment should be directed at maintaining the hemodynamic balance, identifying the cause of bleed, and provide specific treatment for both the present episode and also prevention of future episodes.

Chapter 37.6

Liver Abscess

Upender Shava, Anshu Srivastava

Liver abscesses have been increasingly reported in children in recent years, especially from developing countries. The incidence varies from 1 to 79 per 100,000 pediatric admissions. Most of the liver abscesses in children are pyogenic, followed by amebic etiology. Rare causes include tuberculosis, helminthic infections like ascariasis and fungal infection (especially in patients with immunocompromised state).

PATHOGENESIS

Liver abscess can result from seeding of bacteria from portal venous system, biliary system, hepatic arteries or direct extension from surrounding organs like lungs, subdiaphragmatic space or from penetrating injuries (**Fig. 1**). Pyogenic liver abscess (PLA) can also occur due to secondary bacterial infection of amebic abscess or hydatid cyst. Septic emboli secondary to septicemia or thrombophlebitis in portal system (umbilical catheterization, appendicitis, colitis, etc.) get trapped in sinusoids and may become a nidus for abscess formation. Cholangitis is an important etiology for liver abscess, though less common in children than adults. Biliary tract anomalies (choledochal cyst, Caroli disease), choledocolithiasis, biliary ascariasis or post-Kasai portoenterostomy predispose the child to recurrent cholangitis and abscess formation which are almost always multiple.

Immunodeficiency disorders [chronic granulomatous disease (CGD), complement deficiency and hyper-IgE syndrome] may also cause liver abscess as a part of multi-systemic infections. Recurrent abscesses at multiple sites like liver, lung and skin are an important clue to CGD. Malnourished children with poor immune functions and residing in overcrowded, unhygienic conditions in the developing world are also at an increased risk. Invasive intestinal amebiasis is the cause of amebic liver abscess (ALA), although a history of same is not always forthcoming.

Figure 1 Routes of entry of infection in liver

Keys: 1, Systemic infection through hepatic artery; 2, Infection from biliary tree; 3, Infection from gut through portal vein; 4, Direct trauma/infection from surrounding tissues

PATHOLOGY

The abscess may be single or multiple. The contents are yellow or greenish which may be foul-smelling, particularly if due to anaerobic organisms. Microscopically, acute abscess contains necrosis and polymorphs, and bacteria may or may not be identified on Gram stain. In subacute or chronic abscess, the wall is replaced by granulation and fibrous tissue. Presence of supportive cholangitis or portal pylephlebitis may indicate the source of infection.

Amebic liver abscess is usually single, large and located in posterior portion of right lobe. The abscess contains odorless (unless secondarily infected) reddish-brown pus resembling anchovy sauce. The abscess wall is ragged, and its lining contains three layers: inner most composed of necrosis and occasional ameba, next layer of granulation tissue and fibrosis with few inflammatory cells, and the outer most layer of compressed normal liver tissue.

More than 75% of the liver abscess occur in right lobe of liver and most are solitary; 20–25% are multiple. Right branch of portal vein continues in the direction of main portal vein whereas left branch is more horizontal and this results in relatively more volume and flow of blood from portal system to the right lobe of liver. Thus, infections are more commonly localized to the right lobe of liver.

MICROBIOLOGY

Staphylococcus aureus is the most common etiology of PLA in children, accounting for ~65–85% cases. *Enterococcus faecalis*, *Escherichia coli*, *Klebsiella*, *Acinetobacter baumannii* and *Enterobacter* species are responsible for the remaining cases. Gram-negative organisms are more common in infants. Anaerobic organisms like *Bacteroides fragilis* and *Fusobacterium necrophorum* are also isolated in a small proportion of children. Uncommon organisms include *Salmonella* (as a complication of enteric fever leading to cholangitis), fungi (in immunocompromised states like CGD, leukemia, etc.) and *Mycobacterium tuberculosis*.

Amebic liver abscess is a common extraintestinal manifestation of intestinal amebiasis and constitutes about 20–30% of liver abscess in children reported from developing countries. The diagnosis is made if there is negative pus culture with positive amebic serology. If a patient has both positive amebic serology as well as positive pus culture, it is difficult to know if it is primarily an ALA with secondary bacterial infection or a pyogenic abscess with positive amebic serology due to previous invasive intestinal amebiasis. These cases may be labeled as indeterminate.

In some children, no cause is found and the abscess is labeled as *cryptogenic*. Liver abscess may be polymicrobial in a few patients. The abscess may also be sterile, mostly due to prior antibiotic use or inadequate culture techniques, especially in case of anaerobic organisms.

CLINICAL FEATURES

Pyogenic liver abscess usually presents with fever, right hypochondrium pain and tender hepatomegaly. Other symptoms include fatigue, nausea and vomiting, anorexia and weight loss. Some children may present with pulmonary complications, like consolidation, pleural effusion or empyema. Abscess in sub-diaphragmatic location may cause referred pain to shoulder and cough due to irritation of diaphragm. Some children may present in a very sick state with septicemia and abscesses at multiple sites. **Table 1** shows the common presenting features in series from India and other developing countries.

Most of the patients present insidiously, possibly as a result of inappropriate use of antibiotics, except for a few with fulminant presentation due to sepsis or rupture of abscess into peritoneum

Table 1 Pediatric liver abscess studies

[‡]PCD, percutaneous drainage; NA, not available.

or pleural space. Most of the patients with amebic abscess present subacutely with low-grade fever, dull aching right upper abdominal pain, weight loss, fatigue and anemia. Clinical features usually do not help to differentiate ALA from PLA. ALA is reported to occur in ~1–7% of invasive amebiasis. However, less than 50% patients give history of diarrhea in the recent past and ~10% patients may concomitantly have dysentery with ALA. Jaundice is uncommon in liver abscess, except when it occurs due to biliary obstruction and cholangitis. Splenomegaly may be seen in few cases. Upper gastrointestinal bleeding (UGIB) may occur, mostly due to erosions/ulcer secondary to nonsteroidal anti-inflammatory drug intake or stress. Presence of UGIB with jaundice suggests hemobilia. In contrast to the developed world, where immunodeficiency states and intra-abdominal sepsis are often seen in patients with liver abscess, no predisposing factor is usually seen in patients in the developing world. Neonates with liver abscess present with non-specific symptoms and a high index of suspicion is required, particularly in high-risk groups like premature babies and those with necrotizing enterocolitis or umbilical catheterization.

INVESTIGATIONS

The aim of investigations is to confirm the diagnosis, determine the etiology, detect presence of complications and plan management.

- **Hematology and biochemistry:** Leukocytosis, anemia and raised ESR are common. Liver function tests show elevated alkaline phosphatase and hypoalbuminemia with mild elevation of transaminases in some patients. Low platelet

count with deranged prothrombin time suggests disseminated intravascular coagulation (DIC) in patients with coexistent septicemia.

- **Chest X-ray:** Elevation of right dome of diaphragm and collapse of right basal segments of lung with pleural effusion may be present. Increase cardiothoracic ratio suggests presence of pericardial effusion.
- **Blood culture** should always be sent in all cases with liver abscess prior to starting antibiotics. Pus aspirated from the liver abscess or abscess at other sites should be sent for Gram stain and culture sensitivity (aerobic and anaerobic). Trophozoites of ameba are usually not detected in aspirates from amebic abscess, as they are located in the abscess wall.
- **Amebic serology:** ELISA or hemagglutinin tests are useful investigations with sensitivity and specificity of ~95%. In endemic areas, a positive serology may not be helpful in diagnosis, but a negative serology favors pyogenic over ALA.
- **Ultrasonography:** It is the imaging of choice as it is cheap, safe, easily available and has a good diagnostic accuracy. Abscesses are round or oval, with thick walls and irregular margin. Early suppuration appears as hypoechoic solid mass while completely liquefied abscess appears as a cystic lesion, which may be anechoic. Multiple septae and internal debris may also be seen. Ultrasonography can detect abscess of size as small as 1.5 cm with a sensitivity of 90%. In addition to liver abscess, other intra-abdominal collections, ascites, biliary obstruction and pleural effusion can also be assessed. Impending rupture

is suggested when the liver rim around the abscess is less than 1 cm. The differential diagnoses of liver abscess include hydatid cyst, hematoma and simple cyst with hemorrhage or infection. Rarely, neoplastic lesions like lymphoma and metastases from neuroblastoma or Wilms tumor may simulate abscess.

- **Other imaging modalities:** Contrast enhanced CT scan is required in some cases. It helps in providing information about the accurate location, presence of air within abscess, relation to surrounding structures, and features of rupture and other complications. In noncontrast CT, abscess appears as a hypodense lesion which shows rim enhancement on contrast injection. In large abscesses, multiple septations may give a *honeycomb* appearance (**Fig. 2**).

MRI is more sensitive to detect small abscess and it is required in select cases, e.g., biliary disease. Abscesses are hypointense on T1 and hyperintense on T2 weighted images, and they show enhancement on gadolinium contrast.

MANAGEMENT

The main pillars of management are antibiotics, supportive therapy, and drainage (percutaneous or surgical) (**Flow chart 1**). *Supportive therapy* consists of antipyretics, analgesics and intravenous hydration. Management of complications like empyema, correction of anemia and nutritional support in malnourished children is very important.

Antibiotics

Correct choice and duration of antibiotic is essential. A combination of cloxacillin or vancomycin, third generation cephalosporins, and metronidazole is a good first choice in children. Later, the antibiotics can be changed as per culture sensitivity and clinical response. Injectable antibiotics are preferred for the initial 2 weeks or until the patient is afebrile. Thereafter, oral antibiotics are given for a total duration of 4–6 weeks. A longer duration of antibiotics with antifungals is required for CGD patients with liver abscess. Most of the ALA respond to antiamebic therapy. Metronidazole is the drug of choice (35–50

mg/kg/day in 3 divided doses for 10 days, IV or oral). Tinidazole (50 mg/kg/day for 5 days) followed by paramomycin (25–35 mg/kg/day in 3 divided doses for 7–10 days) or diloxanide furoate (500 ng TDS \times 5 days) may also be used.

Drainage

Nearly 40–80% hospitalized children with liver abscess require drainage (**Table 1**). There are two main modalities of drainage: percutaneous (needle aspiration or catheter drainage) and open surgical drainage. Percutaneous drainage is preferred as it is less invasive, cheap and gives good results. The indications for drainage largely include nonresponse to antibiotics (persistence of fever or features of persistent sepsis after 48–72 hours of antibiotics) or presence of complications (**Flow chart 1**).

Percutaneous Drainage

Percutaneous catheter drainage (PCD) is more efficacious than percutaneous needle aspiration (PNA). *Needle aspiration* may be tried in solitary, small, unilocular abscess. Though it provides pus for culture sensitivity, multiple sessions may be needed, and there is a risk of peritoneal contamination and inadequate drainage. *Catheter drainage* is preferred in patients with large abscess (> 6 cm), abscess with impending rupture or localized rupture and also in critically ill patients as a temporary measure before surgery. Catheter is removed when there is reduction of size of abscess cavity and drain output is less than 10 mL for three consecutive days. The average duration of PCD is about 7–14 days, and it is successful in about 90% cases. Complications include iatrogenic infection, hemorrhage (into peritoneum or hemobilia) and bile leak.

Open Surgical Drainage

It is the modality of choice in patients with ruptured abscess with peritonitis, multiple large abscesses, multiloculated abscess, thick pus not drainable by catheter, failed PCD and patients requiring surgery for other coexistent abdominal conditions. Intraoperative approach allows drainage of multiple abscesses and intraoperative USG helps to identify deep-seated abscesses. In patients not responding to antibiotics and drainage, other causes like tubercular abscess, fungal abscess or infected hydatid cyst should be considered.

COMPLICATIONS AND OUTCOME

Rupture into surrounding organs (pleural space leading to empyema and hepatopulmonary fistulas, subdiaphragmatic space and peritoneum leading to peritonitis, pericardium causing pericardial effusion and tamponade) is the most common complication. Septic shock, hemobilia, portal vein or hepatic vein thrombosis are the other complications. Large and multiple abscesses, sepsis, hypoalbuminemia, jaundice, encephalopathy and liver failure are poor prognostic indicators. Mortality in liver abscess ranges from 0% to 11%, with a decrease over the last two decades due to advances in imaging and interventions (**Table 1**).

PREVENTION

Prompt treatment of infections (gastrointestinal, biliary and others) with appropriate antibiotics can prevent development of PLA. Correction of malnutrition, anemia and provision of safe water and food to children in developing world will also go a long way in preventing infectious diseases including liver abscess.

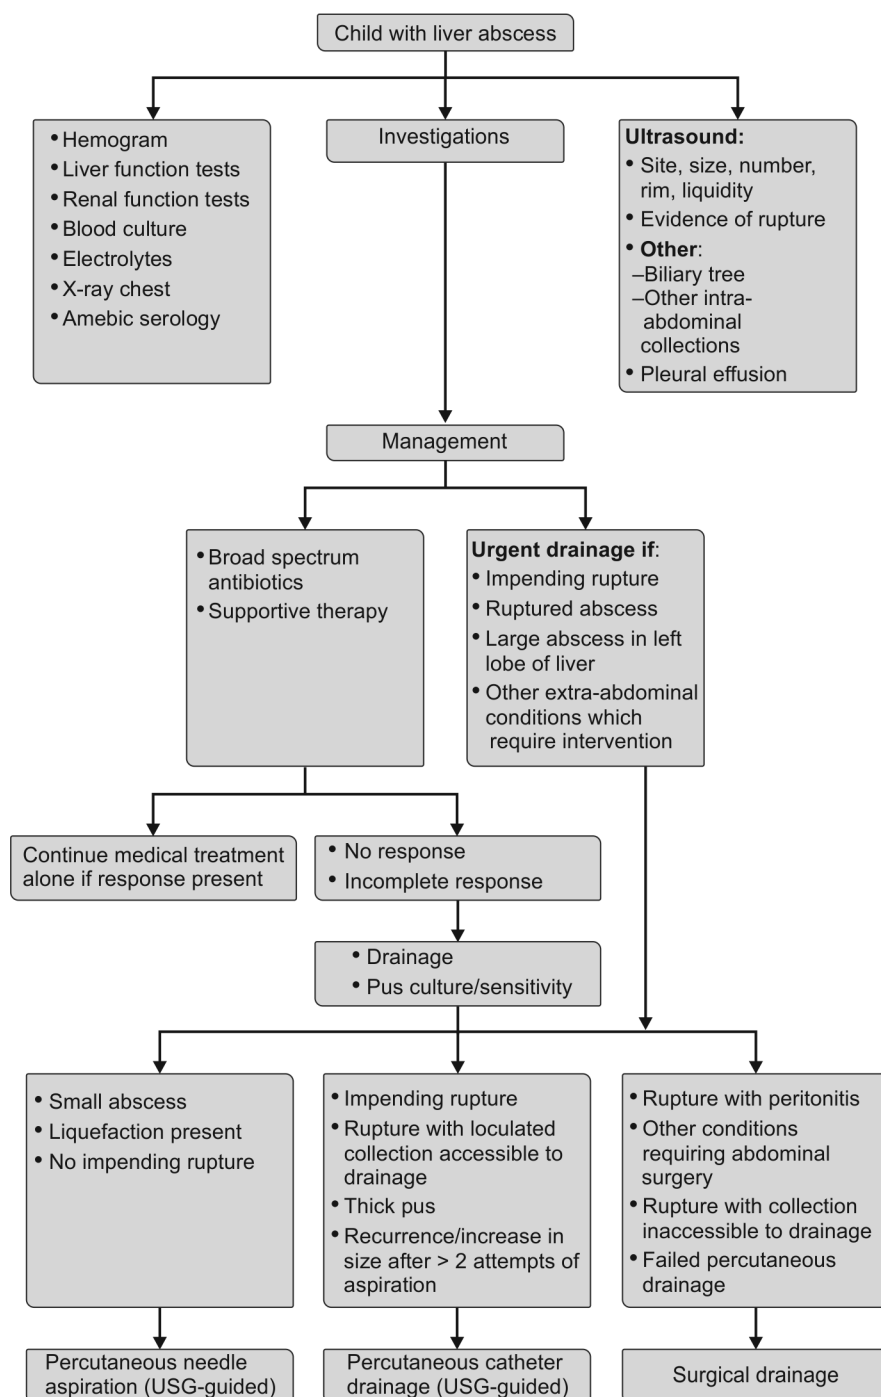

Figure 2 CT scan showing a multiloculated liver abscess (*honeycomb*) with impending rupture

Flow chart 1 Approach to management of liver abscess

IN A NUTSHELL

1. Most liver abscesses are pyogenic, less commonly amebic, and rarely tubercular or fungal.
2. Predisposing factors include malnutrition, intra-abdominal infections, immune deficiency disorders, particularly CGD and biliary anomalies.
3. Most of the abscesses are single and occur in the right lobe. Fever, right hypochondrial pain and tender hepatomegaly are predominant presenting features.
4. *Staphylococcus* is the most common organism in pyogenic abscesses. Gram-negative organisms are commoner in infants. *Entamoeba histolytica* causes ALA.
5. Ultrasonography is the first imaging modality for diagnosis. CECT scan is required in complications like rupture, or where USG is not diagnostic.
6. Complications include rupture into surrounding organs (peritoneum, subdiaphragmatic space, pleural cavity), jaundice, hemobilia and dissemination of infection with septic shock.
7. Antibiotics and drainage is the mainstay of treatment. A combination of cloxacillin/vancomycin with ceftriaxone and metronidazole is given first and later modified as per response and culture sensitivity of isolated organism. Recommended duration of antibiotics for pyogenic abscess is 4–6 weeks.
8. Ultrasound-guided percutaneous drainage (needle aspiration or catheter drainage) is preferred over open surgical drainage. Drainage is indicated in patients not responding to antibiotics in 48–72 hours, impending rupture, or rupture.

Chapter 37.7

Acute Hepatitis

Barath Jagadisan

Acute hepatitis is a nonspecific term that refers to an acute inflammation of the liver resulting from a wide range of etiologies. Even though the presentation may be acute, it does not always result from an acute disease process. Many of the etiologies may have a long-standing silent disease process preceding the acute presentation. The clinical presentation can be overlapping and therefore, finding the etiology of acute hepatitis can be a diagnostic challenge. Depending on the etiology, acute hepatitis may show a self-limiting course; or recovery in response to treatment or withdrawal of offending agent. It may also result in a fulminant course leading to an acute liver failure (ALF).

DEFINITION

The syndrome of *acute hepatitis* is usually diagnosed in the presence of elevated serum transaminases. The cut-off for diagnosis is usually variable ranging from five to ten times elevation to the upper limit of normal. Alkaline phosphatase (ALP) elevation is seen in all cases of acute hepatitis but is usually less than three times of upper limit of normal. The ALP elevation is proportionately less for the degree of jaundice if present. Visible jaundice or bilirubin elevation is not a must for the diagnosis of acute hepatitis. A pathological diagnosis of acute hepatitis on liver biopsy specimen is made if it reveals hepatocellular necrosis which may range from patchy necrosis to zonal necrosis and massive necrosis associated along with evidence of inflammation. The histopathology looks similar across most of the conditions and, therefore, is often not useful in etiological diagnosis.

CLINICAL FEATURES

Acute hepatitis resulting from most etiology has similar clinical features. The characteristic clinical features of acute hepatitis include nausea, vomiting, right hypochondrial pain and jaundice. The prodromal phase of nonspecific symptoms, including myalgia and anorexia, is characteristic of viral hepatitis, but may also be seen in other conditions. Severe cases manifest with encephalopathy, coagulopathy, sometimes ascites and other features of ALF. Further clinical evaluation may point toward specific etiology.

The disorders that may present with acute hepatitis are listed in **Table 1**. Nonhepatotoxic conditions, like acute cholangitis and large tumor emboli of the liver may also have an *acute hepatitis*-like presentation. Common causes are discussed below.

Infections with Hepatotropic Viruses

Hepatotropic viruses are the most common causes of acute hepatitis worldwide. Hepatitis A virus (HAV) and hepatitis E virus (HEV) are transmitted by feco-oral route, while Hepatitis B virus (HBV) and Hepatitis C virus (HCV) are parenterally transmitted. The parenterally transmitted viruses also cause chronic hepatitis and cirrhosis.

Hepatitis A virus is the most common cause of acute viral hepatitis in India. More than 80% of children over 10 years of age are seropositive for HAV. The infection may be asymptomatic or present with anicteric hepatitis in children of age less than 2 years. Children older than 5 year are more likely to present with acute hepatitis. Up to 50% of children between the age of 6–14 years present with jaundice as opposed to only 10% of children below 6 years of age. The presence of a phase of prodrome preceding

Table 1 Etiology of acute hepatitis in children and adolescents

Viral etiologies
• Hepatotropic viruses:
– Hepatitis A virus
– Hepatitis E virus
– Hepatitis B virus (acute infection and also reactivation of chronic infection)
– Hepatitis C virus (not common)
– Hepatitis D virus in patients with hepatitis B infection
• Nonhepatotropic viruses:
– Cytomegalovirus
– Epstein-Barr virus
– Adenovirus
– Enterovirus
– Herpes simplex virus
– Dengue virus
– Coxsackievirus
– Paramyxovirus
– Rubella
– Varicella-zoster
– Arbovirus
– Parvovirus B ₁₉
Nonviral infections
• Leptospirosis
• Enteric fever
• Tuberculosis
• Histoplasmosis
Drug-induced liver disease
Autoimmune liver disease
Wilson disease
Ischemic hepatitis
Acute Budd-Chiari syndrome
Systemic diseases , e.g., systemic lupus erythematosus, macrophage activation syndrome associated with juvenile idiopathic arthritis, hemophagocytic lymphohistiocytosis presenting with liver failure
Reye's syndrome
In pregnant adolescents
• Acute fatty liver of pregnancy
• HELLP syndrome (hemolysis, elevated liver enzymes, low platelets)

the jaundice, which is characterized by anorexia and nonspecific symptoms, is very characteristic of viral hepatitis. The case fatality rate, resulting from acute liver failure (ALF) in HAV infection, is less than 1% in children. Relapsing hepatitis with intervening improvement of hepatitis is unique to HAV infection. There may also be a phase of cholestatic hepatitis where the transaminases start falling and the bilirubin elevation with predominant ALP elevation are accompanied by pruritus. The diagnosis is usually confirmed by demonstrating IgM anti-HAV antibodies.

In some areas of India, HEV infection is endemic and causes acute hepatitis which is indistinguishable from that caused by HEV. The diagnosis may be established by demonstrating IgM anti-HEV antibody. ALF is less common with HEV than HAV infection.

Hepatitis B virus (HBV) infection is more often seen in children as a result of vertically transmitted chronic infection which remains in an immunotolerant phase in the initial few years of life. Horizontally transmitted HBV infection may also present as acute hepatitis and in such cases the infection frequently gets cleared. Otherwise it persists as a chronic infection. In the background of chronic HBV infection, an acute on chronic hepatitis may occur due to immune activation attempting at clearance of the virus, which may or may not result in seroconversion. Similarly, reactivation

of HBV virus years after seroconversion may also lead to an acute hepatitis even though this phenomenon is more likely to be seen in an older adult. The diagnosis is made by looking for hepatitis B surface antigen (HBsAg) and IgM anti-HBc antibody. HBsAg may be absent during seroconversion in acute HBV infection or rarely in the setting of chronic HBV infection when HBsAg is being lost and anti-HBs antibody appears. IgM anti-HBc antibody, therefore, should be sent in all cases. It diagnoses acute HBV infection even in the absence of HBsAg in acute infection. It should be remembered that demonstration of IgM anti-HBc antibody is not specific for acute HBV infection as it is also seen in exacerbation of hepatitis in chronic HBV infection, even though the titers may be comparatively low. In a given case, unless there is previous documentation of a chronic infection or there is clinical or histopathological evidence of chronicity, confident differentiation between an acute HBV infection and acute exacerbation of a chronic hepatitis based on the titers of IgM anti-HBc antibody alone can be difficult.

Hepatitis C virus infection rarely presents with an acute hepatitis like picture.

Infections with Nonhepatotropic Viruses

Epstein-Barr virus infection presents with features of infectious mononucleosis along with hepatitis. Cytomegalovirus infection presents with mononucleosis like syndrome and acute hepatitis is a part of this systemic disorder. Herpes simplex virus (HSV) infection and enterovirus infection are important causes of acute hepatitis and liver failure in the neonatal period. The presence of vesicles and definite demonstration of HSV in the mother are not essential in the diagnosis of HSV infection in a newborn. Since a delay in diagnosis increases mortality, all children with neonatal liver failure are treated with acyclovir directed against HSV. In India, dengue has been known to present with features of acute hepatitis.

Nonviral Infections

Leptospirosis is a frequent cause of acute febrile hepatitis in India. The illness is biphasic and may be anicteric. The second phase may be characterized by aseptic meningitis, myalgia, nausea and vomiting. In the severe form of the disease, leptospirosis is a febrile icteric illness with high bilirubin in the presence of a moderate transaminase elevation. This dissociation is because of the absence of hepatic necrosis in leptospirosis. Acute kidney injury resulting from acute tubular necrosis is characteristic of the illness. Hemorrhagic manifestations are accompanied by features of capillary leak. The febrile illness, presence of similar infections in the community in an endemic area or during an epidemic and the dissociation between the bilirubin and the enzyme are useful clues in diagnosis.

Enteric fever is a common infection in India and a common differential diagnosis of acute viral hepatitis, the only major differentiating feature being the presence of fever. The jaundice in enteric hepatitis is usually mild initially. The acute febrile hepatitis of enteric fever may even manifest as ALF. The ratio of alanine aminotransferase (ALT) to lactate dehydrogenase (LDH) (in multiples of the upper limit of normal) that is less than 4 is often suggestive of enteric hepatitis. Enteric fever may also manifest as cholecystitis or liver abscess.

In the Indian context, it is to be remembered that simultaneous infections are not uncommon, for example, hepatitis A infection occurring along with enteric fever. Other common infections like scrub typhus occurring in endemic areas are also known to cause acute hepatitis.

Malaria, a common endemic infection, presents with conjugated jaundice in severe cases due to hepatopathy. This malarial hepatopathy is a febrile illness in which the transaminase

levels are usually low but high levels have also been documented. Invariably, acute inflammation is never seen in malarial hepatopathy and hence does not qualify as *hepatitis* in the strict sense of the term.

Autoimmune Liver Disease

Autoimmune liver disease (AILD) is a chronic disease characterized by autoantibodies against antigens in the liver leading to progressive liver damage. This may or may not be associated with autoimmune diseases affecting other organs. In up to 40% of the cases, the presentation may be in the form of an acute hepatitis. AILD is more often seen in adolescent girls but it may be seen even in young children including infancy. The type 1 AILD is characterized by antibodies to smooth muscle antigen (anti SMA) and antinuclear antibodies (ANA) while the type 2 has antibodies to liver-kidney microsomes type 1 (anti-LKM 1). Over two-thirds of AILD in children is type 1. Both types can present with acute hepatitis but a presentation with ALF is more often seen in type 2. The diagnosis of AILD in this situation is usually suspected after infectious, drug, toxic and metabolic disorders are ruled out. Investigating for IgG elevation and anti-SMA and ANA at 1:20 dilution and anti-LKM 1 at 1:10 dilution are part of work-up but elevation of IgG or seropositivity for the autoantibodies are not essential for a diagnosis of AILD. Even though the classical histopathological feature of AILD is described as an interface hepatitis and plasma cell infiltration, these are always not found. The absence of plasma cell infiltrate does not rule out AILD. Centrilobular necrosis as seen in acute viral hepatitis and toxic hepatitis may be seen with a mononuclear infiltrate. AILD may manifest as steatosis or steatohepatitis. Close attention to details might reveal associated autoimmune disease in 20% cases. Early diagnosis of AILD hinges on carefully excluding other etiology.

Wilson Disease

Wilson disease, one of the most common causes of chronic liver disease in children, may present with manifestations suggesting an acute hepatitis. Often such presentation can be fulminant, resulting in liver failure. In the setting of an ALF, diagnosis of Wilson disease can be a challenge. Kayser-Fleischer ring is not present in most children with hepatic presentation in the first decade. The demonstration of a low ceruloplasmin in ALF may not be indicative of Wilson disease as it may very well be the result of poor hepatic synthetic function. Elevated 24-hour urine copper may also be ascribed to the extensive liver necrosis in ALF. A family history may not be present in every case. Associated neurological manifestations or preceding deterioration in school performance or handwriting, if present, might give a clue. Up to one-fourth of these patients may have an associated Coomb's negative hemolytic anemia or a hemolytic episode in the past. The aspartate aminotransferase (AST) is raised more than the ALT, indicating the mitochondrial damage that is characteristic of Wilson disease. Also the ALP is disproportionately low for the bilirubin elevation. A ratio of ALP in IU/L to serum bilirubin level in mg/dL that is less than 2 is indicative of possible Wilson disease. More often the diagnosis is made from a combination of findings that include hemolysis and the above-mentioned enzyme ratios. Children with acute fulminant form of Wilson disease may also have renal failure because of the pigmentary acute tubular necrosis caused by hemolysis. Presentation with ALF, especially with renal failure, almost always requires liver transplantation for survival. For lesser degrees of decompensation, the new Wilson index is used to predict survival (**Table 2**). Children with a score of more than 11 do not survive without transplantation. This score needs to be validated further with larger studies.

Table 2 Prognostication in Wilson disease—the new Wilson index

Score	Serum bilirubin ($\mu\text{mol/L}$)	International normalized ratio	Serum aspartate transaminase (IU/L)	Total leukocyte count ($10^9/\text{L}$)	Albumin (mg/dL)
0	0–100	0–1.29	0–100	0–6.7	> 4.5
1	101–150	1.3–1.6	101–150	6.8–8.3	3.4–4.4
2	151–200	1.7–1.9	151–300	8.4–10.3	2.5–3.3
3	201–300	2.0–2.4	301–400	10.4–15.3	2.1–2.4
4	> 300	> 2.4	> 400	> 15.3	< 2

Note: Score more than or equal to 11 indicates poor prognosis and mortality.

Drug-induced Liver Disease

Drugs are known to produce a varied spectrum of hepatic injury. Acute hepatitis is most common manifestation of drug-induced liver disease (DILI). Drug-induced liver injury is classified based on the histopathological features in liver biopsy. In acute hepatitis, it manifests as inflammatory infiltration along with zonal, bridging, patchy or panlobular necrosis (depending on the drug and the severity of the injury). Biochemically, predominant hepatocellular damage is characterized by an ALT level greater than two times the upper limit of normal or the ALT-to-ALP ratio is more than or equal to 5. There may also be a picture of overlap between hepatitis and cholestasis.

Based on the probable mechanistic model of causation and the clinical and laboratory features, two different types of acute hepatitis are known: (1) *immunoallergic type* and (2) mediated through *metabolic idiosyncrasies*. The former is not related to the dose of the offending drug. It starts manifesting anytime from 2 to 10 weeks after starting the drug and is not usually affected by other coadministered drugs. The illness is usually preceded or associated with fever and extrahepatic manifestations like rash and lymphadenopathy. From one-third to two-thirds of these patients have eosinophilia on peripheral smear and also demonstrated in tissues. Autoantibodies may be demonstrable. The disease subsides rapidly with the withdrawal of the drugs and reappears rapidly in a few days of reintroduction. Drugs, like phenytoin, sulfonamides and nitrofurantoin are known to present with immunoallergic hepatitis.

In contrast, *metabolic idiosyncrasies* are known to be underlying mechanism in acute hepatitis caused due to isoniazid and pyrazinamide. The onset of liver injury ranges from 2 weeks to 6 months and in some cases up to 1 year. There may not be a dose relation to the injury as the hepatitis is a result of metabolic idiosyncrasies. A few drugs are known to have a partial relation to the dose. Coadministered drugs may affect metabolic pathways and augment liver injury. Unlike in the previous type, fever and extrahepatic systemic manifestations are not usually seen. Eosinophilia and autoantibodies are less common. The recovery may not be dramatic with drug withdrawal and the children may continue to worsen or recover slowly. Rechallenge after recovery may result in recurrence of manifestations but unlike in the immunoallergic type, one-third of these children may tolerate the drug with no symptoms and if at all with only mild transaminase elevation.

Acetaminophen toxicity is a dose dependent liver injury that may have very high transaminase levels but has predominantly zonal or massive necrosis in the liver without much inflammation to qualify as hepatitis.

Phenytoin Hepatotoxicity: A Prototype for Immunoallergic Reactions

Phenytoin, a commonly used anticonvulsant, is known to cause a wide range of hepatic manifestations. Yet the most common form is acute hepatitis, which can be life-threatening when associated with liver failure. The hepatitis due to phenytoin may be mistaken for

mononucleosis-like syndrome caused by viruses as it presents with systemic manifestations of fever, lymphadenopathy, leukocytosis, and lymphocytosis. Eosinophilia is prominent. Skin reactions may range from morbilliform lesions to Steven-Johnson syndrome and toxic epidermal necrolysis. The hepatic involvement may be restricted to transaminitis and mild jaundice or may go on to hepatic failure with ascites and encephalopathy. The histopathology may be characterized by inflammation, patchy necrosis or more extensive hepatocellular loss. Prompt withdrawal of the drug is important. Despite the anecdotal nature of the evidence, steroids are often used in these cases. The possible mechanism is a deficiency of an epoxide hydrolase enzyme that is involved in the detoxification of the arene oxide metabolite of phenytoin, thereby resulting in haptens that initiate an immunological injury. There is also an evidence against this hypothesis, thus questioning the exact mechanism. There is also a suspicion that coadministration of phenobarbitone may increase the severity of phenytoin induced hepatotoxicity.

Isoniazid Hepatotoxicity: A Prototype for Hepatitis Due to Metabolic Idiosyncrasies

Isoniazid is a common cause of acute hepatitis in India. Patients on both therapeutic and prophylactic isoniazid may develop acute hepatitis. The frequency is higher with simultaneous use of rifampicin and pyrazinamide. Patients with severe types of tuberculosis, like meningitis and malnourished children, tend to develop acute hepatitis more often. The simultaneous use of phenobarbitone is a potential setting for acute hepatitis. This may be due to cytochrome p450 stimulation by phenobarbitone. It is believed that rapid acetylators who synthesize the acetyl isoniazid intermediate faster have higher rates of liver injury. There may be partial dose relation to the hepatotoxicity even though some studies do not show higher frequency of hepatitis with higher doses.

Usually 10% of the patients on isoniazid are known to develop transient elevation in transaminases. Up to one-third of patients have been documented to have transaminitis in other studies. Patients with elevation of transaminase levels above five times the baseline values, especially with bilirubin elevation, warrant withdrawal of the drug. Elevation over ten times of the baseline is known to develop severe symptoms. Symptoms include nonspecific features, such as anorexia, nausea and vomiting. Systemic features, such as fever, lymphadenopathy, rashes and eosinophilia are not seen. The patient may develop jaundice and features of liver failure such as encephalopathy and coagulopathy. Liver failure indicates poor prognosis and may result in liver transplantation. Patients, in whom the drug is stopped early before the onset of failure, tend to improve with drug withdrawal.

The histopathology in half of these patients shows a picture indistinguishable from acute hepatitis with patchy necrosis and inflammation along with hydropic changes in the rest of the cells. Massive hepatocellular necrosis is seen in severe cases.

Rechallenge with the drugs has been shown to produce an accelerated recurrence of symptoms, but Indian studies show that, with gradual reintroduction of the drug, majority of the patients can be restarted on the drug.

Serial monitoring of enzymes is advocated after starting isoniazid to detect hepatitis early but this does not prevent all cases of hepatitis. The monitoring protocol can be quite variable. Attention to symptoms and detecting the early nonspecific features can be very useful.

Ischemic Hepatitis

Ischemic hepatitis is more commonly seen in a hospital setting in a child who has experienced a hypotensive episode as a result of either septic shock or hemorrhage or congestive cardiac failure with or without an underlying cardiac condition. Documentation of hypotension may not be there in all cases. The child presents with high levels of serum transaminases (in thousands). Transient elevation of prothrombin time may also be seen. The rise in bilirubin is seen after 1 or 2 days. The transaminases normalize rapidly in 7–10 days. The survival of the patient depends on the underlying precipitating condition rather than on the liver injury itself. The importance lies in recognizing the entity and avoiding confusion with either viral, autoimmune, toxic, or drug induced liver injury. The associated LDH elevation with an ALT to LDH ratio less than 1.5 might help in differentiating from viral hepatitis. Even though liver biopsy is not warranted and never done for the condition itself, biopsy might show necrosis, especially centrilobular. This might mimic the necrosis in viral hepatitis, except for the fact that inflammation is characteristically absent. Thus, histopathologically this entity does not behave as *hepatitis*.

TREATMENT

Close monitoring of liver function tests for any worsening of prothrombin time and clinical features suggestive of liver failure is an essential aspect of early supportive management. Specific management may vary depending on the etiology. Early withdrawal of the offending drug, early immunosuppression in autoimmune hepatitis and appropriate antibiotics in case of leptospirosis and enteric fever are a few examples. D-Penicillamine in case of Wilson disease may not be effective in cases presenting as ALF and renal failure and early transplantation is necessary. No disease-specific treatment is applicable for HAV or HEV-induced acute viral hepatitis or ischemic hepatitis.

IN A NUTSHELL

1. Acute hepatitis is a nonspecific term that refers to an acute inflammation of the liver resulting from a wide range of etiologies.
2. It is characterized by elevated transaminases with or without jaundice along with ALP elevation that is proportionately less in comparison to the degree of jaundice.
3. Liver biopsy in acute hepatitis may show hepatocellular necrosis which may range from patchy necrosis to zonal necrosis and massive necrosis associated along with evidence of inflammation.
4. It does not always result from an acute disease process.
5. Acute viral hepatitis caused by HAV is the most common cause of disease in children in India.
6. Enteric fever and leptospirosis are important causes of acute febrile hepatitis.
7. Drug induced hepatitis is not uncommon and a careful history and early withdrawal can be lifesaving.
8. Presence of hemolysis, the ratio of AST to ALT and ratio of ALP to bilirubin can be useful pointers toward a diagnosis of Wilson disease when it presents with ALF.
9. The absence of autoantibodies does not rule out the possibility of autoimmune hepatitis as a cause of acute hepatitis.
10. Close monitoring of INR is essential in managing a case of acute hepatitis.

Chapter 37.8

Chronic Liver Disease

Seema Alam, Rajeev Khanna

Chronic liver disease (CLD) refers to a spectrum of liver diseases including a wide range of disorders which may be genetic or acquired. These disorders may be infective, metabolic, storage, vascular, structural and autoimmune. The definition for CLD, which includes the symptom duration of more than 6 months or 26 weeks, may not apply to infants where many inborn errors of metabolism cause CLD yet are apparent for less than 6 months. Since most acute liver diseases settle down within 12 weeks, any prolongation should raise suspicion of potential CLD. CLD is defined based on evidences seen clinically, biochemically, radiologically and histopathologically (**Table 1**).

The clinical spectrum of CLD may vary from asymptomatic presentation, organomegaly, jaundice, to end-stage liver disease. Recognizing CLD early is important in children as some of these disorders are reversible with early intervention. Compensated CLD is likely to be asymptomatic and go unrecognized. On decompensation, CLD becomes symptomatic with jaundice, encephalopathy or ascites. If the acute decompensation has rapidly developed within 4 weeks in the foreground of pre-existent CLD, then this syndrome is called *acute on chronic liver failure* (ACLF) (**Box 1**). Causes of acute decompensation could be acute viral hepatitis, drug or exacerbation of the underlying cause of CLD.

BOX 1 Definition of acute on chronic liver failure

Acute on chronic liver failure (ACLF) is defined as acute hepatic insult manifesting as jaundice and coagulopathy (Bilirubin > 5 mg/dL, INR > 1.5) complicated within 4 weeks by ascites and/or encephalopathy in a patient with previously diagnosed or undiagnosed chronic liver disease.

Abbreviation: INR, international normalized ratio.

CLASSIFICATION

Parenchymal CLD Presence of jaundice with or without ascites, coagulopathy and hepatic encephalopathy (HE) would suggest a parenchymal liver disease. Parenchymal CLD cases can be broadly categorized into infective, metabolic (including storage), immunologic and vascular etiologies (**Table 2**).

Cholestatic CLD Presence of jaundice, pruritus, and clay stools suggest a biliary disease causing cholestatic CLD. Causes of cholestasis in children are depicted in **Table 2**.

EPIDEMIOLOGY AND ETIOLOGY

The exact prevalence of CLD in children is not known. On an average, tertiary care hospitals in India manage 100 cases of CLD

per year. The results from a single center in USA show 522 children with CLD included in the liver waiting list: 294 (56%) were girls and 345 (66%) were below 1 year of age. The diagnoses were: 377 (72%) biliary atresia (BA), 54 (10%) alpha-1 antitrypsin deficiency, 40 (7.6%) cryptogenic cirrhosis, 33 (6.3%) autoimmune hepatitis (AIH), 11 (2%) type 1 tyrosinemia, 5 (1%) biliary hypoplasia and 2 (0.3%) Wilson disease. In contrast the most common causes of CLD as evident from three tertiary care centers in India are chronic hepatitis B infection and Wilson disease (**Table 3**). But we must remember that chronic hepatitis B may not show evidence of CLD in childhood except fibrosis on histopathology. Among the cholestatic liver disease, BA is common world over.

PATHOPHYSIOLOGY**Development of Fibrosis and Cirrhosis**

Fibrosis is the wound healing response to a variety of acute and/or chronic stimuli, including viral infection, toxins, metabolic disease, cholestasis and drugs. Fibrosis is associated with a number of pathological and biochemical changes leading to structural and metabolic abnormalities, as well as with increased hepatic scarring. Hepatic fibrosis develops due to an increase in fibrillar collagen synthesis and deposition along with insufficient remodeling. Cirrhosis lies at the extreme end of the pathological spectrum and is characterized by fibrosis, architectural distortion and conversion of normal liver architecture into abnormal nodules. Cirrhosis is representing a state of competing processes of cell-injury related inflammation leading to cell death (necrosis) or response to injury (fibrosis), and regeneration (nodule formation). If necrosis predominates with little regeneration, hepatocellular failure or synthetic liver failure occurs resulting in ascites and coagulopathy. If fibrosis and regeneration predominate, portal hypertension (PHTN) is the result. Fibrosis of portal tracts will cause increased resistance to portal blood flow precipitating PHTN. It also leads to compression of biliary structures: this architectural distortion decreases oxygen and metabolites reaching the hepatocytes which in turn leads to continued cell injury even after the original cause of insult is over.

Host and Genetic Predisposing Factors

Apart from gender and duration of exposure, ethnicity and host genetic factors are likely to influence disease progression and prognosis. For example, although, patients with chronic hepatitis C virus (HCV) infection may develop cirrhosis after 20–50 years but long duration of infection, male gender, and alcohol consumption with positive family history may play an important role in early cirrhosis due to HCV. *Angiotensinogen* is an example of a candidate gene that is involved in Caucasians with chronic HCV.

In autoimmune hepatitis, the anomalous presentation of human leukocyte antigen (HLA) class II in hepatocytes, causes

Table 1 Evidence of chronic liver disease in children

Clinical	Biochemical	Imaging (Ultrasonography/CT)	Histopathology
History	Synthetic dysfunction	Signs of cirrhosis	• Increased liver fibrosis
Recurrent jaundice	Low albumin	Increased echogenicity	• Presence of regenerative nodules
Abdominal distension, Altered sensorium,	Reversal of A:G ratio	Irregularity of hepatic (nodular) surface	• Collapse of the normal lobular architecture
Swelling over body	Elevated INR	Enlarged caudate lobe	
Upper gastrointestinal bleed	Impaired secretory function	Evidence of portal hypertension	
Physical findings	Elevated ammonia	Splenomegaly	
Firm sharp or shrunken liver with or without splenomegaly	Elevated bilirubin	Dilated splenoportal axis	
Cutaneous signs of liver disease	Hypersplenism	Reversal of portal flow	
Periumbilical collaterals	Thrombocytopenia + Leucopenia/	Presence of collaterals	
Evidence of free fluid	Anemia		

Table 2 Etiology of the chronic liver disease in different age groups

Classification Age-group	Parenchymal				Cholestatic
	Metabolic	Immunologic	Vascular	Infective

cell-mediated immune responses against the host liver, leading to liver fibrosis. Similarly some reports suggest that in addition to gender, certain HLA-II alleles and genetic variations of tumor necrosis factor alpha (TNF- α) influence both susceptibility and disease progression in primary sclerosing cholangitis (PSC). Metabolic disorders such as hemochromatosis and Wilson disease are typically accompanied by chronic hepatitis and fibrosis. In hereditary hemochromatosis, the excessive absorption and accumulation of iron in tissues and organs including liver is related to mutations in the *HFE* (High-iron) gene. Wilson disease is a genetic disorder leading to copper accumulation in the liver due to mutations in the ATPase (ATP7B) that transports copper. Inborn errors of metabolism with their genetic predisposition would be discussed presented later in the laboratory work-up section.

Molecular Mechanism of Fibrosis

Several cell types like hepatic stellate cells (HSC), Kupffer cells and hepatocytes are involved in the pathogenesis of hepatic fibrosis. Molecular pathogenesis of hepatic fibrosis is depicted in **Figure 1**.

- Following injury to the hepatocytes, quiescent HSCs become activated and acquire a myofibroblast-like phenotype losing

their typical star-shape by increasing the expression of α -smooth muscle actin. They become proliferative, motile, profibrogenic, contractile and show abundant rough endoplasmic reticulum.

- Damaged hepatocytes release lipid peroxidation products, metabolites of drugs or hepatotoxins, as well as reactive oxygen species (ROS) (hydrogen peroxide, superoxide radical) and induce HSC activation.
- Activated Kupffer cells release two potent profibrogenic cytokines (TGF- β and platelet-derived growth factor) activating HSC further.
- Kupffer cell phagocytic activity generates large amounts of ROS that activate HSC and induce their fibrogenic potential. ROS also up-regulate the expression of critical fibrosis-associated genes such as *COL1A1*, *COL1A2*.
- Increased permeability due to disruption of the intestinal epithelial barrier, bacterial overgrowth and altered gut flora promote bacterial translocation. Decreased bile acid secretion and impaired intestinal motility in liver cirrhosis also contribute to bacterial overgrowth. In cirrhosis, entry of bacteria and bacterial products to the liver induces activation of Kupffer cells and HSC through toll-like receptors (TLRs).
- Matrix metalloproteinases (MMPs) are the main enzymes responsible for degradation of extracellular matrix (ECM) while TIMPs (tissue inhibitor of metalloproteinases) inhibit MMPs. The balance of MMP-TIMP balance is crucial for remodeling of ECM. Activated HSC also produce MMP1 and MMP13. Moreover, activated HSC upregulate the expression and synthesis of TIMP1 and TIMP2. The net result is the deposition of mature collagen fibers within the *space of Disse* and thus scarring.

Portal Fibrosis

In the fibrotic or cirrhotic liver, the composition of the ECM has some qualitative and quantitative changes in the periportal and perisinusoidal areas. The amount of fibrillar collagens and proteoglycans increases up to six times than in normal livers. This leads to loss of endothelial cell fenestrations, altered hepatocyte function and subsequent nonparenchymal cell damage. Apart from hepatic fibrosis, portal fibrosis is another important event happening concurrently in cirrhosis. There are three cell types which play a role in portal fibrosis:

- Portal fibroblasts which lie quiescent in normal liver, form onion-like configurations around biliary structures. They also acquire a myofibroblast phenotype, and cause early deposition of ECM in portal zones.
- Mesenchymal cells emerging from epithelial-to-mesenchymal transition (EMT) after injury, derived either from resident hepatocytes or from biliary epithelial cells. EMT could be

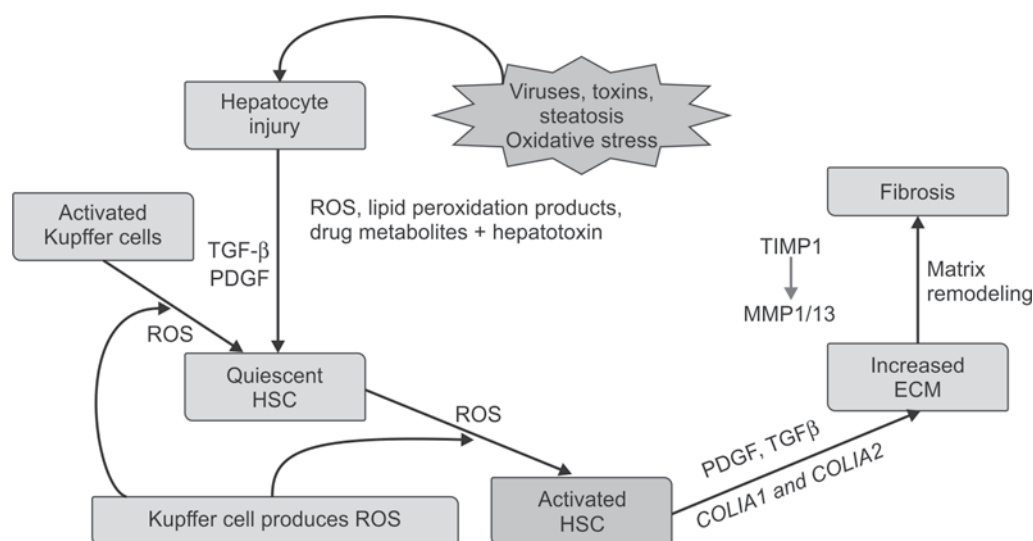

Figure 1 Molecular pathogenesis of fibrosis and cirrhosis

considered a mechanism participating in the pathogenesis of cholestatic liver disease.

3. Bone marrow-derived mesenchymal stem cells have the capacity to differentiate into hepatocytes, biliary epithelial cells, sinusoidal endothelial cells and even Kupffer cells.

CLINICAL FEATURES

Children with CLD or cirrhosis may present with failure to thrive, anorexia, easy fatigability and muscle weakness. Jaundice is sometimes present but not always noticeable. Alternatively, when CLD decompensates, jaundice, ascites, GIT hemorrhage, coagulopathy, spontaneous bacterial peritonitis, encephalopathy or hepatopulmonary syndrome (HPS) may signal the onset of the disease. Fever is occasionally present in decompensated CLD. Abdominal pain may be present and can be caused by peptic ulcer disease, gastritis, gastroesophageal reflux, or gallstones. Pallor could be due to anemia of CLD. Steatorrhea or fat malabsorption in CLD leads to malnutrition and rickets, often with pathological fractures. A history of epistaxis, hematemesis and hematochezia may be related to the coagulopathy of liver disease or to PHTN with esophageal and rectal varices. Hypersplenism is also a sign of portal hypertension.

Stigmata of Chronic Liver Disease

Amenorrhea, delayed puberty, pedal edema, ascites, clubbing or spider angiomas, palmar or plantar erythema and telangiectasia indicate the chronic nature and likelihood of hepatic fibrosis or cirrhosis. *Palmar erythema* is a nonspecific red discoloration of the palms and fingertips, indicative of a hyperdynamic circulation associated with cirrhosis (**Fig. 2A**). Skin flushing is frequently seen in cirrhotic patients due to increased circulatory vasodilators. In infants, palmar erythema may be accompanied by plantar erythema, which in older children is difficult to see due to keratinization of the soles. *Spider nevi* are telangiectasia consisting of a central arteriole with radiating small capillaries looking like a spider (**Fig. 2B**). These blanchable lesions, if more than 5 in number, are suggestive of CLD. Superficial distended capillaries (telangiectasia) on face (**Fig. 2C**) are common in CLD. Skin and extremity changes include jaundice, cyanosis, and pallor. Pallor may be present because of the anemia of CLD. Digital clubbing is seen due to chronic hypoxemia

secondary to HPS (pulmonary-systemic shunts and ventilation-perfusion mismatching) or in cases of biliary cirrhosis (**Fig. 2D**). Dupuytren contracture, gynecomastia, testicular atrophy and feminization are rarely seen in childhood. Pruritus is a common feature of cholestatic disorders which can be nocturnal or diurnal and affect the daily activities of the child. Scratch marks on the skin and shining nails are characteristic features of cholestatic liver disease, e.g., progressive familial intrahepatic cholestasis (PFIC) (**Fig. 2E**). All children of cholestatic liver disease should be carefully looked up for fat-soluble vitamin deficiency including toad-like skin, xerophthalmia, hematomas and rickets. Moreover PFIC type 1 and type 2 are short-statured children (**Fig. 2F**).

Nutritional Status of a Child with CLD

Table 4 shows the organic and nonorganic causes of malnutrition in CLD. Nutritional manifestations of cirrhosis include malnutrition, anorexia, malabsorption, steatorrhea, hypoalbuminemia, and fat-soluble vitamin deficiencies. Malnutrition is a common complication of liver disease, especially if the onset of liver disease is in infancy. CLD impairs the growth and pubertal spurt. Standard weight underestimates the extent of malnutrition in children due to associated ascites; the triceps skinfold thickness is more accurate assessment of patient's nutritional status. Vitamin A deficiency and rickets are commonly seen in all CLD and vitamin K deficiency can exacerbate other complications of cirrhosis, such as coagulopathy.

Ophthalmoscopic Examination

Cataract in infantile liver disease suggests the diagnosis of galactosemia. The characteristic greenish-brown ring at the periphery of the cornea called Kayser-Fleischer (K-F) ring is due to copper deposition in the Descemet membrane in Wilson disease. Visualization of K-F ring requires a slit-lamp examination, although sometimes it may be seen on torchlight. K-F rings may be present in 50% of the cases with liver disease and almost 100% of neurologic cases. The K-F ring may also be seen in patients with cholestatic liver disease. Sunflower cataract, though less common, is another ophthalmologic feature of Wilson disease. It is grayish-brown in color that may develop because of deposits of copper in the anterior and posterior lens capsule. Some of the lipid storage disorders (Gaucher disease and Niemann Pick type C) can present

Figures 2A to F (A) Palmar erythema; (B and C) Spider nevi and telangiectasia; (D) Clubbing in biliary cirrhosis; (E) Scratch marks in a patient with severe pruritus; (F) Short stature and rickets in a case with progressive familial intrahepatic cholestasis (PFIC2)

Table 4 Causes of malnutrition in childhood chronic liver disease

<ul style="list-style-type: none"> • Organic causes <ul style="list-style-type: none"> – <i>Reduced intake</i> <ul style="list-style-type: none"> ▪ Anorexia ▪ Early satiety: Compression of abdominal viscera by enlarged liver, spleen or ascites – <i>Malabsorption</i>: Reduced bile acids to the duodenum leading to malabsorption – <i>Alterations in metabolic milieu</i> <ul style="list-style-type: none"> ▪ Abnormalities in amino-acid and glucose metabolism ▪ Increased resting energy expenditure (Hypercatabolism) – <i>Endocrinal factors</i>: Reduced insulin-like growth factor-1 production by the liver • Nonorganic causes <ul style="list-style-type: none"> – Imposed restriction of fat and due to taboos, misbeliefs or improper education. – Restriction of protein intake during episodes of encephalopathy
--

with cherry-red spot on fundus examination. Vertical gaze palsy is seen in Niemann Pick type C and oculomotor apraxia in Gaucher disease. *Posterior embryotoxon* on slit-lamp examination in a cholestatic child would suggest Alagille syndrome.

Abdominal Examination

A shrunken and nodular liver is definitely CLD but if liver is enlarged, then firm to hard consistency (with well-defined or sharp margins) would indicate CLD. The spleen is enlarged, especially in the setting of PHTN. Ascites may be present and often is associated with hypoalbuminemia. Splenomegaly, ascites, caput medusae, hemetemesis, malena, prominent or distended abdominal veins

(Fig. 3), or rectal varices suggest PHTN and singly could be the only evidences of CLD in some patients. When seen in an infant, splenomegaly and/or ascites could also suggest an intrauterine infection and metabolic liver disease. A hard enlarged liver is almost always seen in the infantile and childhood cholestatic liver disease. Infants and younger children with cholestatic liver disease (e.g., biliary atresia) rapidly progress to biliary cirrhosis and PHTN. Older children with cholestasis (e.g., PSC) have much slower progress.

Neurological Examination

Presence of mental changes, asterexis, prolonged relaxation of deep tendon reflexes and positive Babinski's sign can indicate central nervous system involvement in CLD. The encephalopathy may be obvious, or it may present in subtle forms such as deterioration of school performance, depression or irritability. To diagnose encephalopathy in younger children needs a high degree of suspicion as even inconsolable cry can be suggestive sign. For more details, the readers are referred to the chapter on encephalopathy.

CHARACTERISTICS OF VARIOUS CAUSES OF CLD

Wilson Disease

Clinical manifestations of Wilson disease are rarely apparent before age 5 years. It is more common in older children closer to or in second decade of life. Copper first accumulates in the liver followed by accumulation in nervous system, cornea, kidneys, and other organs and tissues. Hence, the liver involvement is seen during childhood, whereas ophthalmological and neurological involvement is more common in adolescents and adults. In the age group 5–10 years, over 80% affected children present with hepatic involvement and rest with neuropsychiatric symptoms; in the second decade, 50% each present with hepatic and neuropsychiatric symptoms; and in adulthood, 25% present with

Figure 3 Prominent abdominal veins indicative of portal hypertension. Umbilical hernia due to tense ascites

hepatic whereas 75% with neuropsychiatric symptoms. Malaise, anorexia, fatigue, abdominal pain, and nausea may precede the onset of jaundice and hepatic dysfunction. Cholelithiasis (copper-deficient cholesterol-rich stones), due to hemolysis, is relatively common in adolescents. Precocious puberty and recent poor school performance is suggestive of Wilson disease. Family history suggestive of neuropsychiatric disorder should be sought. Renal, endocrine, and hematologic involvement causes symptoms in the second decade. A combination of liver dysfunction and other organ system involvement, at any age, should alert to possibility of Wilson disease.

Autoimmune Hepatitis

There are two types of AIH depending upon the type of associated antibodies. *Type 1 AIH* is when antismooth muscle antibodies (Anti-SMA) are present which accounts for two-thirds of the cases. If anti-liver kidney microsomal (Anti-LKM 1) antibodies are present, then it is *Type 2 AIH*. Three-fourths of all AIH cases are girls in both types. History of fever and features of autoimmune disorders (skin rashes, arthralgia/arthritis, thyroiditis, autoimmune anemia, inflammatory bowel disease, vitiligo, insulin-dependent diabetes, and nephrotic syndrome) would indicate etiologic possibility of AIH. History of diarrhea with or without blood could be point to an association with celiac disease or inflammatory bowel disease, respectively. The most common presentation of AIH is episodes of relapsing jaundice (without typical prodrome), with progressive fatigue, anorexia and weight loss present for months to years. There may be flares and spontaneous remissions which delay the diagnosis. Fewer cases of AIH present with CLD and PHTN, with no history of jaundice. Because of variable presentation, all progressive liver disease should be investigated for AIH in childhood. Anti-LKM1-positive patients are younger and present more often with acute liver failure. About 20% of autoimmune polyendocrinopathy candidiasis ectodermal dystrophy (APECED) may have type 2 AIH.

Chronic Viral Hepatitis

Chronic HBV is a relatively infrequent cause of CLD in children as it mostly remains silent. Of these children, however, 3–5% develop cirrhosis while 0.01–0.03% may end up with hepatocellular carcinoma (HCC). History of exposure in the form of transfusions (e.g. thalassemia or hemophilia), tattooing, earpiercing, renal dialysis, surgery, hospitalizations or intravenous drug abuse could suggest HBV- or HCV-associated CLD. HBV-positive mothers can clear the HBV during pregnancy, so HBV-positive child may have resulted from vertical transmission in an HBV-negative mother. There is possibility of horizontal transmission if there is an HBV-

positive household contact. Although incidentally detected cases are more often seen, previous history of jaundice with preceding prodromal phase and arthritis suggests an episode of acute HBV. Like HBV, HCV infection is also more common in the background of hematological disorders, e.g., thalassemia or hemophilia where repeated blood transfusions are needed. Chronic HCV is a slowly progressive disease so they usually present with CLD in adulthood and is an uncommon cause of CLD in pediatric age group.

Hepatic Vein Outflow Tract Obstruction

Hepatic vein outflow tract obstruction (HVOTO) could be present in 7–8 % of all childhood liver disease. History of ascites with abdominal pain without jaundice would suggest vascular cause, e.g., HVOTO. Outflow tract obstruction explains the tender enlarged liver which is associated with these cases. Prominent or engorged abdominal and back veins, refractory (rapidly filling) ascites, pedal edema, enlarged liver or shrunken right lobe and compensatory enlargement of left lobe of liver, and mild or no splenomegaly despite other evidences of PHTN are the most prominent features of HVOTO. Majority of the cases of HVOTO at our center had a chronic form of presentation which is the most common presentation. Pedal edema suggests inferior vena cava (IVC) obstruction. History of deep vein thrombosis in the child and family may be present. History of intake of contraceptive pills in adolescent girls or anabolic steroids or herbal tea can be present in HVOTO.

Metabolic Liver Disease

These inborn errors of metabolism include liver disease as a clinical entity. Suggestive family history, consanguinity and dysmorphism with history of abortions or sib loss indicate metabolic liver disease (MLD). History of hypoglycemia, encephalopathy, seizures and failure to thrive in an infant or child would further suggest MLD. An infant with CLD presenting with hypoglycemia could be galactosemia or tyrosinemia type 1. These infants will decompensate with ascites, jaundice and rarely encephalopathy by the end of first 6 months of life. Infants with galactosemia may have cataract, seizures and associated *E. coli* sepsis. Children with tyrosinemia type 1 may have boiled cabbage body odor and refractory rickets. Hereditary fructose intolerance (HFI) should be suspected if there is history of vomiting and diarrhea following addition of fructose (in form of fruit juice or honey or sugar syrups, etc.) to the diet. Sometimes the timing of presentation could coincide with addition of medications in form of syrups and drops. Aversion to sweets in an older child would be present in fructose intolerance. Glycogen storage disorder (GSD) type 4 and Gaucher disease also may present as CLD. Children suffering with GSD type 4 may develop cirrhosis and PHTN in early childhood, whereas patients with Gaucher disease become cirrhotic in adolescence to adulthood. Gaucher disease presents with prominent splenomegaly, pallor and petechial rashes (due to bone marrow infiltration) and skeletal dysostosis in younger children (See Section 3 for details of Gaucher disease).

Drug-induced Liver Injury (DILI)

A small proportion of patients may develop CLD due to liver injury caused by various medications, herbs, or xenobiotics, with the exclusion of other common etiologies. Typically, the clinical history indicates a suspect drug with reasonable temporal association to the illness. Combination antituberculosis drugs were the most common cause, followed by the anticonvulsants, phenytoin and carbamazepine in a group of 39 Indian children and adolescents.

Cholestatic Liver Disease

Biliary cholestasis is the prominent finding in all the cholestatic diseases, mostly presenting with jaundice, pruritus,

hyperpigmentation, xanthomas and fat soluble vitamin (Vitamin A, D, E, K) deficiencies. Pruritus is a predominant symptom in certain cholestatic disorders like PFIC, Alagille syndrome and sclerosing cholangitis. Cholangitis presenting with fever, jaundice, pain abdomen and pale-colored stools is seen in postoperated BA, sclerosing cholangitis and structural defects (choledochal cyst type 4a and 4b and Caroli disease). Cholestatic liver diseases progress slowly to cirrhosis except those presenting in infancy (biliary atresia, subacute sclerosing cholangitis, progressive familial intrahepatic cholestasis).

Biliary Atresia

Biliary atresia without Kasai surgery proceeds to cirrhosis with PHTN in infancy and only 10% may survive up to 2–3 years of life. Among those operated, 20% may require liver transplantation in childhood. About 80% of children with BA with successful Kasai surgery would go through to adult life with the native liver, albeit with cirrhosis and PHTN. The operated cases of BA, who have repeated episodes of cholangitis, are more likely proceed to cirrhosis and PHTN.

Progressive Familial Intrahepatic Cholestasis

Progressive familial intrahepatic cholestasis refers to a group of autosomal-recessive cholestatic liver disorders of childhood. The estimated incidence varies between 1/50,000 and 1/100,000 livebirths. PFIC1 is due to defect in *ATP8B1* encoding the FIC1 protein which impairs the transport of bile constituents, e.g., phosphatidylcholine. PFIC2 is caused by defect in *ABCB11* encoding bile salt export pump (BSEP) protein. Defects in *ABCB4*, encoding multidrug resistance 3 protein (MDR3) impair biliary phospholipid secretion, resulting in PFIC3. PFIC1 and PFIC2 have onset in the early infancy. Onset of PFIC3 may be in late infancy or childhood or even during young adulthood.

The main clinical manifestations include cholestasis, pruritus and jaundice. PFIC patients usually develop fibrosis and end-stage liver disease before adulthood. PFIC 1 and PFIC 2 can be differentiated on the basis of some extrahepatic features which are associated with PFIC 1. The *ATP8B1* gene is expressed in various organs, including the liver, pancreas, kidney and small intestine, but is more highly expressed in the small intestine than in the liver. Therefore, it is thought to be also involved in the enterohepatic cycling of bile salts. This may also explain the chronic diarrhea present in a few children with PFIC1 which may worsen after liver transplantation. Other extrahepatic features associated with PFIC1 include persistent short stature, deafness and pancreatitis. These suggest a general cell biological function for *FIC1*. The phenotypic spectrum of PFIC3 ranges from neonatal cholestasis to cirrhosis in young adults.

Sclerosing Cholangitis

Sclerosing cholangitis are chronic cholestatic inflammatory diseases which cause obliterative fibrosis of the bile ducts, leading to biliary cirrhosis. Four clinical forms seen in children:

1. *Neonatal sclerosing cholangitis*: It is most probably an autosomal recessive disease. It presents as neonatal cholestasis, so not within the purview of this chapter.
2. *Primary sclerosing cholangitis*: PSC of unknown etiology is relatively infrequent in children with likely incidence 0.2 cases per 100,000 patient years. The largest pediatric PSC series include only 214 cases in all, and centers manage 2–3 cases per year. PSC is a slowly progressive disease of the older children and is very often associated with ulcerative colitis. Common presenting symptoms are pain in abdomen, jaundice and pruritus. Often it takes years for the biliary cirrhosis and PHTN to get established in childhood PSC.

3. *Secondary sclerosing cholangitis (SSC)*: SSC secondary to various diseases, including Langerhans cell histiocytosis (LCH), primary immunodeficiencies and acquired immunodeficiency syndrome. SSC is usually seen in young infants and children where the abnormal cells cause sclerosis of the bile ducts resulting in sclerosing cholangitis.
4. *Autoimmune sclerosing cholangitis (ASC)*: ASC has similar presentation as the AIH and is particularly frequent in pediatric age, where it is more common in girls, responds to immunosuppressive treatment and has a better prognosis than classical PSC.

CLASSIFICATION OF CIRRHOSIS

Two macroscopic (appearance of the liver as seen by the naked eye) types of cirrhosis have been described. However, a mixed pattern may also be seen: (a) *Micronodular cirrhosis* (< 3 mm nodules)—where the liver is usually enlarged with small nodules of uniform size. This is associated with drug, chronic hepatitis, chronic venous obstruction, hemochromatosis and chronic biliary disease; and (b) *Macronodular cirrhosis* (> 3 mm nodules)—where the liver is almost always shrunken with large bulging nodules. This is the common form seen in chronic viral hepatitis, chronic AIH and Wilson disease. Some of these causes may have mixed (micronodular and macronodular) picture.

DIFFERENTIAL DIAGNOSIS

Moderate to massively enlarged spleen, PHTN and normal liver functions go against the diagnosis of CLD. An ultrasound Doppler done in such a patient would decide whether the diagnosis is having extrahepatic portal vein obstruction (EHPVO) or noncirrhotic portal fibrosis (NCPF) (**Flow chart 1**). Liver histology in NCPF would show no evidence of cirrhosis or parenchymal injury. Hepatic venous portal gradient would be normal in both these disorders. Moderate to massively enlarged splenomegaly, with or without PHTN with history of recurrent cholangitis is suggestive of *congenital hepatic fibrosis*. This is an autosomal recessive inherited fibropolycystic disease defined histopathologically by a variable degree of periportal fibrosis and irregularly shaped proliferating bile ducts.

COMPLICATIONS OF CIRRHOSIS

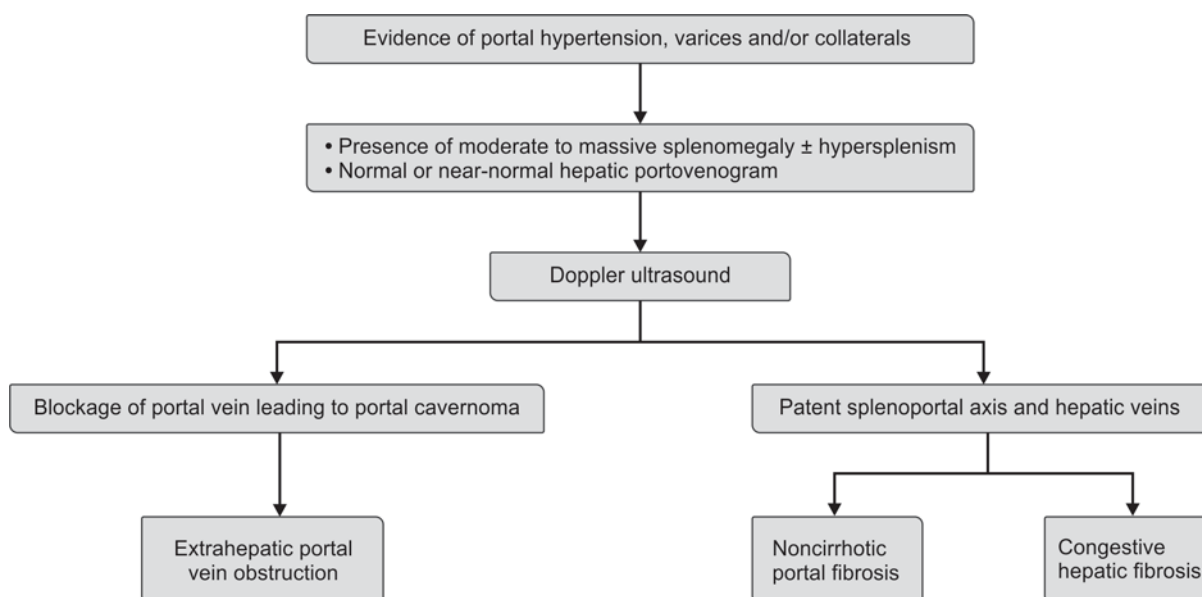

Since encephalopathy and PHTN with associated variceal bleed, ascites and spontaneous bacterial peritonitis are being detailed elsewhere, we have left them out of the present discussion.

Hepatopulmonary Syndrome

Hepatopulmonary syndrome is a triad of liver disease, intrapulmonary vascular dilatation and arterial hypoxemia. HPS is present in 9–20% of children with cirrhosis and PHTN. It can be asymptomatic or can present with growth retardation, cyanosis, dyspnea, platypnea, orthopnea, spider angioma or finger clubbing. PHTN causes bowel ischemia, increasing gut permeability and bacterial translocation of bacteria, which leads to the activation of VEGF-dependent signaling pathways and pulmonary angiogenesis.

Hepatorenal Syndrome

Hepatorenal syndrome (HRS) and acute kidney injury (AKI) are rare complications in pediatric CLD. Whereas AKI encompasses all etiologies (prerenal, renal and postrenal) which predispose to sudden acute deterioration in renal functions over 2 weeks, HRS refers to a specific type of prerenal failure, which develops secondary to intense renal vasoconstriction as a compensatory response to splanchnic vasodilatation secondary to PHTN. Among the two types of HRS identified: type 1 is acute and rapidly progressive developing after a precipitating event like

Flow chart 1 Portal hypertension with moderate to massive splenomegaly

GIT bleed or spontaneous bacterial peritonitis; whereas Type 2 is a slowly progressive form of renal failure associated with chronic ascites. In children it can be defined as oliguria (< 1 mL/kg/hour) with renal dysfunction (in the absence of usage of diuretics and other nephrotoxic drugs) and nonresponsive to albumin infusion. HRS is a reversible condition with poor prognosis for type 1.

LABORATORY WORK-UP

When the evidence for CLD has been found biochemically (as mentioned in **Table 1**) and on imaging (**Figs 4A to C**), liver biopsy gives further directions regarding the cause of the disease (**Fig. 5**). Synthetic liver dysfunction and elevated transaminases go in favor of parenchymal injury and elevated serum alkaline phosphatase (SAP) and/or Gamma glutamyl transferase (GGT) indicate cholestatic causes. In **Table 5**, the parenchymal causes of CLD in the different age groups have been discussed including the screening tests, confirmatory tests and the genetic testing of the various etiologies. **Table 6** discusses the causes of cholestatic CLD based on the GGT level being low or high and whether pruritus is part of the presenting feature or not.

MANAGEMENT OF CHRONIC LIVER DISEASE

General Management

Basic management of an infant or child with CLD is focused on: (1) nutritional support and rehabilitation, careful surveillance for growth and complications with subsequent management, and regular assessment for need for liver transplantation.

Nutritional support and rehabilitation An aggressive approach to nutritional support is essential in management of an infant or child with CLD as poor nutritional status is associated with poor brain growth, delayed mental development and susceptibility to recurrent infections. Pretransplant nutritional status also determines the outcome, speed of recovery and cognitive performance after liver transplantation. Nutritional goals and recommendations for infants and children with CLD are mentioned in **Table 7**. Vigorous growth monitoring is indicated in some patients, especially those who are candidates for liver transplantation, or those with severe cholestasis. Bolus dose of vitamins A (oral or intramuscular) and D (intramuscular) is indicated in cases with well-established features of xerophthalmia and rickets, respectively. Specific nutritional management for certain disorders is discussed in later sections.

Figures 4A to C (A) Ultrasonography of upper abdomen showing small shrunken liver with coarse echotexture (arrows); (B) Contrast-enhanced computerized tomography (CECT) of abdomen showing nodular liver surface; (C) CECT abdomen showing splenomegaly (open arrow) and presence of numerous splanchnic venous collaterals (arrows)

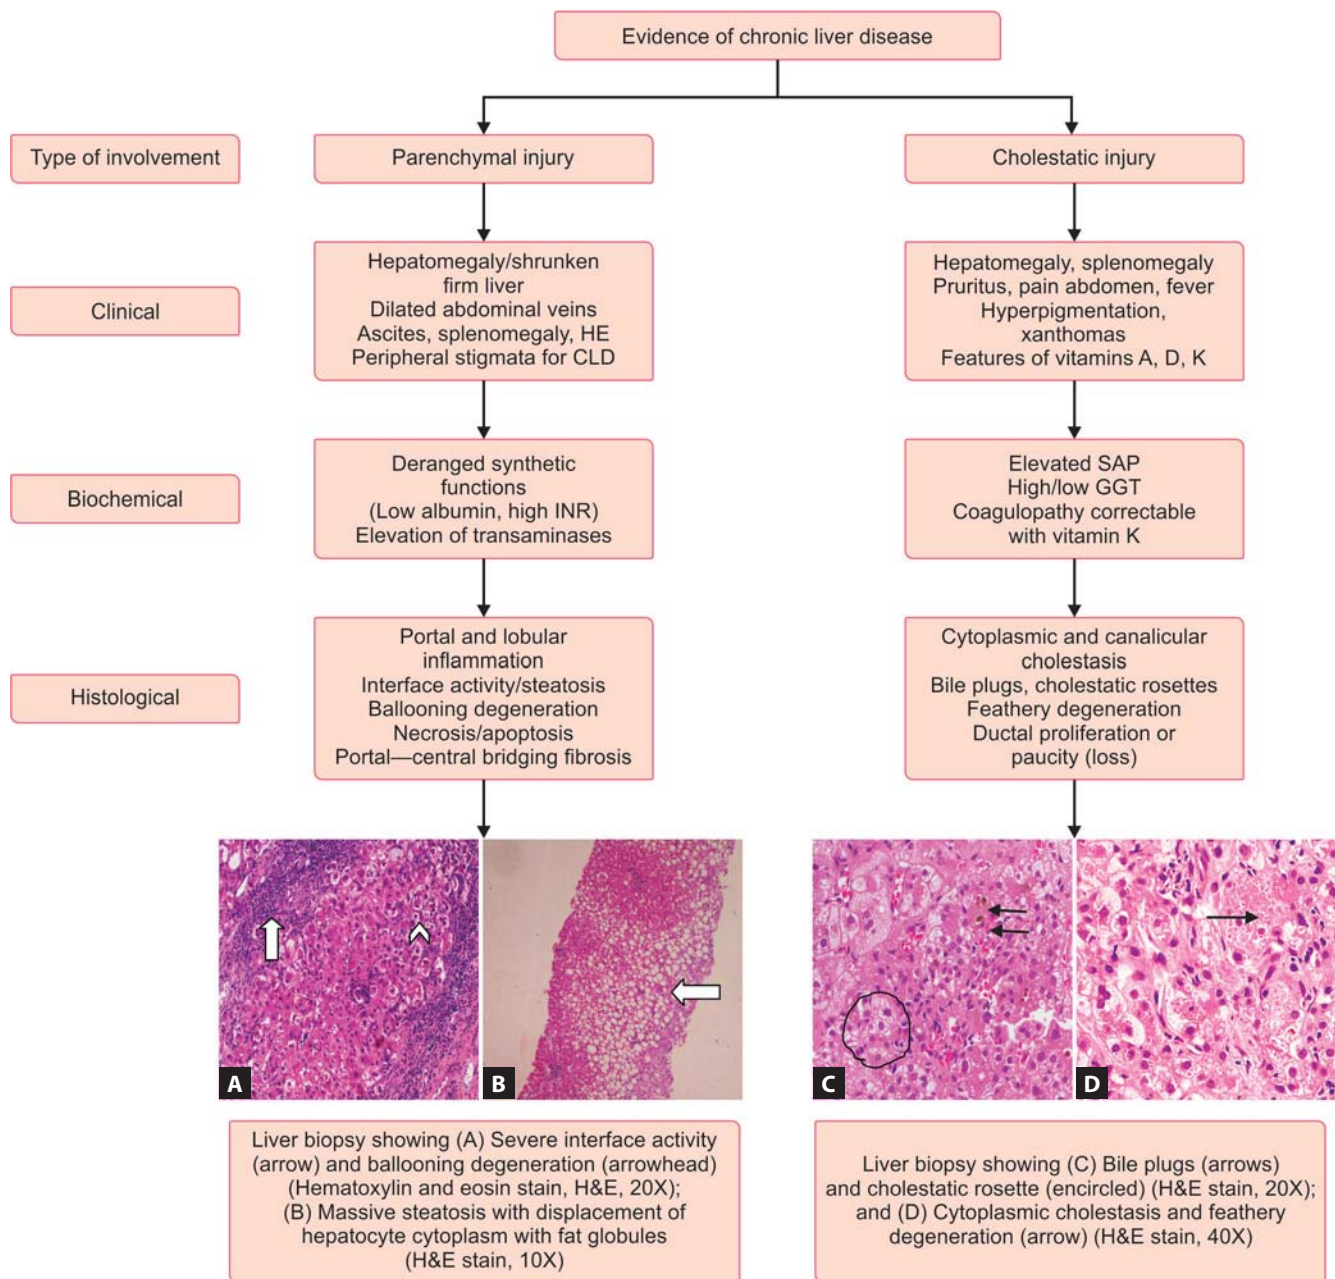

Figure 5 Approach to a child with chronic liver disease

Surveillance Surveillance strategies in infants and children with CLD are not well defined and some of these have been adapted from adult guidelines (**Table 8**). Screening UGIE should be early (~6 months) and more frequent in cases of BA where PHTN is known to be rapidly progressive. Alpha fetoprotein (AFP) should be done in cases with known predisposition for HCC like BA, PFIC-2, hepatitis-B, glycogen storage disease and tyrosinemia, and in the later, the surveillance should be more frequent (~3 monthly). Age-appropriate cut-offs for AFP should be considered suggestive. HRS should be looked for with every episode of infection (urinary tract, pneumonia, spontaneous bacterial peritonitis, sepsis), large volume paracentesis, diarrhea or vomiting.

Candidacy for liver transplantation At each follow-up, patients should be assessed both clinically as well as biochemically regarding candidacy for liver transplantation on the basis of

available severity scores (**Table 8**). A value of CTP > 7, MELD > 14 or PELD > 12 indicates candidacy for liver transplantation. Other indications in children may differ for the primary disease—severe excruciating pruritus, growth failure despite adequate nutritional rehabilitation, recurrent cholangitis, ascites which is rapidly filling or refractory to medical management, episode of SBP, two or more episodes of HE and development of HPS.

Ursodeoxycholic Acid

Ursodeoxycholic acid (UDCA) is a hydrophilic, tertiary biliary acid normally constituting small proportion (< 3%) of the human bile-acid pool. In the body, it is formed by 7-epimerization of chenodeoxycholic acid, thus making it more hydrophilic in nature. UDCA, being hydrophilic, replaces the toxic hydrophobic bile-acids from both the bile-acid pool as well as the hepatocellular membranes and improves bile-salt-dependent bile flow. It also facilitates bile

Table 5 Evaluation of childhood CLD with parenchymal liver injury

	Consider	Screening test	Confirmatory test/Further testing	Genetic testing
Parenchymal liver diseases				
< 1 year	Galactosemia	Positive urine NGRS	Low GALT assay	Gene located on 9p18 Mutations—N314D, Q188R
	Tyrosinemia	High AFP	High urine succinylacetone	Gene located on 15q25.1 Mutations—IVS12+5ga
1–3 years	Hereditary fructose intolerance (HFI)	Fructose tolerance test*	Low aldolase B assay	Gene located on 9q22.3 Mutations—A149P
	Tyrosinemia	As above	As above	As above
	HFI	As above	As above	As above
	Glycogen storage Disorder type IV	PAS-positive cytoplasmic inclusions in hepatocytes	Abnormal glycogen with fewer branch points ultrastructurally and histochemically	Gene located on 3p12
	Hepatic venous outflow tract obstruction (HVOTO)	Doppler for hepatic veins and IVC patency and flow	Contrast-enhanced CT or MR venography	Prothrombotic predisposition Janus-kinase 2 (V617F) Prothrombin (G20210A) MTHFR (C677T) Factor-V Leiden (R605Q)
> 3 years	Wilson disease	Ceruloplasmin < 20 mg/dL K-F ring on slit-lamp examination 24 hours Urine Copper > 40 µg/day	Liver copper (> 250 µg/g of dry weight) MRI brain	ATP7B gene located on 13q14 Mutations—H1069Q, p.C271, R778L, p.E122fs
	Autoimmune hepatitis	High IgG or reversal of A:G ratio Antibodies (ANA, SMA, LKM)	Liver biopsy Clinical and histological response to treatment	HLA-DR
	Chronic HBV	HBsAg + for > 6 months	HBeAg Anti-HBe HBV-DNA (Quant)	Resistant mutants of HBV Lamivudine M204V/I**, L180M Adefovir A181V, N236T Entecavir T184G/S, S202I, M250V
	Chronic HCV	Anti-HCV+	HCV-genotyping HCV-RNA (Quant)	IL-28/ITPA polymorphism [#]
Any age with splenohepatomegaly	HVOTO	As above	As above	As above
	Gaucher's	Gaucher cells (macrophages with wrinkled tissue paper appearance) in bone-marrow, liver and lymph nodes	Low acid-β-glucosidase	Gene located on 1q22 Mutations—N370S, L444P
	Niemann-Pick C	Foam cells (lipid-laden macrophages) within bone marrow and liver	Impaired cholesterol esterification and filipin staining in cultured fibroblasts	Genes located on 18q11-q12 (NPC1) and 14q24.3 (NPC2). > 130 mutations

* Following an oral fructose load, there is development of hypoglycemia, hypophosphatemia, hyperuricemia, hypomagnesemia and hypertriglyceridemia.

** YMDD mutation; [#] Polymorphism determines treatment responsiveness in genotype-1 hepatitis C.

Table 6 Evaluation of childhood CLD with cholestatic liver injury

<i>Presentation</i>	<i>Pruritus</i>	<i>Differentials</i>	<i>Supportive findings or tests</i>	<i>Confirmatory tests</i>	<i>Genetic linkage</i>
Low GGT	++	Progressive familial intrahepatic cholestasis (PFIC) type 1/2	Growth failure; Low biliary BA 1 → Extrahepatic features (diarrhea, pancreatitis, deafness); bland cholestasis on liver biopsy 2 → Gallstones; giant cell hepatitis on liver biopsy	1 → Coarse granular bile (Byler's) on electron microscopy 2 → Deficient immunostaining for BSEP	1 → ATP8B1 (or FIC1) gene on chr 18q21-22 2 → ABCB11 (or BSEP) gene on chr 2q24
	±	BASD	Steatorrhea, growth failure Low serum BA	Abnormal bile-acid conjugates on LSIMS/GC-MS	Mutations in HSD3B7 gene
High GGT	+++	Alagille syndrome	Facial dysmorphism, slit-lamp examination for posterior embryotoxon, X-ray spine for vertebral defects, peripheral pulmonary artery stenosis (murmur in axilla or back)	Liver biopsy—Paucity of bile ducts (Bile duct: Portal tract < 0.4)	Mutations in Jagged1 (on chr 20p12.1-p11.23) and NOTCH2 genes (on chr 1p13-p11)

Table 7 Nutritional recommendations for infants and children with CLD

• Energy: 125% of RDA based on weight for height at 50th percentile. Consideration should be given to night-time or continuous nasogastric feeds or, in specialized settings, gastrostomy feeds.	
• Fat: Medium chain triglycerides (MCT) should comprise 60–70% of total fat intake. MCT should be supplemented in a dose of 1–2 mL/kg/day. Corn-oil or safflower oil should be added in the diet to prevent essential fatty acid deficiency.	
• Protein: 2–3 gm/kg/day. During periods of hepatic encephalopathy, the protein intake needs to be reduced to 0.5–1.0 gm/kg/day, with restriction of animal protein and adequate supplementation of branched chain amino-acids.	
• Fat-soluble vitamins: 3–5 times of RDA.	
– Vitamin-A:	5,000–25,000 U/day orally
– Vitamin-D:	3–5 µg/kg/day of 25-OH-D or 0.05–0.2 µg/kg/day of 1,25-OH ₂ -D
– Vitamin-E:	25–200 IU/kg/day as α-tocopherol or 15–25 IU/kg/day of TPGS
– Vitamin-K:	2.5–5.0 mg twice a week to daily dose orally as menadione (or phytonadione)
• Water-soluble vitamins: 1–2 times of RDA	
• Minerals and Trace elements	
– Calcium	25–100 mg/kg/day as CaCO ₃ tablets or syrups orally (max 800–1,200 mg/day)
– Phosphorus	25–50 mg/kg/day orally (max 500 mg/day)
– Magnesium	1–2 mEq/kg/day of MgO orally, or 0.3–0.5 mEq/kg/day of MgSO ₄ (50%) IV (slow)
– Zinc	ZnSO ₄ 1–2 mg/kg/day orally for 2–3 months
– Iron	5–6 mg/kg/day of elemental iron

salt-independent bile flow by direct effect on cholangiocyte Ca²⁺-activated Cl[−] secretion, resulting in bicarbonate-rich choleresis. Apart from these choleretic actions, UDCA also has hepatoprotective effects—stabilization of hepatocellular membranes, improvement of mitochondrial oxidative phosphorylation and prevention of mitochondrial membrane permeability transition, the later effect helps in protecting against both apoptotic as well as necrotic cell injury. It also reduces expression of HLA-1 antigens on hepatocytes, thus having immunomodulatory properties. It is used in a dose of 10–30 mg/kg/day (maximum 1,500 mg/day in 2–3 divided doses) and has been shown to improve biochemical tests and pruritus, and reverse fibrosis and liver injury. Important side effect is diarrhea. The drug is poorly absorbed in case of severe cholestasis and there is concern of increased conversion to hydrophobic lithocholic acid, which is known to have carcinogenic potential.

Treatment of Pruritus

General measures include cool baths, moisturizers, topical steroid creams, topical anesthetics, antihistaminics and sedatives. Fingernails should be trimmed; and in young children at night, long-sleeve shirts should be worn and hands should be covered with stockings. Targeted approach is directed toward the possible etiopathogenetic theories related to development of pruritus—

choleretics (UDCA, phenobarbitone, removal of pruritogens (bile-acid sequestrants like cholestyramine, colestipol, colesvelam; plasmapheresis and extracorporeal albumin dialysis), alteration of metabolism of pruritogens (rifampicin); or modulation of central or peripheral pruritogenic signals (opioid antagonists, serotonergic). With failure of medical management, surgical options are considered—partial external (PEBD) or internal biliary diversion (cholecysto-jejuno-colonic anastomosis). Theoretical basis for diversion surgery is interruption of enterohepatic circulation of bile-acids, thus causing an overall reduction of bile-acid pool. Diversion surgery results in improvement in pruritus and growth, and resolution of fibrosis, but is advisable only before cirrhosis has set in, otherwise the child is considered for liver transplant. A step-wise management is advised for the management of pruritus (**Table 9**).

Immunization

All the infants and children with CLD need to be immunized against hepatitis-A and B. The decision should preferably be taken after testing for immunoglobulin G (IgG) antibodies (antihepatitis-A and antihepatitis-B) titers. Candidates awaiting liver transplant should receive all live (polio, measles, mumps, rubella, BCG, varicella) and inactive vaccines (diphtheria, pertussis, tetanus, *Haemophilus influenzae* B, pneumococcal influenza and typhoid).

Table 8 Surveillance of infants and children with CLD

Evidence of portal hypertension (Varices or PHG on UGIE)	
No varices	UGIE every 1–2 years
Small varices (< 5 mm in size), no RCS	UGIE every 6 months–1 year
Large varices (> 5 mm in size) or small varices with RCS	
Decompensation —Presence of any one of the following:	OPD visit every 3 months
<ul style="list-style-type: none"> Increasing jaundice Development or worsening of pre-existing ascites Hepatic encephalopathy Variceal bleed 	
Hepatopulmonary syndrome	Every 3–6 months
Orthodeoxia (difference in supine and upright SpO ₂ > 4%) PO ₂ and A-aO ₂ on ABG (at room air)	
Saline contrast echocardiography (when above two tests abnormal)	
Hepatorenal syndrome/Acute kidney injury	During and after each predisposition
Patients on diuretics	Every 1–3 months
Malignancy (Hepatocellular carcinoma)	AFP and ultrasound 6 months
Candidacy for liver transplantation	Every FU 3–6 months
CTP score	Bilirubin, Albumin, Ascites, HE and INR
PELD score (≤ 12 years)	Bilirubin, Albumin, INR, Age < 1 year, Growth
MELD score (≥ 12 years)	Bilirubin, Creatinine, INR, Need for hemodialysis within 2 weeks
MELD-sodium (MELD-Na)	Incorporation of serum Na into MELD score

MANAGEMENT OF COMPLICATIONS

Ascites, spontaneous bacterial peritonitis, HE, variceal bleed, HPS and HRS are various complications of CLD seen in children. As the first four complications are discussed elsewhere in this Section, we are discussing here the remaining two complications.

Table 9 Management algorithm for pruritus in children

Action	Drug	Dose (mg/kg/day)	Frequency/day	Side effects/Precautions
Start	UDCA	10–30	2–3	Diarrhea
	+ Hydroxyzine	0.5–1	1–2	Sedation
Add	Cholestyramine	250–500	2–4	Fat-soluble VAD, unpalatability, steatorrhea
Add Rifampicin	Rifampicin	5–10	1–2	Hepatotoxicity
Add/Substitute	Naltrexone	0.25–0.5	1–2	Opioid withdrawal
Consider adding/ substituting	Ondansetron	0.45–0.9	2	Constipation
	Phenobarbitone	5–10	2	Sedation
	Cyproheptadine	0.2–0.4	2	Sedation
Nonsurgical treatments		Surgical management		
Plasmapheresis		Cirrhosis absent		Cirrhosis absent
Extracorporeal albumin dialysis		Biliary diversion		Liver transplantation
Ultraviolet-B radiation		External or internal		

Management of Hepatopulmonary Syndrome

Bedside screening for HPS is done with demonstration of orthodeoxia—difference of > 4% in oxygen saturation on pulse oximetry [or PO₂ on arterial blood gas (ABG)] between lying down and upright positions. The alveolar-arterial oxygen gradient (A-aO₂) is increased (>15 mm Hg) with or without hypoxemia. Confirmation is done by demonstration of air bubbles after 3 cardiac cycles on left side of heart after injection of agitated saline intravenously (saline contrast echo) along with exclusion of cardiopulmonary disease. Shunt fraction is quantified on Technetium-99m-labeled macroaggregated albumin (^{99m}Tc-MAA) scan depending on the proportion of radio-labeled isotope reaching brain in comparison to that retained in lungs. Various drugs have been used in adults but with a limited role. Liver transplant reverses HPS in 80% of cases, although those with severe hypoxemia may have delayed recovery and risk of mortality.

Management of Hepatorenal Syndrome and Acute Kidney Injury

It is diagnosed in a cirrhotic patient with an acute rise in creatinine level (> 1.5 mg/dL, or doubling over 2 weeks period) with absence of response (not > 50% reduction) to volume expansion with albumin 1 g/kg for 2 days and to diuretic withdrawal, along with absence of shock, usage of nephrotoxic drugs or intrinsic renal disease. Key points in management are stopping of diuretics and nephrotoxic drugs; and initiation of antibiotics, albumin and vasoconstrictors. Vasoconstrictors most commonly used in adults are terlipressin and norepinephrine. However, the definitions as well as management are not well defined in the pediatric age-group. AKI and HPS can be prevented by preventing variceal bleed with usage of β-blockers.

DISEASE-SPECIFIC MANAGEMENT

Treatment of Wilson Disease

Management of Wilson disease is centered on attaining a negative copper balance with usage of lifelong chelators and zinc. Liver transplantation, which corrects the underlying defect, is reserved for severe cases with new Wilson index (NWI) score ≥ 11 (See Chapter 37.7). Recently questions have been raised regarding the efficacy of NWI. Approach is individualized depending on the severity of symptoms and whether predominantly hepatic or neurologic involvement.

Chelators Various chelators used for achieving cupriuresis are described in **Table 10**. The most commonly used is D-penicillamine, which is supplemented with pyridoxine (25 mg/

Table 10 Drugs used in the treatment of Wilson disease

Drug	D-Penicillamine	Trientine	Ammonium tetrathiomolybdate	Zinc
Mode of action	Chelator, induces cupruria	Chelator, induces cupruria	Chelator, induces cupruria	Blocks copper absorption
Dose	Initiation phase: 20 mg/kg/day in 2–3 divided doses (maximum 1,500 g/day) Maintenance phase: 25–50% of dose	20 mg/kg/day in 2–3 divided doses Maintenance phase: 25–50% of dose	(dose not defined for children)	150 mg/day in 3 divided doses
Side effects	Fever, rash, proteinuria, nephritic syndrome, aplastic anemia, lupus	Gastritis, loss of taste, skin rash	Anemia, neutropenia Aplastic anemia	Gastritis, Zinc toxicity, Hepatotoxicity
Neurological worsening	10–20%	10–15%	Rare	Nil or very rare
Precautions	Gradual escalation of dose in neurological WD. 1 hour before or 2 hours after meals	Forms toxic complex with iron. 1 hour before or 2 hours after meals	Investigational	1 hour before or 2 hours after meals
Tests for monitoring efficacy	<i>Initiation phase:</i> 24 hours; Urinary Cu excretion as 200–500 mcg/day as target Non-Cp-bound Cu < 20 mcg/dL <i>Maintenance phase:</i> Non-Cp-bound Cu < 10 mcg/dL	Same as for D-penicillamine	Same as for D-penicillamine	<i>Initiation phase:</i> 24 hours; Urinary Cu excretion 75 mcg/day as target <i>Maintenance phase:</i> Non-Cp-bound Cu < 10 mcg/dL
Tests for monitoring side effects	Hemogram, urine for albuminuria, skin examination	Hemogram, iron studies	Hemogram	Serum zinc levels

day). The risk of neurological worsening has been described up to the tune of 10–50% and is related to sudden release of copper from the basal ganglia. Following adequate chelation, liver synthetic functions recover and there is improvement in clinical signs, such as jaundice and ascites typically during the first 2–6 months of treatment. Noncompliance to chelation leads to significant progression of liver disease in another 1–12 months needing liver transplantation.

Zinc Zinc induces intestinal metallothionein, which has greater affinity for copper than for zinc, preferentially binds copper present in the enterocytes and inhibits its entry into the portal circulation. Copper, thus bound, is not absorbed but is lost into the feces. Zinc therapy alone is helpful in cases with clinically as well as biochemically silent WD (asymptomatic cases detected on family screening), and is also recommended in those with neurological WD, where there is risk of neurological deterioration with chelators.

Combination treatment For patients who present with decompensated CLD, combining zinc with D-Penicillamine has become a popular treatment strategy despite a lack of extensive validation. The two types of treatments must be temporally dispersed through the day, with at least 4–5 hours between administration of the two drugs, or else they may neutralize each other.

Low-copper diet Patients with Wilson disease should remain life-long on a low-copper diet with elimination of organ meats, shellfish, nuts, chocolate and mushrooms. In case of concerns of high copper content in drinking water system, a copper-removing device should be installed in the plumbing system. Response to treatment is assessed clinically and biochemically in terms of resolution of jaundice, hemolysis and ascites, reduction in transaminases, improvement in international normalized ratio (INR) and albumin, and attainment of negative copper balance.

Liver transplantation Liver transplantation in Wilson disease is indicated in cases with fulminant presentation or those with decompensated end-stage liver disease unresponsive to medical therapy. In cases with predominantly neuropsychiatric involvement, indications for liver transplantation could be mild neurological involvement which could reverse with time after transplantation.

Treatment of Autoimmune Hepatitis

Immunosuppression remains the mainstay of therapy in cases with AIH. Children have more severe disease in comparison to adults perhaps because of frequent delays in diagnosis and also because of concurrent other autoimmune process. There are two different schools of thoughts—first one administer steroids alone, whereas the second one combines this with azathioprine right from the beginning (**Fig. 6**). The former regimen can be used in presence of severe cytopenia or thiopurine methyl transferase (TPMT) deficiency and pregnancy. More than 85% of children who receive steroids alone ultimately require addition of azathioprine. Although an 80% decrease of transaminases is seen within 6 weeks of initiation of immunosuppression, complete normalization may take months. Relapse while on treatment is seen in 40% of children with AIH and requires a temporary increase in dose of steroids. About 10% of cases respond either to mycophenolate mofetil, cyclosporine or tacrolimus. In children, it is often unsuccessful to withdraw immunosuppression in type-2 AIH.

Treatment of Chronic Hepatitis-B

The aim of management in children with cirrhosis related to hepatitis-B is to reduce the viral burden as low as possible with the use of antivirals irrespective of the levels of ALT or DNA or histological activity. Interferon preparations are contraindicated once cirrhosis has set in as they may precipitate decompensation. Long-term oral nucleoside analogues, like

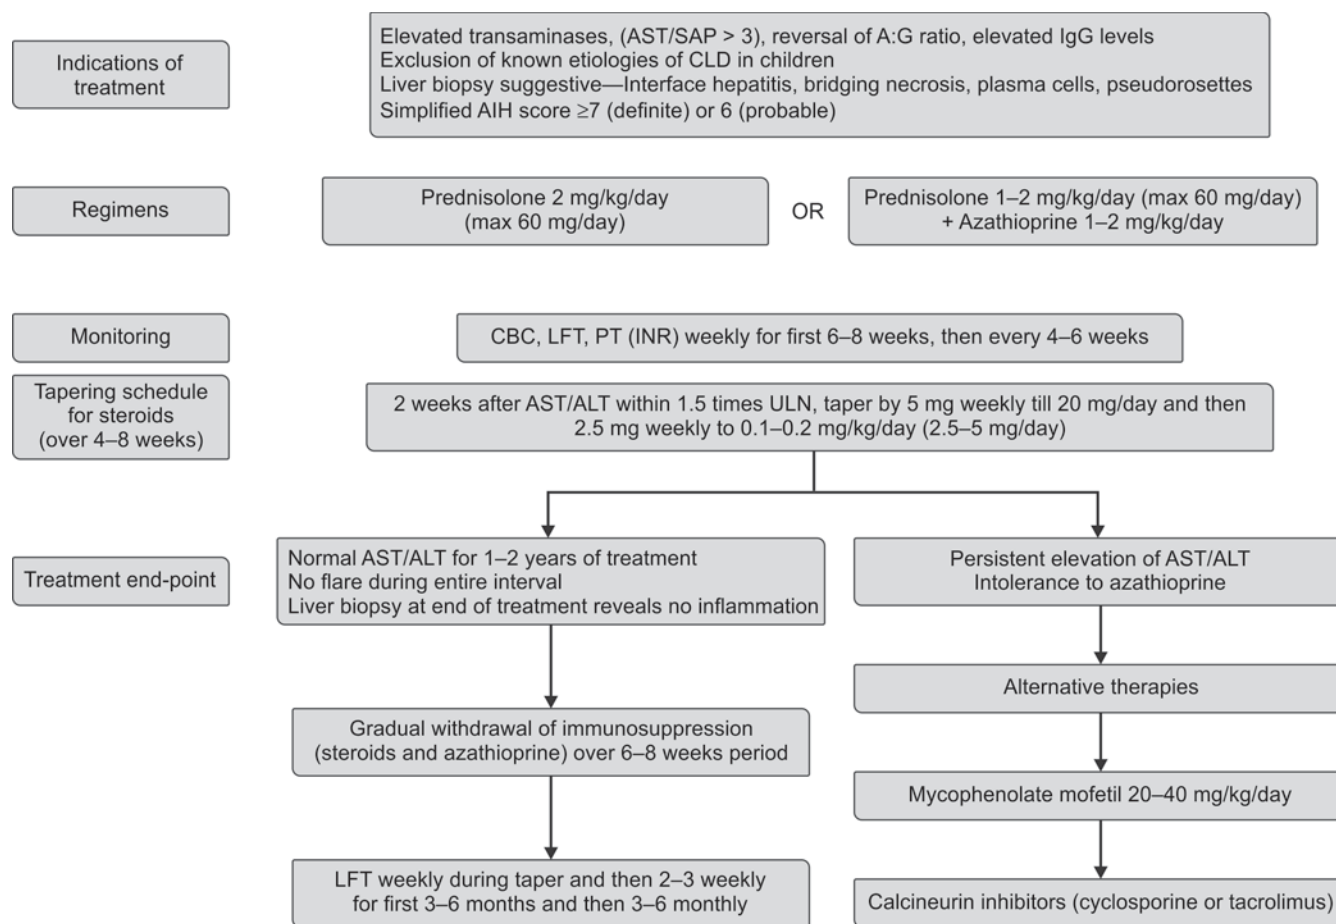

Figure 6 Treatment regimes for autoimmune hepatitis

lamivudine, adefovir, entecavir or tenofovir may be tried in these children.

Treatment of Metabolic Disorders

Some of the metabolic disorders like galactosemia and HFI can be well controlled by dietary restrictions. Elimination of galactose from the diet of children with galactosemia results in improvement of liver synthetic functions (prothrombin time and albumin) within a week, resolution of symptoms (like diarrhea, vomiting, seizures, ascites and cataract), normalization of growth and an overall improved survival. However, long-term sequels in the form of mental retardation, neurologic disorders, ovarian failure and growth inhibition continue to occur among survivors due to endogenous production and presence of minute amounts of galactose in all foods. Similarly, exclusion of fructose, sucrose and sorbitol in HFI leads to dramatic clinical and biochemical recovery. Younger infants recover more slowly from fructose exposure than older infants and children.

Tyrosinemia is difficult to treat with diet alone as restriction of essential amino-acids like tyrosine and phenylalanine interferes with the growth of the child. On subsidence of the acute phase, phenylalanine and tyrosine are provided in a restricted manner. Nitisinone or NTBC [2-(2-nitro-4-trifluoromethyl benzoyl)-1,3-cyclohexanedione] inhibits 4-hydroxy phenylpyruvate dioxygenase, which is an enzyme upstream in the tyrosine

metabolism pathway and, thus, the drug prevents formation of toxic metabolites. Nitisinone is administered in a dose of 1 mg/kg/day in divided doses with a target to maintain complete absence of detectable plasma and urine succinylacetone. Its usage has been shown to prevent acute hepatic and neurologic crises and avert need for liver transplantation when introduced within 1 month of age.

Treatment of Cholestatic Disorders

The management of cholestatic disorders like PFIC and PSC is concentrated on management of pruritus (*See above*). However, medical management does not prevent the progression of hepatic disease or resolution of extrahepatic manifestations. Liver transplantation is indicated in cases with intractable pruritus, growth failure despite adequate nutritional rehabilitation and recurrent cholangitis. SSC requires treatment for the associated disorder, e.g., LCH or primary immunodeficiencies. Certain cholestatic disorders like bile acid synthetic defects are reversible by medical management—primary bile acid therapy replacement in these disorders in the form of oral chenodeoxycholic acid (125–250 mg/day) and cholic acid (10–15 mg/kg/day, maximum 250 mg/day) results in clinical and biochemical recovery and transplant-free long-term survival.

IN A NUTSHELL

1. Definition of CLD based on duration is not practical for infants and children. Clinical, biochemical, radiological and histopathological evidences can be used to identify CLD.
2. CLD is classified into *Parenchymal type* and *Cholestatic type*.
3. The most common causes of parenchymal CLD are metabolic liver disease in the west and chronic HBV and Wilson disease in India.
4. The most common cause of cholestatic CLD is BA world over.
5. Hepatic stellate cells, Kupffer cells and hepatocytes are involved in the pathogenesis of hepatic fibrosis. Following injury to the hepatocytes, quiescent HSCs become activated, proliferative, motile, profibrogenic and contractile.
6. Among the complications of CLD, HPS is more frequent in children. HRS is uncommonly associated with childhood CLD.
7. Basic management of an infant or child with CLD is focused on nutritional support and rehabilitation, careful surveillance for growth and complications with subsequent management, and regular assessment for need of liver transplantation.
8. Management of Wilson Disease aims at attaining a negative copper balance with lifelong usage of chelators and zinc.
9. Combination therapy with steroids and azathioprine have good efficacy in treating AIH.
10. Some of the metabolic disorders like galactosemia and HFI can be well controlled by dietary restrictions. Tyrosinemia needs Nitisone and dietary elimination of tyrosine and phenylalanine.

Chapter 37.9

Hepatic Encephalopathy

Moinak Sen Sarma, Surender Kumar Yachha

Hepatic encephalopathy (HE) refers to a variety of reversible neurologic abnormalities seen in patients with liver diseases (mainly cirrhosis and liver failure). HE depends on three factors: (1) portosystemic shunting; (2) alterations in the blood-brain barrier; and (3) the interactions of toxic metabolites with the central nervous system (CNS).

This chapter will give a global overview of the presentation and management of hepatic encephalopathy in children. As HE is an important component of acute of liver failure (ALF), there will be considerable overlap in the management of both. ALF and chronic liver diseases (CLD) will be dealt separately elsewhere in the hepatobiliary section. HE in mitochondrial hepatopathies, urea cycle defects, Reye syndrome and congenital portosystemic shunts are rare but important disorders in children. These will be briefly elaborated at the end of this topic. Most studies on HE are adult-based and their experience is extrapolated to children.

PATHOPHYSIOLOGY

Exact pathophysiology is not well understood. A few hypotheses are discussed.

Ammonia Hypothesis (Acute Liver Failure Model)

Altered ammonia metabolism is a well-accepted postulation, depicted in **Figure 1**. Ammonia is produced by gut bacteria by converting glutamine to glutamate by enzyme glutaminase. About 80% of ammonia is usually removed from the portal vein blood in its *first pass* from the gut and detoxified in liver through urea cycle. The remaining 20% is removed primarily by the kidneys, in which the ammonia is protonated and excreted as a means of maintaining systemic acid-base balance. Muscle tissue also can absorb and metabolize ammonia. The brain also can take up ammonia and

detoxify it, mostly by production of glutamine, which then is metabolized to α -ketoglutarate.

In liver diseases there is abnormal handling of ammonia due to portosystemic shunting, parenchymal necrosis and muscle wasting. Additionally a state of respiratory alkalosis causes kidneys to retain the ammonia. A defective blood brain barrier (BBB) occurs due to endothelial dysfunction secondary to cytokines from inflammation. Contributory factors like hypokalemia, metabolic alkalosis and superimposed sepsis allow toxic metabolites to interact in the brain. Ammonia causes excitation by reduced inhibition of CNS and thus decreases the seizure threshold. In addition, the excess ammonia coupled with glutamate forms glutamine with the help of glutamine synthetase. Astrocytes swell up due to the excess glutamine and causes cerebral edema further worsening the encephalopathy.

Animal protein and blood in gut are rich sources of ammonia. Delayed intestinal transit by ileus, hypokalemia and constipation cause stasis and allow bacteria to produce more ammonia. The ammonia model also explains the encephalopathy encountered with urea cycle defects, organic acidemias, mitochondrial hepatopathies, congenital portosystemic shunts and Reye syndrome.

Other Hypotheses

Other toxic metabolites that contribute to HE are mercaptans, short and medium chain fatty acids (produced by gut bacteria) and increased gamma-aminobutyric acid (GABA) activity by neurosteroids. CNS inhibition contributes further by benzodiazepines (endogenous or as sedative drug). Decreased plasma branched chain amino acids (BCAA) levels allow aromatic amino acids (AAA) to influx through the BBB and produce *false neurotransmitters* like tyramine, octopamine and tryptamine (instead of true neurotransmitters: dopamine, norepinephrine and serotonin) cause HE.

Pathophysiology in Cirrhosis

Florid cerebral edema, intracranial hypertension and seizures are rarely seen in cirrhotics due to pre-existing cerebral atrophy and various compensatory mechanisms that are not present in acute liver failure. Manganese accumulation in basal ganglia in particular is seen in cirrhotics with extensive portosystemic shunts.

Figure 1 Pathophysiology of hepatic encephalopathy

Abbreviations: SBP, spontaneous bacterial peritonitis; BZD, benzodiazepines; BBT, barbiturate; NH₃, ammonia; SV, splenic vein; IVC, inferior vena cava; BBB, blood brain barrier; CNS, central nervous system.

DIAGNOSIS

The modified staging of HE is shown in **Table 1**. In smaller children, neurological signs are difficult to be elicited. Stages I and II are difficult to differentiate as they have similar clinical manifestations. Clinical assessment of staging in children includes constructional apraxia in stages I and II. Simple, age-related tasks are useful tools for the day-to-day assessment of inattentiveness and apraxia. In older children or adolescent, subtraction of serial sevens, recall of events, writing and figure drawings are appropriate tasks that can be asked to repeat daily in order to assess early encephalopathy. Younger children may be asked to color a figure in a simple coloring book while ward rounds are being completed. On the physician's return to the patient's bedside, it may be found that the task is not completed (inattentiveness) or that the once excellent *colorer* has scribbled far outside the lines (constructional apraxia). Handwriting may worsen which may be confirmed by the mother. The conventional drawing of a five-point star practiced in older children may not be expected till the child is 8–9 years of developmental age. Instead the child may be asked to draw simple shapes that are fine motor developmental age-appropriate. Asterixis (tremor of wrist in dorsiflexion with forearm and fingers extended) may be seen in older children. It denotes postural lapse and consists of rapid flexion-extension movements akin to wing flapping of birds. Other neurological signs are hyper-reflexia, hypertonia, disruption of smooth pursuit of eye movements (SPEM) and occasionally nystagmus.

ETIOLOGY

Hepatic encephalopathy occurs as a result of ALF, chronic liver disease, or as a result of systemic disease (**Table 2**). The Pediatric Acute Liver Failure Study Group (PALFSG) has recently defined ALF as HE with international normalized ratio (INR) more than 1.5 (uncorrectable coagulopathy) or INR more than 2 without encephalopathy in the presence of biochemical liver injury and absence of pre-existing CLD.

NOMENCLATURE

After discarding the term *portosystemic encephalopathy*, the Hepatic Encephalopathy Consensus Group in 1998 standardized the nomenclature as shown in **Flow chart 1**. The differences between Type A and Type C HE are shown in **Table 3**. Definitions of different types of HE are given in **Table 4** and **Figures 2A to D**.

Table 2 Common causes of hepatic encephalopathy in children

Cause	Neonates and infants	Older children and adolescents
Acute liver failure	<ul style="list-style-type: none"> Galactosemia Tyrosinemia Hemochromatosis HLH Herpes simplex Hepatitis B Mitochondrial hepatopathy⁺ 	<ul style="list-style-type: none"> Hepatitis A, B, E Non-A-E (EBV, Parvo, Adenovirus) Drugs (paracetamol, ATT, valproate, halothane) Leptospirosis Reye syndrome[¥] Mushroom poisoning
Chronic liver disease	<ul style="list-style-type: none"> Decompensated biliary atresia Secondary biliary cirrhosis (choledochal cysts) Indian childhood cirrhosis PFIC (types I and II) GSD (type IV) Galactosemia Tyrosinemia Infantile sclerosing cholangitis 	<ul style="list-style-type: none"> Wilson disease Autoimmune liver disease Chronic hepatitis B or C Budd-Chiari syndrome Veno-occlusive diseases GSD (type III) PFIC (type III)
Systemic diseases	<ul style="list-style-type: none"> Malaria with complications Dengue shock syndrome Complicated typhoid Inborn errors of metabolism* Macrophage activation syndrome Connective tissue disorders (lupus hepatitis) Lymphoreticular malignancies 	

Abbreviations: HLH, hemophagocytic lymphohistiocytosis; PFIC, progressive familial intrahepatic cholestasis; GSD, glycogen storage disorders; ATT; anti-tubercular therapy.

⁺Mitochondrial hepatopathy refers to respiratory chain defects and some of the fatty acid oxidation defects presenting with acute liver failure.

^{*}Inborn errors of metabolism refers to mainly urea cycle defects, aminoacidopathies, organic acidemias and fatty acid oxidation defects presenting as acute intoxication and liver being a part of its multisystem involvement.

[¥]Age-specific (5–16 years): In classic or idiopathic variety often attributed to influenza, varicella or aspirin intake. In less than 5 years, (atypical) Reye-like syndrome is a manifestation of mitochondrial diseases, organic acidurias or urea cycle defects.

Table 1 Staging of hepatic encephalopathy: differences between infants/children and adults

Stage	Clinical	Reflexes	Neurological sign	EEG changes
0	None	Normal	None	Normal
I	<i>Infant/child:</i> Inconsolable crying, inattention to task; child is not acting like self to parents <i>Adult:</i> Confused, mood changes, altered sleep habits, forgetful	Normal or hyper-reflexic	Difficult or impossible to test adequately	Difficult or impossible to test adequately
II	<i>Infant/child:</i> Same as in stage I <i>Adult:</i> Drowsy, inappropriate behavior, decreased inhibitions	Normal	Tremor, apraxia, impaired handwriting	Normal or diffuse slowing to theta rhythm, triphasic waves
III	<i>Infant/child:</i> Same as in stage I <i>Adult:</i> Drowsy, inappropriate behavior, decreased inhibitions	Same as in stage I	Same as in stage I	Same as in stage I
IV	<i>Infant/child:</i> Somnolence, stupor, combativeness <i>Adult:</i> Stupor, obeys simple commands	Hyper-reflexic	Dysarthria, ataxia	Abnormal, generalized slowing triphasic waves
	<i>Infant/child:</i> Somnolence, stupor, combativeness <i>Adult:</i> Stupor, obeys simple commands	Hyper-reflexic Babinski sign +	Same as in stage I	Same as in stage I
	<i>Infant/child:</i> Comatose, arouses with painful stimuli (4a) or no response (4b) <i>Adult:</i> Comatose, arouses with painful stimuli (4a) or not	Absent	Rigidity	Abnormal, generalized slowing triphasic waves
	<i>Infant/child:</i> Comatose, arouses with painful stimuli (4a) or not	Absent	Decerebrate or decorticate	Abnormal
	<i>Infant/child:</i> Comatose, arouses with painful stimuli (4a) or not	Absent	Decerebrate or decorticate	Abnormal, very slow delta activity

Flow chart 1 Nomenclature and classification of hepatic encephalopathy (HE)
(World Congress of Gastroenterology: Hepatic Encephalopathy Consensus Group, 1998)

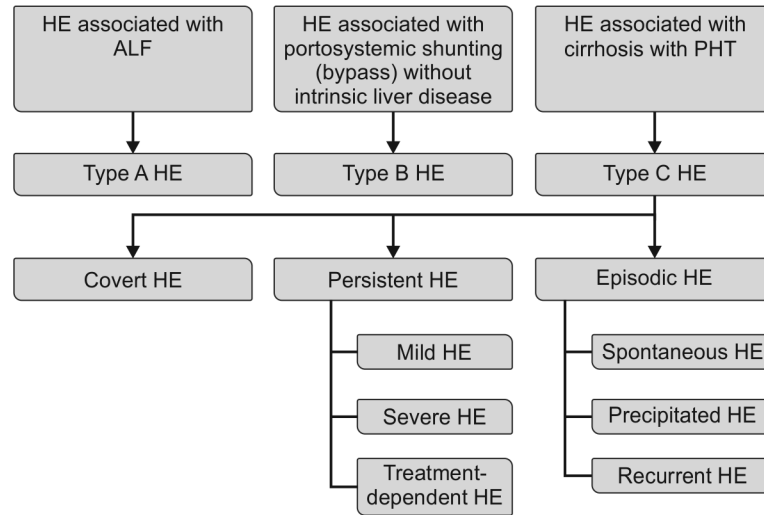

Table 3 Differences between Type A and Type C hepatic encephalopathy

Parameters	Type A	Type C
Pathology	Acute hepatocellular necrosis	Chronic hepatocellular injury Fibrosis, nodular regeneration Portosystemic shunting
Etiology	Acute liver failure	Chronic liver disease (cirrhosis)
Onset	Acute	Variable: insidious, acute
Precipitating factors	Uncommon	Common
Cerebral edema	High-grade edema	Low-grade edema
Nutritional status	Normal	Malnourished
Ascites	Absent	Usually present
Portosystemic shunts	Absent	Present
Treatment	Treat acute liver failure Consider liver transplantation	Treat precipitating cause with empirical therapy
Immediate survival	Low	High
Persistent neuropsychiatric sequelae after acute episode	No	Worsen cognitive functions

MINIMAL HEPATIC ENCEPHALOPATHY

Minimal hepatic encephalopathy (MHE) occurs classically in subjects with cirrhosis and is characterized by mild cognitive, psychomotor deficits and cerebral edema, affecting mainly attention, speed of information processing, motor abilities and coordination. MHE has also been recently reported in 35–50% of adult patients and 30% of children with extrahepatic portal venous obstruction (EHPVO) despite normal liver functions. Possible mechanism of MHE in EHPVO seems to be due to shunting of splanchnic blood directly into the systemic circulation bypassing

Table 4 Definitions of types of hepatic encephalopathy (HE)

Episodic HE	Encephalopathy of varying degree but lasting for short duration (Fig. 2A) <i>Precipitated HE</i> : Secondary to an identifiable precipitating factor <i>Spontaneous HE</i> : HE in the absence of a recognized precipitating factor
Recurrent HE	HE occurring \geq two times in 1 year with periods of symptom-free interval (Fig. 2B)
Persistent HE	Cognitive impairment at baseline lasting > 2 weeks secondary to liver disease (Fig. 2C). Affects social functioning
Minimal HE	Clinically normal mental status and normal neurologic examination but presence of cognitive defects in neuropsychometric tests
Overt HE	Clinically apparent encephalopathy of various degrees. Refer to Table 1 for classification
Covert HE	Clinically inapparent but revealed by psychometric tests. Encompasses minimal and subtle features of stage 1 HE (Fig. 2D).

hepatic detoxification. It is important to recognize MHE as it impairs the quality of life, which may improve with therapy. Other than ammonia, tumor necrosis factor alpha (TNF- α) has been shown to be a cause of MHE in children. MHE rarely occurs in EHPVO after surgical shunts.

DIAGNOSTIC TESTS TO CONFIRM HEPATIC ENCEPHALOPATHY

Laboratory tests are not routinely recommended for confirmation of HE. Altered mental status in a patient with CLD or ALF created as HE unless proved otherwise.

Serum Ammonia

In ambiguous case scenarios, high serum ammonia (arterial/venous) helps to differentiate HE from other causes of encephalopathy.

- Blood should be collected from a stasis-free vein.
- Avoid clenching fist or application of tourniquet as ammonia may be released from skeletal muscle.
- Collect in a lithium or heparin vacutainer. Heparin inhibits release of ammonia from red cells.

Figures 2A to D Pattern of hepatic encephalopathy. The curved line depicts the pattern of hepatic encephalopathy. (A) Episodic HE; (B) Recurrent HE; (C) Persistent HE; (D) Covert HE

- Samples should be stored and transported in an ice bath within 20 minutes for assay.
- Normal ammonia levels vary in different age groups (**Table 5**).
A definite cut-off level for ammonia has not been established in HE. However, it has been shown in adult studies that ammonia levels less than 100 $\mu\text{mol/L}$ have overall better chances of survival. Levels less than 150 $\mu\text{mol/L}$ in severe HE have less chances of cerebral herniation. Levels more than 200 $\mu\text{mol/L}$ are invariably associated with cerebral herniation and poor outcome.

Psychometric Tests

These tests are difficult to perform in children. These are:

- *Paper and pencil tests*: Figure and number connection tests, Indian child intelligence test (6–12 years), Wechsler adult intelligence scale (> 13 years)
- Computerized psychometric tests (Clicker frequency test).

Electroencephalogram

Interpretation of electroencephalogram (EEG) changes (**Table 1**) in various stages of HE requires expertise by a pediatric neurologist.

Magnetic Resonance Imaging and Spectroscopy of Brain

Magnetic resonance imaging (MRI) changes in brain (high signal intensities in T1 weighted images or diffuse white matter signal intensities in fluid-attenuated inversion recovery [FLAIR] images) do not correlate with severity of HE.

Table 5 Normal ammonia levels in children

Age	Value ($\mu\text{mol/L}$)
< 30 days	21–95
1–12 months	18–74
1–14 years	17–68
>14 years	19–71

Other Tests

These include liver function tests (LFTs) including prothrombin time, metabolic profile (serum electrolytes, blood sugar, arterial blood gas analysis, kidney function tests), sepsis profile (complete blood count, blood and urine cultures, chest X-ray), ascitic fluid analysis and culture (for spontaneous bacterial peritonitis) and specific tests for underlying cause of ALF or CLD.

TREATMENT

A four-pronged treatment approach is advocated: (1) supportive care for altered mental status; (2) treating the underlying cause (disease-specific); (3) treating the precipitating cause; and (4) medical therapy.

Supportive Care

A child with hepatic encephalopathy should ideally be managed in an intensive care environment. The first step in management involves taking care of the airway, breathing and circulation as in all emergencies. Other steps in management are listed below:

- Fluid, electrolyte and blood sugar are management as per ALF protocol
- Nasogastric (NG) tube for feeding or oral drug delivery
- Nutrition through NG tube: 100–150 kcal/kg/day + 1 g/kg protein
- Positioning for prevention of decubitus ulcers
- Prophylactic acid suppressants (proton pump inhibitors) to prevent aspiration pneumonitis (gastroesophageal reflux due to NG tube) and prevent stress (Cushing's) ulcers and gastrointestinal (GI) bleed (which aggravates encephalopathy)
- Elective intubation (impending respiratory compromise) and prophylactic anticonvulsants in grade III or IV are controversial issues. Intravenous phenytoin 20 mg/kg loading followed by 5 mg/kg maintenance for impending seizures due to cerebral edema and nonconvulsive status epilepticus (not clinically apparent)
- Prophylactic antibiotics with adequate cover for Gram-positive and Gram-negative organisms

- 20% mannitol or 3% hypertonic saline in cerebral edema of ALF (not required in CLD).

Treatment of Precipitating Factors

Prompt identification and correction of precipitating factors (Table 6) may increase the recovery rates to 80–90%. Due to overlap or multiple precipitating factors, sometimes it is difficult to ascertain what actually reversed the encephalopathy.

- Aggressive treatment of sepsis with antimicrobials ± antifungals is warranted. Sepsis is capable of inducing encephalopathy on its own.
- GI bleed generates a large amount of ammonia through gut flora that precipitates hepatic encephalopathy. The absence of amino acid isoleucine from hemoglobin makes it more ammoniagenic than other forms of protein.
- Prevent constipation with laxatives (lactulose).
- Daily monitoring of fluid intake-urine output, serum electrolytes and metabolic parameters (arterial blood gas [ABG], creatinine) is recommended.
- Diuretics are preferably withheld or used with caution and vigilance.

Medical Therapy

Gut cleansing by catharsis (lactulose) or antimicrobials (e.g., rifaximin) is the mainstay of therapy for overt HE or for prophylaxis in cirrhotics. Other agents may have a role in minimal or mild HE (Table 7).

Lactulose

Lactulose is a nonabsorbable disaccharide. It lowers the colonic pH favoring formation of nonabsorbable ammonium ions, allows preferential growth of nonurease producing bacteria, reduces formation of potentially toxic short chain fatty acids, and has a cathartic action that flushes out bacteria from gut.

Though widely used as first-line therapy, there is lack of robust data to support use in overt HE. Many have argued that its efficacy is related to simple cathartic action that could be comparable to any other laxatives. Limited data is available to show that it is superior to placebo in covert or minimal HE. Dose is 1–2 mL/kg/dose in 3–4 doses orally or through NG tube. Goal is to have 2–3 acidic (pH < 6) loose stools/day. It can also be administered as enema, especially in the setting of constipation or ileus in HE. Side effects include: abdominal cramping, gaseous distension, diarrhea and flatulence.

Table 6 Factors precipitating or worsening hepatic encephalopathy (HE)

Precipitating factors	Confounding factors in HE (These are additional contributory factors that could worsen the underlying HE)
• Sepsis	• Status epilepticus or postictal state
• Gastrointestinal bleed	• Metabolic acidosis due to sepsis
• Dyselectrolytemia (hypokalemia, alkalosis, hyponatremia*)	• Sedatives (benzodiazepines) during procedure, seizures or combativeness
• Dietary protein overload	• Intracranial hemorrhage due to coagulopathy
• Dehydration	• Uremia (renal failure) due to sepsis or end-stage disease
• Diuretic use	
• Constipation or ileus	

*Hyponatremia may precipitate HE or aggravate cerebral edema. It is not clear whether hyponatremia is a true pathogenic factor or not.

Table 7 Medical therapy in hepatic encephalopathy

Therapy in overt HE	Prophylactic therapy in cirrhotics
<i>Lactulose</i> : First-line therapy	<i>Lactulose</i> : First-line therapy
<i>Rifaximin</i> : Second-line add on therapy	<i>Rifaximin</i> : Second-line add on therapy (lactulose failure)
<i>Sodium benzoate</i> : adjunct in refractory HE or first-line in urea cycle defects (UCD)	LOLA (L-ornithine L-aspartate): adjunct therapy
<i>Neomycin</i> : abandoned	<i>Sodium benzoate</i> : Adjunct therapy
intravenous flumazenil (short-lasting therapy in adults)	<i>Diet</i> : Vegetable protein-based diet Branched chain amino acid supplement
<i>Protein intake</i> : Protein restriction is no longer recommended except transiently to approximately 0.5 mg/kg during the phase of acute encephalopathy. After recovery, daily protein intake should be 1.2–1.5 g/kg/day for ensuring growth and muscle mass. Small meals or liquid nutritional supplements evenly distributed throughout the day and a late night snack should be offered to prevent hypoglycemia.	
Vegetable or dairy-based protein diet is preferred as it contains high ornithine and arginine that facilitate ammonia disposal and low sulfated amino acids (methionine and cysteine) that are precursors of indoles and mercaptans (precipitants of HE). In addition, the fiber from the plant based diet also enhances ammonia disposal by faster intestinal transit, lowering colonic pH and allowing proliferation of favorable microbiota. Short chain fatty acids released from undigested fiber in colon provide additional calories to the patient. Hence, vegetable-based protein diet offers higher calorie: nitrogen ratio as compared to animal protein. Oral BCAA serves as supplement to the existing dietary protein or to those who are intolerant to the same.	
Primary prophylaxis for prevention of episodes of overt HE is not required, except in patients with cirrhosis with a known high-risk to develop HE.	

Rifaximin

This is a broad-spectrum antibiotic with poor oral bioavailability. It is solubilized by bile salts with maximum action on small bowel bacteria. Once bile salts are absorbed into enterohepatic circulation, rifaximin becomes less active and, therefore, action on colonic bacteria is minimal. Though widely used, studies have not yet shown its superiority over other agents in acute HE. However, it prevents recurrent HE episodes in cirrhotics, especially in those with lactulose treatment failure in adult. Dose schedule is not available for children; in adults it is given as 550 mg twice daily. Combination of rifaximin and lactulose has shown to be superior to lactulose alone in cirrhotic adults with overt HE.

Neomycin and Other Antibiotics

Recent studies have shown no benefit over lactulose or placebo. It inhibits anaerobes and also intestinal mucosal glutaminase activity (reduced ammonia in portal vein). It has been abandoned due to ototoxicity and nephrotoxicity. Metronidazole and vancomycin have also been tried in limited clinical trials with some success in overt HE.

L-Ornithine L-Aspartate

Activates carbamyl phosphate synthetase and ornithine carbamyl-transferase in urea cycle to stimulate glutamine synthesis and detoxify ammonia. L-Ornithine L-Aspartate (LOLA) is administered intravenously 6g three times a day in adults. Experience in children is limited. It is used in mild HE or as prophylaxis in HE, especially those with transjugular intrahepatic portosystemic shunts (TIPS). Oral supplementation of LOLA is ineffective

Branched Chain Amino Acids

This supplement has been used in an attempt to restore the altered BCAA/AAA ratio in the brain to produce *true neurotransmitters*. It is used in early encephalopathy and for prophylaxis in chronic encephalopathy due to hepatic cirrhosis. The dose varies between 0.24 mg/kg/day and 0.45 mg/kg/day once or in two divided doses. An updated meta-analysis of eight randomized, controlled trials (RCTs) indicated that oral BCAA-enriched formulations improve the manifestations of episodic HE whether overt or minimal. There is no effect of IV BCAA on the episodic bout of HE.

Molecular Adsorbent Recirculating System

Just like hemodialysis, molecular adsorbent recirculating system (MARS) *cleanses* blood via an albumin circuit and bicarbonate dialyzer. MARS ameliorates hepatic encephalopathy and other clinical manifestations of ALF by removing both water-soluble and protein-bound toxins. It is a bridge to liver transplantation and is highly expensive.

Liver Transplantation

It should be considered when medical therapy fails or other complications ensue. Recurrent intractable overt encephalopathy in a patient with liver failure is an indication for liver transplant.

MITOCHONDRIAL HEPATOPATHIES

Mitochondria, the *powerhouse* of a cell, are the site for beta oxidation (aerobic pathway) that generates 38 adenosine triphosphate (ATP) through the Krebs's cycle and respiratory chain. Various mutations in mitochondrial deoxyribonucleic acid (DNA) result in enzyme deficiencies that fail to generate energy. Liver, brain and heart (high dependency sites) are most affected as 80% of their functions depend on beta-oxidation. Conventionally, mitochondrial hepatopathies (MH) comprise of fatty acid oxidation and respiratory chain disorders as their presentation overlaps. Defects of fatty acid oxidation have been discussed in detail in Section 3.

Settings to Suspect to Mitochondrial Hepatopathies

- Recurrent symptoms (acidosis, ketosis, high lactate);
- Rapid deterioration with minor illness upper respiratory tract infections (URI) with quick recovery after intravenous (IV) fluids;
- Developmental delay in a child with acute encephalopathy;
- Multisystem involvement (neurodevelopmental delay, cardiomyopathy and peripheral myopathy);
- Reye like illness (details later);
- Unexplained liver failure (toddlers) with negative viral markers; and
- Fatty liver on ultrasound, steatosis on liver biopsy with or without raised transaminases with nonspecific symptoms or multisystem involvement.

Family history of consanguinity (28%), sibling deaths (43%) or affected sibs contribute to the disease. Maternal history of acute fatty liver of pregnancy or HELLP (hemolysis, elevated liver enzymes, low platelet and liver failure) syndrome could indicate very long chain or long chain fatty acid oxidation disorder (FAOD) in fetus. Among the FAODs, medium chain fatty acid defects may present with recurrent encephalopathy but have better prognosis if symptom onset is more than 6 years of age. Long chain and very long chain diseases have worse outcome and a large proportion have multisystemic disease with liver failure. Respiratory chain defects invariably have liver failure.

Urea Cycle Defects

Urea cycle defects (UCDs) result from enzymes deficiencies at various levels of urea cycle pathway leading to severe

hyperammonemia. Severe deficiency presents in the first 2 weeks of life with lethargy, coma and seizures. Moderate deficiency presents in childhood with recurrent or intractable encephalopathy especially after high protein diet. Jaundice and liver failure are usually not associated with urea cycle defects. These disorders are discussed in detail in Section 3 on Metabolic Disorders.

Laboratory Diagnosis

A brief approach to work-up for MH and urea cycle disorders is mentioned in **Flow chart 2**. Creatinine phosphokinase may be elevated in associated myopathies of MH. Certain precautions are important before linking abnormal tests to basic metabolic liver disease. Lactate levels may be elevated in intercurrent sepsis and, therefore, the test should be repeated to document elevated levels in the recovery phase of illness to conclude hyperlactatemia. Urine ketone bodies must be repeated more than once to give a negative label. Serum ammonia levels are 80–200 $\mu\text{mol/L}$ in FAOD and 150–300 $\mu\text{mol/L}$ in UCD. The definite diagnosis of inborn errors of metabolism are done by gas chromatography and tandem mass spectrometry with quantitative assay of the deficient enzyme in blood and toxic metabolites in urine. For MH, liver and muscle biopsy may help in quantifying respiratory chain enzymes. For details, refer to Section 3 on Metabolic Disorders.

Treatment

Acute and long-term treatment of MH and UCD is outlined in **Table 8**. MH is usually treated with supportive management, carnitine and other supplements that have no proven role. UCD is treated with ammonia-lowering agents such as sodium benzoate and phenylacetate and other drugs mentioned in **Flow chart 3**.

Carnitine

The role of carnitine is controversial as no proven benefit exists. It is life-saving in patients who have primary carnitine deficiency and valproate toxicity. Carnitine is usually supplemented in FAOD due to a relative secondary carnitine deficiency in the mitochondria to remove toxic acyl-CoA intermediates. Risk of arrhythmias in long chain FAOD has been noted with carnitine supplementation.

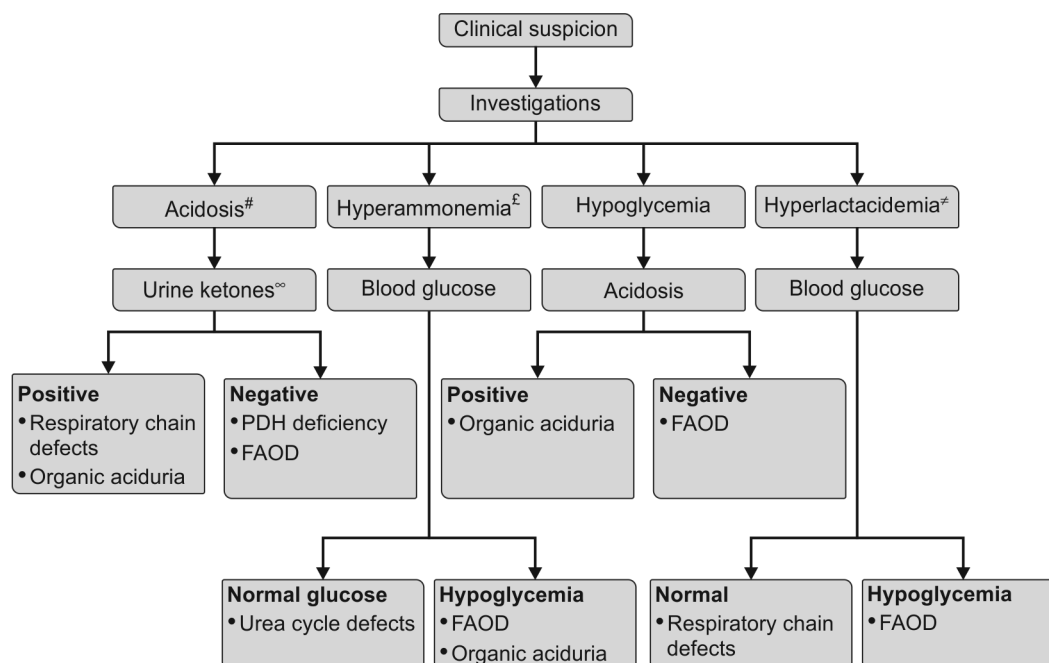

Sodium Benzoate and Phenylacetate

Sodium benzoate and phenylacetate are used in acute HE, particularly in UCD and occasionally in FAOD. Glycine combines with benzoate to form hippurate. Glutamine combines with phenylacetate to form phenylacetylglutamine. These by-products are effectively excreted in urine, thereby reducing the ammonia load that is not being metabolized in a defective urea cycle. Additionally, sodium benzoate has not been shown to be superior to lactulose in randomized trials in adult cirrhotics. It may be used as an adjunct in refractory HE. Excessive sodium precludes its use in those with pre-existing ascites or renal dysfunction.

REYE SYNDROME

Reye syndrome (RS) is a secondary cause of MH. The British Pediatric Surveillance Unit defines RS as an unexplained, noninflammatory encephalopathy in those less than 16 years of age, associated with a serum aspartate or alanine aminotransferases, or plasma ammonia more than three times the normal limit, or hepatic fatty infiltration that is microvesicular in appearance and panlobular in distribution.

Reye syndrome is a biphasic illness. A viral prodrome with infection of the upper respiratory tract with influenza virus (90%) or chickenpox (5–7%) precedes encephalopathy. It is followed several days later by an abrupt onset of encephalopathy heralded as profuse, effortless vomiting. The rate and degree of neurological decline vary. Raised intracranial pressure from brain swelling

Flow chart 2 Approach in mitochondrial hepatopathy, organic aciduria and urea cycle defect

[#] Arterial blood gas to look for pH, bicarbonate and anion gap [sodium – (chloride + bicarbonate), normal 12–18, abnormal > 20], [£] Arterial sample, [±] Arterial sample, [∞] At the time of blood sugar estimation, Abbreviations: PDH, pyruvate dehydrogenase; FAOD, fatty acid oxidation defect.

Table 8 Treatment of mitochondrial hepatopathy and urea cycle defects

Acute	Long-term	Prevention
10–12.5% dextrose infusion	Carnitine 50–100 mg/kg/d	Avoidance of fasting
Bicarbonate, K+ supplementation	Coenzyme Q ₁₀ 3–5 mg/kg/day	Infancy: Feeding every 3–4 hourly or continuous nasogastric feeding
Carnitine (100 mg/kg) intravenous till oral acceptability	Vitamin E 25 IU/kg/day	Older children: Corn starch therapy (1–2 gm/kg/dose) every 4–6 hourly
Sodium benzoate and phenylacetate (100–250 mg/kg till ammonia levels normalize)	Other supplements: creatine and dichloroacetate	Medium chain triglyceride [#] (MCT) supplementation as 20% of caloric intake

[#]MCT does not require carnitine cycle to cross mitochondrial membrane.

may result in death or neurological injury. Aspirin use is strongly associated as a causal role in the illness. Aspirin metabolites inhibit beta oxidation of long chain fatty acids. Precipitation of RS by use of antiemetics is controversial. *Classical* RS presents with the earlier features between 5 years and 15 years. In children less than 5 years of age, FAOD and UCD mimic RS (Reye-like illness). It is also believed that RS in childhood may be one of the first clues of an inborn error presenting later in adulthood. Declining use of aspirin is also associated with declining incidence of RS. Others believe that decline is attributed to increased detection of inborn errors from neonatal screening programs and early management of the same.

As the incidence of RS is dramatically decreasing and newer enzymatic defects are being discovered, it has become imperative to search for inherited metabolic diseases in all age groups (especially < 5 years) with RS. The key laboratory feature that distinguishes RS

from other encephalopathies is near normal bilirubin (< 5 mg/dL) in the presence of very high enzymes, elevated prothrombin time and hyperammonemia. Manifestations and management are same as that of ALF.

CONGENITAL PORTOSYSTEMIC SHUNTS

This is a rare developmental anomaly in children where there is lack of complete involution of embryonic or fetal communications between veins of portal system and inferior vena cava. The diversion of blood flow may be partial or total. Communications can be single or multiple. Location can be extrahepatic (Abernathy malformation and congenital absence of portal vein) or intrahepatic. The condition may be associated with other malformations including biliary atresia, polysplenia, gut malformations and congenital heart diseases.

Diagnosis

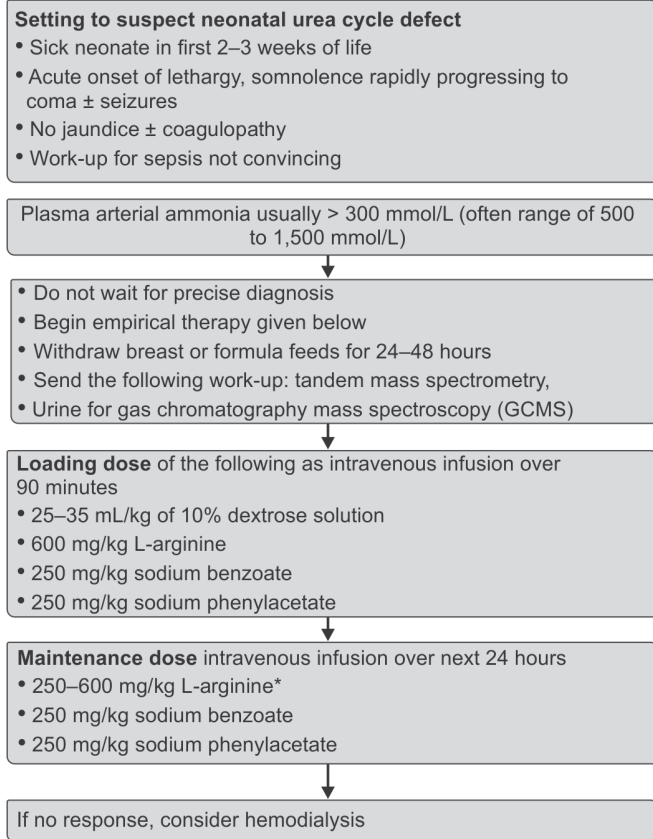

Encephalopathy in congenital portosystemic shunts (CPS) is usually recurrent or intractable. Diagnosis should be suspected in children who have lethargy and confusion especially after meals; those with mental retardation with seizures, learning difficulties, behavioral abnormalities and hyperactivity. Other settings to suspect are enlisted as follows:

- Neonatal cholestasis with recurrent hypoglycemia but non-enlarged liver;
- Early onset pulmonary hypertension (mean: 5 years);
- Hepatopulmonary syndrome without overt features of cirrhosis (mean: 4 years); and
- Incidental radiological finding: small liver (45–65% of estimated volume for age) and absence of portal vein.

Management

Hyperammonemia, slow wave EEG changes and globus pallidus hyperintensities on MRI brain are often seen. Doppler ultrasound

Flow chart 3 Management algorithm for acute neonatal hyperammonemic crisis

- * If precise diagnosis is made by this time, then
- 250 mg/kg of L-arginine for carbamyl phosphate synthetase (CPS) I and ornithine transcarbamylase (OTC) deficiency
 - 600 mg/kg of L-arginine for citrullinemia and argininosuccinic aciduria
 - For argininosuccinic aciduria, arginine therapy alone may suffice.

and portovenography are the key imaging modalities. Long-term complications include liver hemangioma, adenoma or focal nodular hyperplasia (mean: 8 years) with propensity to become malignant. With exception of neonatal cholestasis where the

shunts may resolve spontaneously, the rest persist and require radiological or surgical closure. Early closure is advocated to prevent pulmonary and neurological complications. Liver transplantation is usually not required.

IN A NUTSHELL

1. Hepatic encephalopathy refers to a variety of reversible neurologic abnormalities seen in patients with cirrhosis and liver failure. Manifestations arise because of three factors: portosystemic shunting, alterations in the blood-brain barrier, and the interactions of toxic metabolites with the central nervous system (CNS).
2. Ammonia is the principal toxin responsible for encephalopathy. Hypokalemia, metabolic alkalosis and sepsis contribute to brain dysfunction.
3. Hepatic encephalopathy may occur secondary to acute liver failure, chronic liver disease, mitochondrial defects, or systemic disorders.
4. Minimal hepatic encephalopathy (MHE) occurs classically in subjects with cirrhosis and is characterized by mild cognitive, psychomotor deficits and cerebral edema, affecting mainly attention, speed of information processing, motor abilities and coordination.
5. A four-pronged treatment approach is advocated: supportive care for altered mental status, treating the underlying cause (disease-specific), treating the precipitating cause and medical therapy.

Chapter 37.10

Acute Liver Failure

Anupam Sibal, Vidyut Bhatia, Akshay Kapoor

Acute liver failure (ALF) is a devastating illness with a high mortality rate. It occurs as a consequence of rapid death or injury to a majority of hepatocytes, thereby compromising liver function to a significant extent. Acute on chronic liver failure refers to an acute decompensation of pre-existing liver disease secondary to an identified or unidentified liver disorder. The Pediatric Gastroenterology Chapter of the Indian Academy of Pediatrics (IAP) has published guidelines for the management of ALF in 2013. The management of ALF described in this chapter is largely based on those guidelines.

DEFINITION

The Pediatric Gastroenterology Chapter of IAP defines acute liver failure in the presence of (1) evidence of liver dysfunction within 8 weeks of onset of symptoms (neonates may have only deranged liver functions without overt symptoms); (2) uncorrectable (6–8 hours after administration of one dose of parenteral vitamin K) coagulopathy with international normalized ratio (INR) more than 1.5 in patients with hepatic encephalopathy (HE) or INR more than 2.0 in patients without encephalopathy; and (3) no evidence of chronic liver disease either at presentation or in the past.

INITIAL ASSESSMENT

The history taken at the first contact should include details about the onset of jaundice, changes in the sensorium like excessive sleepiness, excessive crying, altered sleep and wake cycle, evidence of altered coagulation in the form of bleeding from the nose, vomiting of blood, black-colored stools or ecchymosis. History of blood transfusions in the past, onset in relation to recent ingestion of drugs, like acetaminophen, valproate or drugs used for tuberculosis, are also important. Similar presentations in the past would point out to a chronic underlying etiology. History should also include asking for consanguinity or family history suggestive of Wilson disease, early infantile death, viral hepatitis and autoimmune conditions.

Physical examination should include the assessment of growth and search for signs of chronic liver disease. It is important to evaluate the nutritional status of the child. The abdominal examination should include measurement of liver span, the size of the spleen and presence of fluid in the abdomen. A comprehensive systemic examination should be done keeping in mind that ALF has a multisystem involvement.

Management should commence immediately with concurrent etiological work-up.

ETIOLOGY

Few studies have looked into the etiology of ALF in India. There are no prevalence- or population-based studies available. Studies from referral centers reveal that infectious hepatitis (secondary to viral hepatitis type A, E) is the most important cause of ALF (Table 1). Studies from the West, however, show a different picture. In the largest multicentric pediatric study on ALF in 348 children, the etiology included acute acetaminophen toxicity (14%), metabolic disease (10%), autoimmune liver disease (6%), nonacetaminophen drug-related hepatotoxicity (5%), infections (6%) and other diagnosed conditions (10%). The largest proportion of cases (49%) was indeterminate. As a subgroup, in infants and

newborns, inherited metabolic disorders are responsible for the majority of cases.

WORK-UP

The initial investigations should focus on establishing the cause, as also performing a baseline evaluation of the patient's biochemical status (Table 2). It is important to stratify investigations depending on the demographic status of the child. Not all investigations for establishing etiology are needed in every child. For example, a child of 2 years of age should not be investigated for Wilson disease because it is very unlikely to present at this age. Similarly, it is very unlikely that an 11-year-old is likely to suffer from an inherited multisystem disorder of metabolism.

MANAGEMENT

Acute liver failure has a progressively evolving unpredictable course. Raised intracranial pressure, infections and multiorgan failure are the major causes of mortality in children with ALF. Efforts should be made to ameliorate these conditions while waiting for the native liver function to recover or for a liver transplantation. Most management recommendations are based on expert group consensus, or extrapolated from case series or adult studies.

Immediate Measures

The child should be nursed in a calm and quiet environment in an intensive care setting. A central line should be placed to

Table 1 Indian studies on children with acute liver failure

Year of study	Location	n	Contribution by infectious hepatitis (%)
1996	New Delhi	40	75%
1999	Pune	36	61.1%
2002	Chandigarh	67	94%
2004	New Delhi	32	62.5%
2005	Vellore	22	Not clear
2007	Kolkata	45	66.6%
2012	Delhi	43	77%

Table 2 Investigations in infants and children with acute liver failure

Abbreviations: HAV, hepatitis A virus; IgM, immunoglobulin M; HEV, hepatitis E virus; HBcIgM, hepatitis B core antigen; HCV, hepatitis C virus; SLA, soluble liver antigen; SMA, smooth muscle antibody; ANA, antinuclear antibody; LKM, liver-kidney microsomal antibodies; GALT, galactose-1-phosphate uridyl transferase.

assess central venous pressure, administer intravenous (IV) fluids, medications and blood products. Blood samples can also be collected as the line obviates the need for repeatedly pricking the patient. Intravenous fluids are targeted towards meeting daily requirement and insensible losses. The glucose infusion rate should be 6–8 mg/kg/min titrated to maintain a glucose level between 150 mg/dL and 200 mg/dL. The composition of maintenance fluids can be tailored to the electrolyte, sugar and renal status of the patient. Inotropes like dopamine and dobutamine can be used if the patient is hypotensive. Strict fluid charting should be maintained and the fluids given as part of preparing solutions for antibiotics should be accounted for. A nasogastric tube should be inserted for feeding/drainage and a urinary catheter for output measurement. Care of bowel, back, bladder, skin, eyes should be provided. Monitoring of clinical and biochemical parameters should be done frequently until the patient becomes stable (**Table 3**).

Mechanical ventilation of patients in grade III or IV encephalopathy or those with significant hypoxemia is necessary. Sedation in intubated patients may be carried out using midazolam or propofol. For painful or invasive procedures, a short acting agent like propofol is preferred. Medications having the propensity to alter the level of consciousness should be avoided.

Metabolic, Electrolyte and Acid-base Disturbances

An important aspect of the management of ALF is to manage the associated metabolic complications which occur frequently. The most commonly seen disturbances are both low and high levels of sodium, calcium, potassium, low phosphate levels and acid-base disturbances.

Management of Intracranial Hypertension

The most dreaded complication of ALF is the development of intracranial hypertension (ICH). In patients who have grade III–IV hepatic encephalopathy, 70–80% patients can develop ICH. It is also the most common cause of death in these children. In addition, development of raised ICH could preclude the feasibility of liver transplant as the chances of irreversible neurological damage are very high. Head end elevation to 30° and elective endotracheal intubation are recommended. Prophylactic administration of 3% saline is recommended in patients with severe encephalopathy. The target sodium should be at 145–155 mmol/L. 20% mannitol solution can be given as a bolus in a dose of 0.5 g/kg if there is an acute rise of intracranial pressure. Care should be taken to avoid increasing the serum osmolality to more than 320 mOsm/L.

Table 3 Monitoring of clinical and biochemical parameters

• Continuous saturation monitoring
• Continuous monitoring of vital signs
• 6 hourly neurological assessment
• 8 hourly electrolyte, sugar and arterial blood gases
• 12 hourly coagulation studies
• Daily measurements of liver span
• Daily full blood counts, LFT and KFT
• Daily weight (using special weighing scales when the patient cannot be mobilized)
• Daily prescription review
• Twice weekly calcium and phosphate
• Surveillance blood and urine cultures

Abbreviations: LFT, liver function test; KFT, kidney function test.

Management of Coagulopathy and Hemorrhage

Coagulopathy is an inevitable accompaniment of ALF. A single dose of IV vitamin K should be given to correct any reversible coagulopathy. Care should be taken to use vitamin K₁, as routinely available vitamin K preparation can cause hemolysis in G6PD-deficient individuals. Correction of coagulopathy with fresh frozen plasma is not recommended routinely as it interferes in the assessment of the progression of the disease and suitability for a liver transplant. It should only be given when there is active bleeding or when an invasive procedure is planned or if coagulopathy is very severe (INR > 7). Platelet count and function are depressed on account of ALF and contribute to increased coagulopathy. A low platelet count should be corrected if the platelet count falls below $20 \times 10^9/L$ or with active hemorrhage or before any planned invasive procedure. The most common site of bleeding is from the gastrointestinal tract; hence, prophylactic administration of proton pump inhibitors is routinely recommended.

Sepsis

Bacterial infection is one of the leading causes of mortality in patients with ALF. The most common organisms isolated are Gram-positive cocci (staphylococci, streptococci) and enteric Gram-negative bacilli. Fungal infections, especially *Candida* spp., may be present in up to one-third of patients with ALF. Empirical antibiotics should be avoided but are recommended in the IAP guidelines in the following situations: surveillance cultures reveal significant isolates, progression of, or advanced stage (III/IV) hepatic encephalopathy, refractory hypotension, renal failure, presence of systemic inflammatory response syndrome components (temperature > 38°C or < 36°C, white blood cells [WBC] count > 12,000 or < 4,000/mm³, tachycardia) and listing for liver transplant since infection often results in delisting and immunosuppression postliver transplantation is imminent. Broad-spectrum coverage with a third-generation cephalosporin, vancomycin/teicoplanin, and fluconazole are recommended.

Feeding

Oral or nasogastric feeding is usually well-tolerated and should be started as early as possible. Enteral route of feeding, being more physiologic, is preferred. Vegetable source of protein is preferred. The recommended nutritional intake in children with liver failure is summarized in **Table 4**.

Specific Management

Specific therapy should be administered if the underlying cause of ALF has been identified (**Table 5**).

Role of N-Acetyl Cysteine and L-Ornithine L-Aspartate

The evidence for use of N-acetyl cysteine (NAC) in causes other than acetaminophen poisoning is increasingly being recognized. NAC can be used in the dose of 100 mg/kg/day. Although its role has been questioned in a recently published multicentric study, it continues to be used at most centers. A randomized controlled trial on the benefits of L-ornithine L-aspartate (LOLA) failed to demonstrate any benefit in terms of mortality or lowering of ammonia in patients with ALF.

Liver Transplantation

Liver transplantation remains the only definite therapy for ALF in children. It has transformed the management of ALF. Several prognostic scoring systems have been devised to predict mortality and to identify those requiring early liver transplant. These include King's College Hospital (KCH) criteria, pediatric end-stage liver disease (PELD) score, APACHE II and Clichy criteria. The IAP consensus statement recommends using an INR more than

Table 4 Recommended dietary intakes for children with acute and acute on chronic liver failure

Component	Recommended intake	Comments
Calories	150% of recommended allowance	Children with long-standing liver disease already suffer from varying degrees of malnutrition, therefore, need extra calories
Carbohydrates	15–20 g/kg/day	
Fat	8 g/kg/day with 50% as medium chain triglycerides	
Protein (non-encephalopathic)	2–3 g/kg/day	For promoting growth and to maintain positive nitrogen balance. Vegetable and dairy product based
Protein (encephalopathic)	Low-grade (I–II) 1–2 g/kg/day High-grade (III–IV) 0.5–1 g/kg/day	Further protein restriction can exacerbate HE by causing breakdown of endogenous protein

Abbreviation: HE, hepatic encephalopathy.

Table 5 Etiology-specific management of underlying acute liver failure (ALF)

Etiology	Management
Herpes simplex virus	Acyclovir
Acetaminophen poisoning	NAC oral: 140 mg/kg loading dose followed by 17 doses of 70 mg/kg every four hours for a total of 1,330 mg/kg over 72 hours NAC IV intermittent: 140 mg/kg loading dose followed by 12 maintenance doses of 70 mg/kg every 4 hours NAC IV infusion: Loading dose 150 mg/kg infused over 15 minutes, followed by 50 mg/kg infused over 4 hours and then 100 mg/kg infused over 16 hours
Acute severe autoimmune hepatitis	Methyl prednisolone
Galactosemia	Galactose and lactose-free diets
Fructosemia	Fructose-free diets, avoiding fructose and sorbitol infusions
Tyrosinemia	Nitisinone, phenylalanine and tyrosine-free diets
Bile acid synthesis defects	Primary bile acid therapy
Neonatal hemochromatosis	Intravenous immunoglobulin, exchange transfusion

Abbreviation: NAC, N-acetyl cysteine.

4 or factor V concentration of less than 25% as the best available criteria for listing for liver transplant. Contraindications for liver transplantation are active uncontrollable and untreatable sepsis, severe cardiopulmonary disease, multiorgan failure, mitochondrial disease, and hepatic encephalopathy stage IV with severe neurological impairment.

Artificial Detoxification Systems

In ALF, since most of the toxins are albumin-bound and are not filterable using conventional dialysis, different albumin dialysis systems have been developed using albumin as the scavenging

molecule. Artificial support systems can be broadly grouped into the biological (bioartificial liver) and nonbiological (molecular adsorbent recirculation system and prometheus systems) categories. None of these systems have demonstrated any survival benefit in the pediatric population as compared to the conventional management of ALF.

PROGNOSIS AND OUTCOME

In more than 50% of children with ALF, there is poor survival unless liver transplant is offered at the appropriate time. Prognostic factors predicting outcome in acute liver failure include elevated serum bilirubin and prothrombin time, young age of the child, high arterial ammonia and high WBC count, low alanine aminotransferase and presence of encephalopathy. The outcome is better with hepatitis A, acetaminophen overdose and ischemia (approximately 60% spontaneous survival) and poor with drug-induced ALF (non-acetaminophen), hepatitis B, and indeterminate cases (25% spontaneous survival).

IN A NUTSHELL

1. The Pediatric Gastroenterology Chapter of IAP defines acute liver failure (ALF) in presence of (1) evidence of liver dysfunction within 8 weeks of onset of symptoms, (2) uncorrectable coagulopathy; and (3) no evidence of chronic liver disease either at presentation or in the past.
2. Infectious hepatitis (secondary to viral hepatitis type A, E) is the most important cause of acute liver failure in India.
3. Raised intracranial pressure, infections and multiorgan failure are the major causes of mortality in children with ALF.
4. Broad-spectrum coverage with a third-generation cephalosporin, vancomycin/teicoplanin, and fluconazole are recommended.
5. Liver transplantation remains the only definite therapy for acute liver failure in children.

Chapter 37.11

Liver Tumors

Karthick Sundaram, Naresh P Shanmugam

Primary liver tumors are rare in children and the most common neoplasm involving the liver is usually a metastatic disease either from neuroblastoma, Wilms tumor or lymphoma. The reported incidence of liver tumor in children is around 0.5–2.5 per million population. Two-thirds of primary liver tumors are malignant with hepatocyte-derived tumors being more common than the mesenchymal tumors. Hemangiomas and hamartomas are the most common benign liver tumors, while hepatoblastoma is the most common primary malignant liver tumor in children. Majority of liver tumors per se do not cause cholestasis or synthetic dysfunction. **Table 1** enlists the various tumors of the liver.

HEMANGIOENDOTHELIOMA

Hemangioendotheliomas are the most common benign liver tumors and represent around 30% of all hepatic tumors in children. The incidence might be much higher as small hemangioendothelioma remains asymptomatic and involutes spontaneously. They commonly present within first 6 months of life and more than 90% are diagnosed before 6 years of age. Hemangioendothelioma has a female preponderance with 2–4.3

times more common than males. They are derived from the vascular endothelium and the natural history could be divided into three phases:

1. Phase of rapid growth from birth to 12 months, characterized by rapidly dividing endothelial cells, myeloid cells and pericytes.
2. Involuting phase lasting for 5–7 years, where apoptosis predominates.
3. Involved phase where the original lesion is replaced by fibrofatty tissue.

Clinical Presentation

Hemangioendotheliomas usually present with an abdominal mass or with heart failure. Multiple cutaneous hemangiomas should raise the possibility of visceral hemangiomas. Associated abnormalities include atrial septal defect, patent ductus arteriosus, myelomeningocele, renal agenesis and absent common bile duct. A good proportion of hemangioendotheliomas present with cardiac failure due to large arteriovenous or portovenous shunts. Platelet sequestration and consumptive coagulopathy can occur (Kasabach-Merritt syndrome) and sometimes there is an associated hypothyroidism due to overproduction of type 3 iodothyronine deiodinase. Large tumors can cause inferior vena cava compression, abdominal compartment syndrome and respiratory compromise.

Diagnosis

Full blood count and liver function test would be usually normal. In case of Kasabach-Merritt syndrome with disseminated intravascular coagulation, there might be low platelets and coagulopathy. *Ultrasonography* of the liver might reveal a predominantly hypoechoic lesion with well-defined margins and a Doppler might show flow of blood in the lesion. *Contrast computed tomography* (CT) scan would show isodense or hypodense lesions with uniform or centripetal contrast-enhanced lesion. *CT angiography* would reveal flow voids, enlarged hepatic arteries or veins or aortic tapering distal to the origin of hepatic artery indicating shunting. On *magnetic resonance imaging* (MRI), hemangioendotheliomas appear as low signal lesions on T1 weighted images as against high signal lesions on T2 weighted images. Because of lack of Kupffer cells, ^{99m}Tc sulfur colloid *scintigraphy* shows hemangioendothelioma as a cold spot.

Biopsy is usually not required but in case of diagnostic dilemma, an open biopsy is preferred than a percutaneous biopsy due to the vascular nature of the tumor. Biopsy might show two distinguished histological types. Type 1 lesions consist of small vascular channels lined by flat or round endothelial cells displacing the portal tract, with no features of infiltration or mitosis. Type 2 lesions consist of tortuous vascular channels with pleomorphic endothelial cells proliferating into the adjacent hepatic tissue, which might mimic angiosarcoma.

Treatment

Most hemangiomas regress spontaneously. Treatment is indicated only if there are associated complications like high output states such as tachycardia/cardiac failure or pressure effect due to the size of the tumor. Supportive treatment with inotropes and diuretics is warranted in cardiac failure. Definitive treatment includes steroids (prednisolone for 6 weeks), vincristine, cyclophosphamide or daily subcutaneous interferon alpha-2a therapy. Symptomatic hemangioendothelioma that has failed to resolve with medical managements may be treated surgically. Debulking, hepatic artery ligation and radiological interventions like transcatheter endovascular tumor chemoembolization could be tried. Liver transplantation is an option for difficult to treat tumors.

Table 1 Classification of liver tumors

Benign solid tumors	Malignant tumors
<i>Primary liver tumors</i>	
a. Epithelial tumors:	• Hepatoblastoma
• Hepatocellular adenoma	• Hepatocellular carcinoma
• Bile duct adenoma	• Undifferentiated sarcoma
• Biliary cystadenoma	• Biliary rhabdomyosarcoma
• Biliary papillomatosis	• Angiosarcoma
• Peribiliary gland adenoma	• Epitheloid
b. Mesenchymal tumors:	hemangioendothelioma
• Hemangioma	• Rhabdoid tumors
• Infantile hemangioendothelioma	
• Fibroma	
• Angiomyolipoma	
• Lipoma	
• Lymphangioma	
• Mesenchymal hamartoma	
c. Mixed tumors:	
• Teratoma	
d. Tumor-like lesions:	
• Focal nodular hyperplasia	
• Nodular regenerative hyperplasia	
• Microhamartoma (von Meyerburg complex)	
• Inflammatory pseudotumor	
• Focal fatty change	
• Pseudolipoma	
• Microregenerative nodule	
<i>Metastatic liver tumors</i>	
• Neuroblastoma	
• Wilm's tumor	
• Rhabdomyosarcoma	
• Non-Hodgkin lymphoma	
• Adrenal cortical carcinoma	

HEPATOBLASTOMA

Hepatoblastoma (HB) is the most common primary malignant liver tumor in children with a reported incidence of 1.6–2 per million children in western countries. Nearly 70% of HBs are diagnosed within 2 years of age.

Etiopathogenesis

Most HBs are sporadic while some are associated with chromosomal abnormalities like loss of heterozygosity at 11p15.5 locus, trisomies such as 20, 2, 3, and rarely, 18. HB is associated with certain syndromes like Beckwith-Wiedemann, familial adenomatous polyposis (FAP)/Gardener, Li Fraumeni, Soto syndrome and neurofibromatosis type 1. Other associations include hemihypertrophy and adrenal agenesis. For unknown reasons, extreme prematurity and very low birth weight infants have a higher incidence of HB.

Specific mutations of the adenomatous polyposis coli (APC) gene are associated with HBs in FAP. Changes in the expression of *H19* and *IGF2* genes, genetic aberrations involving the *wnt* signaling pathway, hedgehog gene pathway, insulin-like growth factor axis and hepatocyte growth factor/c-met pathway are noted to be associated with HB. Telomerase activation, mutation of *CTNNB* or deletion of *CTNNB* exon 3 is found in a substantial proportion of HBs.

Pathology

Histologically HB is classified based on *International Consensus Classification Histologic Subtypes* (Table 2). Epithelial type accounts for 67% of all HBs, 7% are well-differentiated fetal type, and 5% are small cell undifferentiated tumors. Small cell undifferentiated tumors have a bad prognosis while there is not much of prognostic difference between the other subtypes.

Clinical Presentation

Most common presentation is a painless right upper quadrant abdominal mass. Liver-specific symptoms, such as cholestasis are extremely rare. Fever and anorexia may be present in advanced disease. There are case reports with hypoglycemia as presenting feature probably secondary to insulin like growth factor secreting tumors and isosexual precocity with beta-hCG secreting tumors. Tumor thrombus extending into the IVC or right atrium can present with features of outflow obstruction and heart failure. Tumor rupture is rare and can present with acute abdomen and anemia.

Diagnosis

When suspected of a liver tumor, the cost-effective initial imaging investigation would be ultrasonography of the abdomen.

Abdominal ultrasonography would give good information about extent of the lesion and discerns whether the lesion is solid or cystic and whether it is a solitary or a multifocal tumor. CT and MRI, utilizing appropriate contrast or vascular enhancement, are essential to determine the tumor extension and resectability. Before initiation of chemotherapy, it is recommended to have a CT scan of abdomen along with chest that would help in staging and formulating treatment plan.

Tissue diagnosis is essential before initiating chemotherapy and the only exception is an HB between 6 months and 3 years of age if imaging is typical with high alpha fetoprotein (AFP). The biopsy can be done either percutaneously under ultrasound guidance or by open surgical technique. AFP levels are elevated in more than 90% of children with HB. AFP less than 100 at diagnosis is associated with poor prognosis. Serial levels are helpful in monitoring tumor response to chemotherapy.

Hepatoblastoma Staging

Several staging systems exist for HB of which presurgical pretreatment extent of disease (PRETEXT) staging devised by the Société Internationale d'Oncologie Pédiatrique-Epithelial Liver Tumor Study Group (SIOPEL) is gaining wide acceptance. This staging system was found to be superior in predicting resectability of tumors and outcome, when compared to Tumor Node Metastasis (TNM) or Children Oncology Group (COG) postsurgical-based staging system staging. The SIOPEL suggests neoadjuvant chemotherapy followed by definitive surgery, while the COG suggests primary tumor resection whenever possible.

Liver is divided into four sectors (Fig. 1): (1) Couinaud segments 5 and 8 constitute the right anterior sector, (2) segments 6 and 7 constitute the right posterior sector, (3) segments 2 and 3 constitute left lateral, and (4) left medial sector consists of segments 4a and 4b. PRETEXT staging is based on these sectors. Caudate lobe is given separate staging consideration as extrahepatic disease, tumor focus, tumor rupture, distant metastasis, lymph node involvement, portal, hepatic and inferior vena cava (IVC) involvement (Table 3).

Management

Chemotherapy remains the cornerstone in management of HB. SIOPEL group was formed under the auspices of International Society of Pediatric Oncology in 1987, and has completed three major international collaborative studies in pediatric liver tumors in the process to improve the survival outcome in HB with minimal side effects of chemotherapy (Box 1). Primary resection has been recommended for resectable tumors in USA, while SIOPEL recommend downstaging the tumors with chemotherapy and then to resect. Tumors that were deemed to be unresectable (unifocal PRETEXT 4) have been found to be resectable after

Table 2 International consensus classification histologic subtypes of hepatoblastoma

Monomorphic	Mixed
Epithelial	Teratoid
Fetal:	Stromal derivatives:
• Well-differentiated	• Chondroid
• Crowded or mitotically active	• Osteoid
• Pleomorphic, poorly differentiated	• Skeletal muscle
• Anaplastic	
Embryonal	
Macrotrabecular	
Small cell undifferentiated	
Cholangioblastic	

Figure 1 Schematic diagram of liver showing four sectors: (1) Couinaud segments 5 and 8 constitute the right anterior sector, (2) Segments 6 and 7 constitute the right posterior sector, (3) Segments 2 and 3 constitute left lateral and (4) Left medial sector consists of segment 4

Table 3 PRETEXT staging of hepatoblastoma

Pretext 1	3 contiguous sectors are tumor-free
Pretext 2	2 contiguous sectors are tumor-free
Pretext 3	1 sector tumor-free
Pretext 4	No sector tumor-free
In addition, any group may have:	
V—	ingrowth into the IVC or all three hepatic veins involved
P—	ingrowth into portal vein or involvement of portal bifurcation
E—	extrahepatic contiguous tumor
C—	involvement of caudate lobe
M—	distant metastases

BOX 1 SIOPEL trials on hepatoblastoma and outcome**SIOPEL 1**

All HBs were subjected to preoperative chemotherapy (neoadjuvant) with cisplatin and doxorubicin—termed as PLADO. Each cycle comprised of cisplatin (80 mg/m²) given as a 24-hour IV continuous infusion and doxorubicin (60 mg/m²) as a continuous 48-hour IV infusion. Four cycles are given at 3 weekly intervals followed by either resection or liver transplantation and the chemotherapy course is completed with further two cycles. In case of unresectability at the end of four cycles, reassessment was done after further two cycles.

Overall survival rates were as follows:

100% for PRETEXT 1; 91% for PRETEXT 2; 68% for PRETEXT 3; 57% for PRETEXT 4 and 25% for patients with metastasis.

SIOPEL 2

SIOPEL 2 trial was designed to test the efficacy and toxicity of two chemotherapy regimens. HB was stratified into either *standard risk* and *high-risk* at diagnosis based on tumor confined to liver with at least one tumor-free sector (PRETEXT 1, 2 and 3) or PRETEXT 4/extrahepatic extension/metastasis/serum AFP < 100 units, respectively. Standard risk patients were treated with cisplatin monotherapy and high-risk patients treated with cisplatin alternating with carboplatin and doxorubicin, referred to as *Super PLADO* regimen, preoperatively and postoperatively. Overall 3-year progression-free survival rates were 89% and 48%, for standard and high-risk respectively.

SIOPEL 3

SIOPEL 3 trial prospectively compared either cisplatin alone or PLADO for standard risk tumors and SUPER PLADO for high-risk tumors. The results for SIOPEL 3 for *standard risk* patients confirmed that Cisplatin monotherapy is as effective as PLADO in this standard risk group of patients. SUPER PLADO for high-risk tumors showed increased resectability.

SIOPEL 4

SIOPEL 4 study is underway looking at outcome of high-risk patients with a more intensified chemotherapy employing doxorubicin and cisplatin during preresection and doxorubicin and carboplatin were employed for unresectable tumors and for postresection.

Relapse or resistant tumors:

Other chemotherapeutic agents like irinotecan, topotecan, ifosfamide, etoposide, and certain newer drugs like ixabepilone, gemcitabine and bevacizumab are being tried in relapsing or recurrent tumors.

chemotherapy (**Figs 2A and B**), this is due to the fact that the tumor can stretch the lateral margin and could bulge into the adjacent sector without actually infiltrating it. Usually surgery is planned after four cycles of chemotherapy, but if the tumor is deemed to be unresectable on imaging, further two cycles of chemotherapy are given and reassessed. Downstaging using chemotherapy before surgery helps in better demarcation of anatomical margins and likelihood of having complete resection. In our experience, we have seen tumors with extensive osteoid formation (**Fig. 3**), which did not regress in size with chemotherapy and so resection

Figures 2A and B (A) Large hepatoblastoma at the time of presentation; and (B) Tumor regression after four cycles of chemotherapy

was attempted after six cycles. But resected specimen showed only 5% viable tumor cells, which indicate good response to chemotherapy and this tumor could have been resected after four cycles. Response to chemotherapy should be guided by serial fall in AFP rather than shrinkage in tumor size.

Surgery

Surgical resections would include segmentectomy (single involved segment is removed); hemihepatectomy (either right or left lobe); extended right hepatectomy (only segment 2, 3 and caudate lobe are left behind); extended left hepatectomy (most of segments 5 and 8 are removed along with the left lobe); or central hepatectomy (resection of Couinaud's segments 4, 5, and 8). Children tolerate extensive resection even unto 75% of liver mass, as the remaining liver is non-cirrhotic with well preserved synthetic function. Such extreme surgeries have to be carried out in centers with transplant facilities.

Liver Transplant

Liver transplantation is offered in case of unresectable central tumors or PRETEXT 4 tumors. Primary liver transplantation has a better outcome compared to rescue liver transplantation due to incomplete partial resection or relapse after partial hepatectomy. Ten-year survival after primary liver transplantation is around 85% while with rescue liver transplantation, the survival is only 40%, and, therefore, heroic resections should not be attempted. Lung metastasis and macroscopic extension into the portal vein and/or

Figure 3 Histology in hepatoblastoma showing extensive osteoid formation with mineralization

the hepatic veins/vena cava are only relative contraindications for liver transplantation.

HEPATOCELLULAR CARCINOMA

Hepatocellular carcinoma (HCC) is the most common hepatic malignancy in adults while in children it is the second most common malignancy following HB.

Etiopathogenesis

In contrast to adults where HCC is seen in 80–90% cirrhotic population, only one-third of children have underlying cirrhosis. In children, certain cirrhotic metabolic disorders such as tyrosinemia and progressive familial intrahepatic cholestasis (PFIC) predispose to HCC at very young age. HCC secondary to chronic hepatitis B or C infection occurs in older children. Glycogen storage disease type 1, porphyria, alpha-1-antitrypsin deficiency are few of the other metabolic disorders with increased risk of HCC. Around 40% of children with tyrosinemia develop HCC and this is probably due to mutagenic effect of toxic intermediate compounds such as maleylacetoacetate and fumarylacetoacetate. Nitro trifluoromethyl benzoyl cyclohexanedione, popularly known as NTBC, which is used in the treatment of tyrosinemia, does not reduce the risk of HCC if introduced after 6 months of life. Genetic disorders such as neurofibromatosis and FAP are associated with higher incidence of HCC.

Detailed molecular mechanisms of evolution of HCC are largely unknown. Active inflammation and oxidative damage are the key events. A multihit model with cumulative genetic changes leading to high-grade dysplastic changes in hepatocytes, which lead onto HCC in a time span of 5 years, has been proposed. Intense neoangiogenesis occurs during this transition. An 8q copy gain, down regulation of p5, abnormal regenerative signaling from the sick cells to younger regenerating hepatocytes are few of the proposed mechanism of carcinomatous transformation.

Pathology

Hepatocellular carcinoma can be categorized as *classic* or *fibrolamellar* based on histological characteristics. *Classic HCC* reveals large polygonal cells with central nuclei, frequent mitotic figures and often invasion into surrounding hepatic tissue. Tumor cells in the *fibrolamellar variant* are circumscribed characteristically by bundles of acellular collagen, creating either trabeculae or large nodules of tumor islands. Immunostaining recognizes cytokeratin 7, 8, 18 and 19, chorioembryonic antigen and AFP. Classic type is usually seen in cirrhotic liver, while fibrolamellar variant, which does not have a favorable prognosis, is seen in noncirrhotic liver. Usually HCC appears as a distinctive nodule and as the tumor size increases, portal veins could get involved and the tumor could spread to lymph nodes, adrenals, lungs and bones.

Clinical Features

The initial presentation could be an abdominal mass, weight loss, anorexia, pain, and rarely, jaundice. The diagnosis might be delayed in noncirrhotic disease, as regular surveillance tends to pick-up HCC early in cirrhotic children. Tumor rupture or bone metastasis may be the presenting symptom in a few children. Paraneoplastic manifestations can include diarrhea, hypoglycemia, hypercalcemia secondary to excess production of parathyroid hormone-related protein (PTH-rP), hyponatremia secondary to excess antidiuretic hormone (ADH), polymyositis, thrombophlebitis and skin rashes.

Diagnosis

Ultrasonography would show HCC as a nodule and might be difficult to differentiate it from regenerating nodule or an adenoma. Contrast enhanced ultrasound (CEUS) is a helpful screening technique, as it would differentiate HCC from regenerative nodules. Differentiation of cirrhotic nodules from HCC requires a contrast CT or a dynamic MRI. The presence of intense arterial uptake of contrast (consistent with extensive neoangiogenesis within the tumor) followed by washout in venous phase is highly specific for HCC (**Figs 4A and B**). Biopsy is necessary in nodules exhibiting atypical vascular pattern on contrast CT.

American Association of Study of Liver Disease (AASLD) does not recommend AFP as a surveillance tool in HCC as it lacks sensitivity and specificity to diagnose the condition. Tyrosinemia is a condition where there is an associated raised AFP levels, and any increase from the usual baseline should raise the suspicion of malignant transformation of a nodule. Other tumor markers like lectin bound AFP, des-gamma-carboxy prothrombin and glypican are being studied.

Staging

There is no widely accepted single staging system for pediatric HCC. Okuda classification, TNM staging, Barcelona Liver Clinic Staging (BLCS), Japanese Integrated Scoring, PRETEXT, etc., have been used in adults. BLCS system, which takes into account tumor size, liver function test, and physical condition of the patient was found to be helpful in formulating appropriate management pathway in HCC, and widely used.

Treatment

Several chemotherapeutic agents, such as cisplatin, doxorubicin, vincristine, 5-fluorouracil, etc., have been used with unsatisfactory results. Complete tumor resection remains the corner stone in management, but is feasible only in few because a small HCC nodule can be resected successfully only in a noncirrhotic liver. Cirrhotic liver will have dysplastic nodules in the leftover segments, which could turn malignant and also there is high probability of postoperative liver failure. The Milan criteria was introduced in 1996, to select adults with HCC for a better outcome which includes (a) single tumor diameter less than 5 cm; (b) not more than three foci of tumor, each one not exceeding 3 cm; (c) no angioinvasion; and (d) no extrahepatic involvement. Since the introduction of these criteria, long-term recurrence-free survival after liver transplant in adults with HCC improved from 30% to 75%. In children, where most of the HCC is *de novo* with tumors having different biological and genetic behavior, use of the Milan criteria is questioned. Reported pediatric series has shown that neither the size of tumors, nor the presence of gross vascular invasion were associated with post-transplant tumor recurrence. So, most centers offer liver transplantation to children with large *de novo* HCC, provided there is no extrahepatic involvement.

Percutaneous ethanol ablation (PEA) or radiofrequency ablation (RFA) is reserved for early HCC, where resection is not feasible. RFA is preferred for tumors less than 2 cm, while PEA is

Figures 4A and B (A) Intense uptake of contrast during arterial phase; (B) Tumor washout when compared with the surrounding during venous phase is very typical of hepatocellular carcinoma

preferred for tumors more than 2 cm, tumors close to the biliary tree, abdominal organs or the heart.

Regional chemotherapy (doxorubicin, mitomycin, or cisplatin) in the form of transarterial chemo embolization (TACE) can be tried in unresectable tumors or to downsize the tumor while patient is waiting for transplantation. Apart from providing regional chemotherapy with minimal systemic risks, embolization of feeding arteries may increase the dwell time of chemotherapeutic agents at the tumor site. Temporary or permanent embolizing materials like embocept/lipiodol/stainless steel coils can be used. Sorafenib is an oral multikinase inhibitor. It inhibits Raf kinase and several other tyrosine kinases (VEGF receptor 2, PDGF receptor, and c-kit receptors), thereby inhibiting angiogenesis and cell proliferation. It is used in unresectable tumor as palliative therapy and found to have prolonged the survival.

OTHER TUMORS

Focal nodular hyperplasia (FNH) is rare in children and remains asymptomatic, although some patients present with an abdominal mass or pain. As the name suggests the lesions have features of a well-localized area of liver cell hyperplasia around a fibrous scar. Presence of this central fibrous scar in CT or MRI scans is diagnostic of FNH. Surgical management is required only in patients with pressure symptoms. These tumors do not turn malignant.

IN A NUTSHELL

1. Hemangiomas and hamartomas are the most common benign liver tumors, while HB is the most common primary malignant liver tumor in children.
2. Hepatocellular carcinoma is the most common hepatic malignancy in adults while in children, it is the second most common malignancy following HB.
3. Childhood liver tumors are unique in the sense that some tumors like large hemangioendothelioma could involute spontaneously without treatment, while a small HCC may warrant liver transplantation.

Section 38 DISORDERS OF HEMATOPOIETIC SYSTEM

Section Editor VP Choudhry

Chapter 38.1

The Hematopoietic System

Praveen C Sobti, Shruti Kakkar

Blood is a vital body fluid composed of red blood cells (RBCs), white blood cells and platelets suspended in plasma. All the components play important functions in our body. RBCs carry oxygen to all vital organs; white blood cells are involved in body's defense mechanism and platelets play an important role in blood clotting.

All the cellular components of blood are derived from a pluripotent hematopoietic stem cell (PHSC). PHSC is characterized by its ability of self-renewal and differentiation. The process of formation of mature blood cells from PHSCs is known as hematopoiesis. Hematopoiesis involves a series of steps in which progressively lineage specific cells are produced from undifferentiated stem cells. Around 200 million RBCs, 10 million white blood cells and 400 million platelets are produced by the hematopoietic system every day. The basic understanding of development of the hematopoietic system is vital for understanding the pathophysiology of various hematological disorders (**Fig. 1**).

SITE OF HEMATOPOIESIS

Hematopoiesis begins in human beings as early as 3rd week of gestation. The vascular as well as the hematopoietic system develops from mesodermal cell aggregates in the extraembryonic yolk sac from a common precursor called "hemangio-endothelioblast". After originating in the yolk sac, hematopoiesis occurs sequentially in AGM (aorta, gonad and mesonephros region) and placenta, liver, thymus and spleen, before finally settling in bone marrow (**Figs 2A and B**). Bone marrow continues to be the major site of hematopoiesis from 2nd trimester onwards well into the adulthood.

The initial wave of hematopoiesis arising from the yolk sac, known as primitive hematopoiesis, produces mainly erythrocytes with few macrophages and megakaryocytes (MKs). The next wave of hematopoiesis arises in AGM, blood vessels and placenta. The PHSCs in this region arise de novo or migrate from yolk sac is not clear. The hematopoietic progenitors migrate from AGM region to liver during this phase and produces both erythroid and myeloid cells.

Yolk Sac

The hematopoietic stem cells originate from a mesodermal cell cluster. The cells present centrally disappear to give rise to vascular lumen and cells at the periphery undergo transformation to acquire the properties of endothelial cells. There are small clumps of cells present along the primitive endothelium known as blood islands which form the initial site of hematopoiesis (**Fig. 3**). Both the endothelial and the hematopoietic cells express CD-34 suggesting

a common cell of origin. With the onset of cardiac activity, the yolk sac derived hematopoietic progenitor cells are carried to liver through blood circulation. By day 60, hematopoiesis disappears from the yolk sac.

Liver

Hematopoietic cells do not arise de novo in liver; the yolk sac derived progenitor cells differentiate and mature into the blood elements. The shift in site of hematopoiesis is also accompanied by the switch in the hemoglobin from embryonic to fetal. There is also a change in erythrocyte morphology; definitive macrocytes are formed instead of primitive megaloblasts. Liver remains the major site of hematopoiesis till the 2nd trimester and continues producing cells till 2nd week of postnatal life.

Bone Marrow

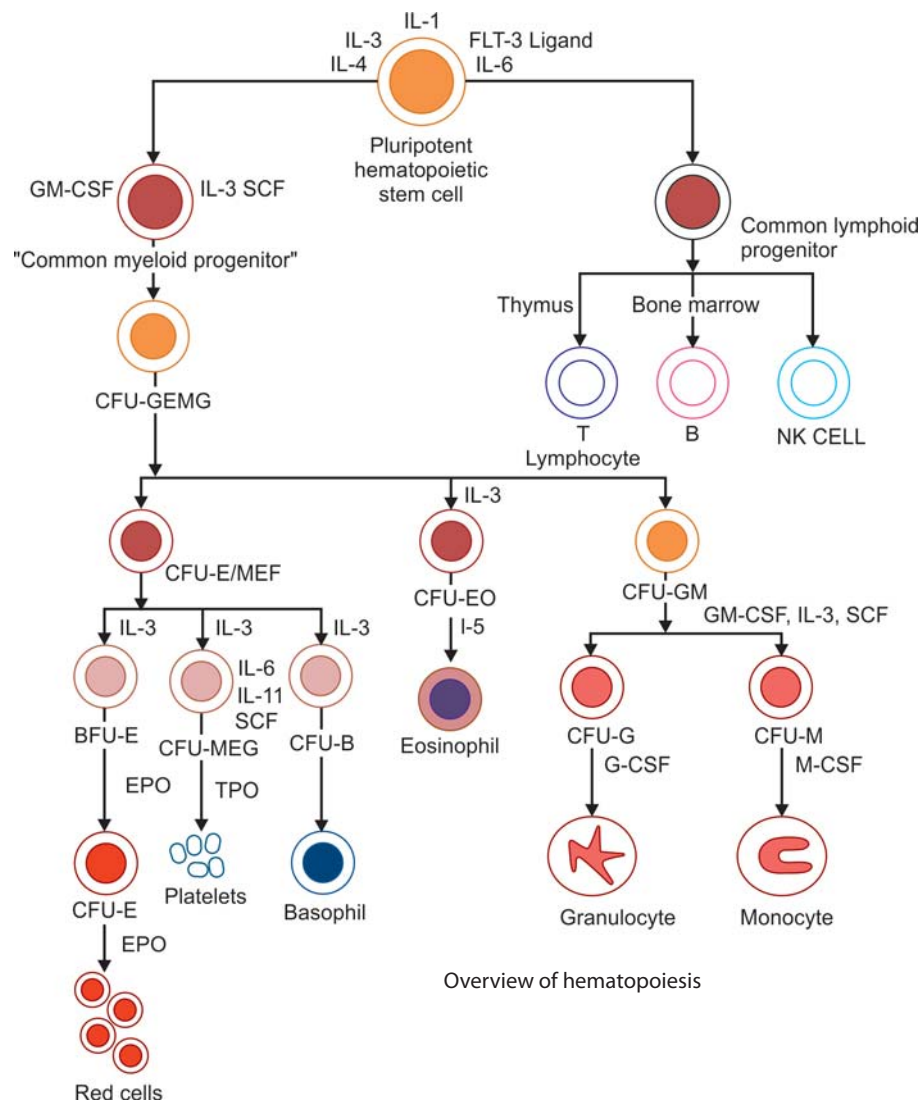

Hepatic hematopoiesis starts declining from the 2nd trimester as the PHSCs settle in the bone marrow and start producing mature blood cells. The ability of the bone marrow to support indefinite hematopoiesis rests in a small pool of PHSCs. In infancy, whole of the bone marrow is active but the hematopoiesis remains restricted to the flat bones and proximal end of femur and humerus in the adult life (**Fig. 2B**). In hemolytic anemia, hematopoiesis can expand to all the bones as well as extramedullary organs (liver and spleen) as in fetal life. T-cells are produced in thymus in embryonic, fetal and adult life.

PLURIPOTENT HEMATOPOIETIC STEM CELL

Hematopoietic stem cell (HSC) is the source of millions of blood cells produced per day. HSC is characterized by its properties of self-renewal and differentiation. HSC lack the cell surface markers expressed by the mature blood cells but express high level of Sca-1 and c-kit. This population of cells that lack the lineage specific markers and express Sca-1 and c-kit are referred to as LSK compartment ($\text{Lin}^-/\text{Sca-1}^+/\text{c-kit}^+$). HSC can be divided into long-term HSC (LT-HSC) and short-term (ST-HSC) reconstituting HSC. LT-HSCs are capable of sustaining lifelong hematopoiesis owing to their extensive self-renewal capacity whereas ST-HSC can sustain hematopoiesis for a short while only. HSCs undergo two types of differentiation: symmetric and asymmetric. In symmetric division, both the daughter cells retain the properties of stem cells. In asymmetric division, one of the daughters retains the property of self-renewal whereas the other one either undergoes differentiation to form a mature blood cell or can undergo apoptosis.

Stem Cell Niche

Stem cell niche refers to the microenvironment that the stem cells inhabit. The stem cell niche apart from providing anatomical space for the growth of stem cells also interacts with the stem cells and provides signals for self-renewal and differentiation. Two HSC niches have been identified in the bone marrow: the perivascular and endosteal niche.

Overview of hematopoiesis

Figure 1 The hematopoiesis involves a series of steps in which differentiated and mature cells are formed sequentially

Abbreviations: CFU-GEMM, colony-forming unit-granulocyte, erythroid, megakaryocyte, monocyte; BFU, burst forming unit; CFU, colony-forming unit; G, granulocyte; M, monocyte; E, erythroid; MK, megakaryocyte; B, basophils; Eo, eosinophil; GEMM, granulocyte, erythroid, megakaryocyte, monocyte; SCF, stem cell factor; EPO, erythropoietin; TPO, thrombopoietin; CSF, colony-stimulating factors; IL, interleukin.

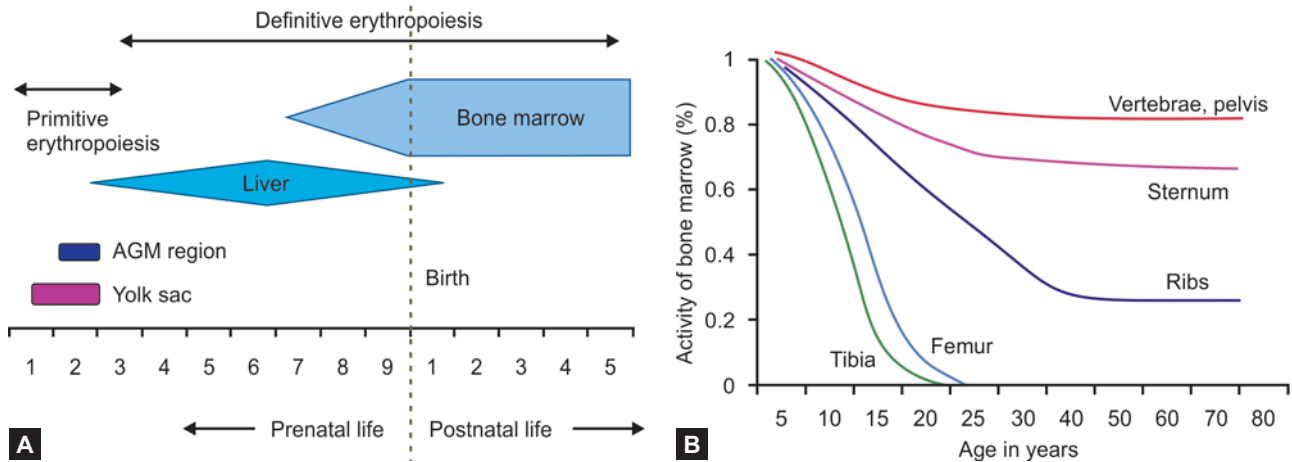

Adapted with permission from: Hoffbrand AV, Moss PA. Haematopoiesis. In: *Essential Haematology*. 6th ed. UK: Wiley-Blackwell Publishing Limited; 2011. ©Wiley.

The endosteal niche is composed primarily of osteoblasts. The perivascular niche is composed of endothelial cells, mesenchymal stem cell, CAR cells (CXCL12-abundant reticular cells), Schwann cells and the stromal cells (**Fig. 4**). It has been suggested that the endosteal niche maintains the HSC in quiescence and cells migrate to the perivascular niche to divide and proliferate. The osteoblasts secrete a variety of signals like angiopoietin 1, transforming growth factor- β (TGF- β), stem cell factor (SCF) for the maintenance of the stem cell pool. The stem cell niche also seems to be controlled by the stem cells as demonstrated by the role of regulatory T-cells in maintenance of allogeneic HSC even if no preparative chemotherapy is given.

ERYTHROPOIESIS

Erythropoiesis occurs in two phases, primitive and definitive, during the fetal life. Primitive erythropoiesis begins in the yolk

sac derived primitive erythroid progenitors. These erythroid progenitors enter the blood stream and mature in the circulation. Primitive erythropoiesis is characterized by the expression of the embryonic hemoglobin chains. Along with primitive erythroblasts, small population of circulating nucleated cells called pyrenocytes are also found in the circulation. These cells resemble the extruded nucleus of the late-erythroblasts and are rapidly engulfed by the macrophages (**Figs 5A and B**). Definitive erythropoiesis occurs in fetal liver after the 6th week of gestation. The earliest committed red cell precursor identified is a burst forming unit-erythroid (BFU-E). These slowly proliferating cells then give rise to mature BFUs which rapidly differentiate into CFU-E (colony forming unit-erythroid). The CFU-E undergoes cell division and differentiation over 2–3 days to give rise to a mature RBC. There is a progressive decrease in the cell size, chromatin condensation, increasing hemoglobin accumulation and finally leading to expulsion of the nucleus (**Fig. 6**).

Figures 2A and B Sites of erythropoiesis: (A) Different sites of erythropoiesis during prenatal and postnatal life (AGM: aorta, gonad and mesonephros region); (B) Hematopoietic activity of bone marrow of various bones. Hematopoietic activity in the bone marrow of long bones decreases with age and is virtually absent by 3rd decade of life. Bone marrow of vertebra, sternum and pelvis remains active throughout life. Adapted with permission from: Papayannopoulou T, Migliaccio AR. Biology of erythropoiesis, erythroid differentiation and maturation. In: Hematology: Basic Principles and Practice, 6th ed. Philadelphia, PA, USA: Saunders-Elsevier; ©Elsevier.

Figure 3 Development of PHSC from mesodermal cell aggregates. The vascular and hematopoietic system develops from a mesodermal cell aggregate in extraembryonic yolk sac. The cells in the periphery transform into endothelial cells and the inner cells disintegrate to form vascular lumen. PHSC develops from a collection of cells called blood islands

Abbreviation: PHSC, pluripotent hematopoietic stem cells.

Figure 4 Hematopoietic stem cell niche. There are two stem cell niches: the endosteal niche and the perivascular niche. The osteoblasts constitute the endosteal niche. The perivascular niche is composed of perivascular endothelial cells, Schwann cells, macrophages and CAR cells

Abbreviation: CAR, CXCL12-abundant reticular cells.

The differentiation erythroid precursors and formation of mature RBCs occurs within the vascular lumen; (B) Definitive erythropoiesis in liver and bone marrow. The entire process of hematopoiesis occurs within the marrow and mature RBCs are released into the circulation. Abbreviations: RBCs, red blood cells; AGM, aorta, gonad and mesonephros region; BFU, burst-forming unit; CFU, colony-forming unit; E, erythroid; HSC; hematopoietic stem cell.

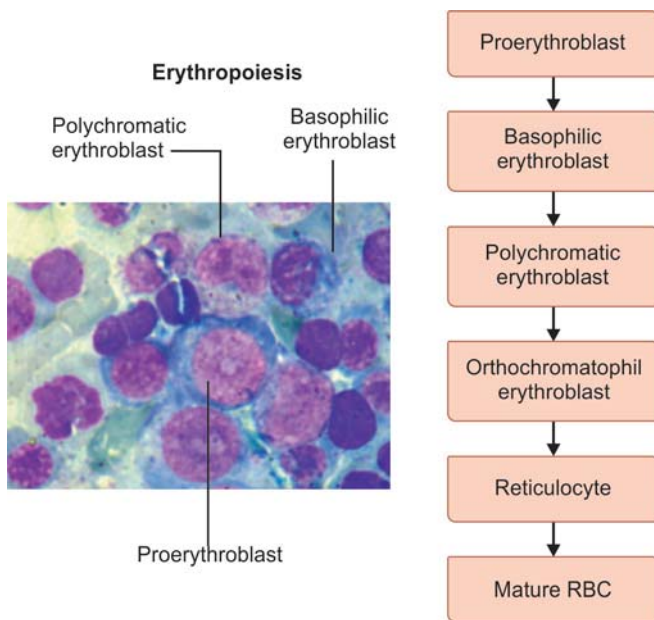

Figure 6 Stages of erythropoiesis: The proerythroblast undergoes a series of changes to form mature red blood cells (RBCs). The hemoglobin (Hb) content increase slowly and the nuclear size decreases with each step, before being extruded finally

Regulation of Erythropoiesis

Erythropoiesis is controlled by various extra- and intracellular factors. Extracellular factors include cytokines, hematopoietic growth factors and extracellular matrix. Various transcriptional regulators and microribonucleic acids (mRNAs) also control erythropoiesis.

Extracellular Factors Controlling Erythropoiesis

Erythropoiesis in fetal life is regulated by the growth hormones produced by the fetus itself and not by maternal growth factors. Erythropoietin (EPO) regulates the erythroid precursors in fetal, neonatal and adult life. The EPO in adults is secreted by the kidneys in response to hypoxia whereas liver appears to be the main source of EPO in the fetus. EPO is produced in the liver by cells of monocytic and macrophage lineage. The switch of EPO production from liver to kidney starts at about 130 days of gestation and completes by 40 days of postnatal life.

Erythropoietin is a glycoprotein (molecular weight 34,000) secreted in response to low oxygen levels. It has a globular three-dimensional structure with 3N-linked polysaccharide and one O-linked group. EPO is secreted as a 198 polypeptide residue from EPO messenger RNA (mRNA), and then undergoes cleavage of an arginine residue at carboxy terminus followed by glycosylation in the Golgi apparatus. The final product is a 166 polypeptide, consisting of 4 α helices stabilized by disulfide bridges. The half-life of EPO in plasma is approximately 7–8 hours. EPO binds to EPO-receptors (EPO-R) on the surface of erythroid progenitor cells. The initial stages of erythropoiesis are highly EPO-dependent, EPO-Rs are gradually lost as more and more mature erythroid cells are formed.

Erythropoietin-R is present on the erythroid progenitors as a homodimer. EPO binding to EPO-R produces conformational change; the intracellular domains move closer resulting in phosphorylation of Junas kinase-2 (JAK-2) kinases and initiation of signal transduction leading to erythropoiesis (Fig. 7). The

Figure 7 Erythropoietin (EPO). The EPO receptor (EPO-R) belongs to the cytokine family of receptors. The binding of EPO results in homodimerization of the receptor, resulting in phosphorylation of JAK-2 kinases present on the intracellular domain of EPO receptor. The phosphorylation of JAK-2 kinases results in activation of multiple intracellular pathways and transcription factors

signal transduction pathways triggered are signal transducer and activator of transcription 5 (stat 5), phosphoinositide-3 kinase/Akt, Shc/Ras/mitogen-activated protein kinase (MAPK) pathway.

Extracellular matrix protein, fibronectin, plays an important role in terminal differentiation and enucleation of the erythrocytes. Fibronectin fragments interact with the $\alpha_4\beta_1$ integrin on the erythroid progenitors.

Transcriptional Regulators of Erythropoiesis

A number of transcriptional regulators, like GATA-1, SCL/Tal-1, LMO-2, are involved in synthesis of micro-RNAs. Micro-RNAs are small regulatory RNAs which downregulate the expression of their target genes. These play an important role in erythropoiesis and regulate various steps, like erythroid-lineage determination, erythroid-progenitor proliferation and differentiation, chromatin condensation and enucleation (Table 1). GATA-1 is a member of zinc finger transcription family that binds to (A/T) GATA (A/G). It has two zinc fingers: one at carboxy terminus which binds to DNA and other at aminoterminal that stabilizes the interaction. GATA-1 is expressed by erythroid, megakaryocytic, eosinophilic, mast and multipotent progenitor cells. Loss of GATA-1 has been shown to result in severe anemia and arrest in erythropoiesis in murine models along with defects in megakaryocytic development. GATA-1 interacts with a wide range of proteins including FOG-1 (friend of GATA), LMO-2, EKLF/Spl and PU-1 for regulation of erythropoiesis.

Table 1 Role of micro-RNAs in erythropoiesis

mRNA	Target	Role
miR-150	MYB	Induces differentiation of megakaryocytic lineage and suppresses erythroid lineage
miR-221 and 222	KIT	Downregulation necessary for terminal differentiation of erythroid progenitors
miR-24	ALK4	Downregulation necessary for terminal differentiation of erythroid progenitors
miR-223	LMO-2	Downregulation necessary for terminal differentiation of erythroid progenitors
miR-144	Klf4	Required for β globin gene expression
miR-451	GATA-2 14-3-3 zeta	Required for steady state erythropoiesis
miR-15a	MYB	Increased expression of fetal hemoglobin gene expression
miR-191	Riok3 and Mxi 1	Downregulation required for chromatin condensation and enucleation of erythrocytes

Hemoglobin and its Variants

Hemoglobin is an iron-containing protein which carries oxygen in the RBCs (**Fig. 8**). Hemoglobin synthesis begins in the proerythroblasts and continues up to reticulocyte stage. The synthesis starts with the binding of succinyl CoA (derived from Krebs metabolic cycle) with glycine. The resultant pyrrole ring thus formed combine to form protoporphyrin IX. Iron is incorporated into the protoporphyrin IX to form heme molecule. Heme molecule joins with polypeptide chain to form hemoglobin chains. The hemoglobin chains are named after the polypeptide derivative as α , β , γ , δ , ϵ , etc. Hemoglobin is a tetramer composed of two α -like and two β -like chains. Various variants of hemoglobin are formed sequentially during the embryonic and fetal life before the production of adult hemoglobin (**Table 2**) which is controlled by two gene clusters; α gene cluster on chromosome 16 and β gene cluster on chromosome 11 (**Fig. 9**).

Embryonic hemoglobin is expressed in primitive erythroblasts developing in the yolk sac. It is composed of two ζ and two ϵ

Figure 8 Structure of hemoglobin

Figure 9 Hemoglobin gene locus. The α -like gene locus on chromosome 16 (5'- ζ - $\alpha 2$ - $\alpha 1$ -3'). The regulatory element HS 40 is located upstream. The β -like gene locus on chromosome 11 (5'- ϵ - γ - δ - β -3') controlled by five regulatory elements upstream which are collectively called locus control region (LCR)

Table 2 Different types of hemoglobin

Hemoglobin	α -like chain	β -like chain	Composition
<i>Embryonic</i>			
Gower 1	ζ	ϵ	$\zeta_2\epsilon_2$
Gower 2	α	ϵ	$\alpha_2\epsilon_2$
Portland	ζ	γ	$\zeta_2\gamma_2$
<i>Fetal</i>			
Hemoglobin F	α	γ	$\alpha_2\gamma_2$
<i>Adult</i>			
Hemoglobin A	α	β	$\alpha_2\beta_2$
Hemoglobin A2	α	δ	$\alpha_2\delta_2$

chains. As the site of hematopoiesis shifts from yolk sac to liver, the production of embryonic ζ and ϵ chains ceases. The production of α and γ chains increases leading to formation of fetal hemoglobin (HbF - $\alpha_2\gamma_2$). In human beings, two γ globin genes are present, $^G\gamma$ and $^A\gamma$, which differ in a single amino acid. The major switch in human hemoglobin happens perinatally, with decrease in HbF and formation of adult hemoglobin ($\alpha_2\beta_2$). The levels of HbF decrease after birth so as HbF constitutes 70% of hemoglobin at birth and falls to only trace levels by 6–12 months of age. Apart from adult hemoglobin HbA, HbA₂ ($\alpha_2\delta_2$) is also present in minor quantity in adult life (**Fig. 10**). In human erythrocytes, there is a very delicate balance between the α and β chains. The balance is maintained by regulatory elements present upstream the α and β gene clusters. In α gene cluster, there is a single element known as HS 40 where in β gene cluster, there are five such elements collectively known as locus control region (LCR). Various transcriptional regulators are involved in fetal-to-adult hemoglobin switch (**Table 3**).

Erythrocyte Indices During Fetal and Neonatal Life

- Hemoglobin (Hb)** Hemoglobin in a fetus of 10 weeks is 10.9 ± 0.7 g/dL and increases to 16.6 g/dL at 39 weeks of gestation.
- Mean corpuscular volume (MCV)** The MCV is a measure of average red cell volume. The MCV in a neonates delivered at 22 weeks is approximately 122 fL. MCV decreases with the gestational age and a newborn at term has an MCV of 105 fL. MCV reaches the adult value by 11th week of postnatal life.

Figure 10 Sequential appearance of different hemoglobin (Hb) chains during pre- and postnatal life

Table 3 Transcriptional regulators of fetal to adult hemoglobin switch

Regulator	Role
BCL11A	Repressor of γ -globin gene expression
SOX6	Interacts with BCL11A to repress-globin gene expression
KLF1 (EKLF)	Repressor of γ -globin gene expression Haploinsufficiency results in HPFH
COUP-TFII orphan nuclear transcription factor	Binds to DR-like sequences in proximal γ -globin gene promoters Repressor of γ -globin gene expression
DRED (TR2/TR4) orphan nuclear transcription factor	Binds to DR1 sequences in proximal γ -globin gene promoters Repressor of γ -globin gene expression
FOP	Directly interacts with and is methylated by PRMT1 Regulator or repressor of γ -globin gene expression

- **Mean corpuscular hemoglobin (MCH)** The MCH measures the average hemoglobin content of the RBCs. The MCH, like MCV, decreases with the gestational age. The MCH falls from 40 pg for a neonate born at 22 weeks of gestation to 36 pg in neonate born at term.
- **Mean corpuscular hemoglobin concentration (MCHC)** MCHC does not change significantly with the gestational age.
- **Reticulocyte count** The reticulocyte count in fetus is approximately 4–8 times that of an adult. Neonates also have high reticulocyte count and red cell volume distribution width (RDW) owing to high erythropoietic activity. Reticulocyte count in a neonate is 3–7% and drops to 0.5–1% in 1st week of postnatal life. It reaches adult levels by 9th week of life.
- **Shape of RBCs** The RBCs in a neonate are heterogeneous. The lower the gestational age, higher is the percentage of abnormally shaped RBCs in circulation. In a neonate, 43% RBCs are disk-shaped and 40% are stomatocytes compared to 78% discocytes and only 18% stomatocytes in adults. In a term neonate, nucleated RBCs are rapidly cleared from the circulation so as no nucleated RBCs are found beyond 2–3 days of life whereas in a preterm neonate, it may take up to a week to clear nucleated RBCs from the circulation.

THROMBOPOIESIS

Platelet production begins in the fetus by approximately 5 weeks of gestation. The first committed MK precursor identified is BFU-megakaryocyte (BFU-MK). A single BFU-MK is capable of giving rise to 50 MKs. BFU-MK matures into a CFU-MK, which gives rise to 3–50 MKs. A MK is a unique cell as it undergoes endomitosis, the division in which nucleus undergoes duplication, but there is no cell division. The cells accumulate increasing deoxyribonucleic acid (DNA) content which can be as high as 128N. MKs are predominantly present in the bone marrow, but can be found in peripheral blood, lungs and spleen under stress. Mature MKs produce platelets by budding, i.e., forming elongated pseudopods called proplatelets (**Fig. 11**). The fetus achieves a platelet count of $150 \times 10^9/L$ by the end of 1st trimester. The platelet production occurs in four main steps.

Production of Thrombopoietic Factor

Thrombopoietin (TPO) is a polypeptide containing 332 amino acids synthesized in the liver. TPO, a c-MPL ligand, is the principle regulator of thrombopoiesis in fetus as well as adults. It stimulates all stages of MK precursors. TPO has been detected in fetus by 6 weeks of gestation. It is composed of two domains, receptor-binding domain and another carbohydrate rich domain which imparts stability to the compound. Binding of TPO to c-MPL results in dimerization of the receptor and activation of signal transduction pathways, like phosphatidylinositol 3-kinase (PIK3), Akt, MAPK and ERK 1 and 2. The circulating level of serum TPO is low (approximately 10 mol/L), but this can increase considerably in thrombocytopenic states. The plasma TPO concentration has been found to be inversely related to platelet levels. Platelets regulate plasma TPO levels by an autoregulatory loop. TPO is removed from circulation by the platelets. Hence, higher the number of platelets in circulation, lower is the plasma TPO level.

Proliferation of Megakaryocyte Precursors

As stated earlier, MKs are unique as they undergo nuclear division without cytoplasmic division, a process known as endomitosis. The endomitosis leads to accumulation of large quantities of mRNA and proteins. Protein tyrosine phosphatases Shp1 and Shp 2 have been discovered recently and thought to play an important role in endomitosis.

Megakaryocytes also produce a lot of granules which are necessary for functioning of the platelets by budding of small vesicles from Golgi apparatus. The different granules found in platelets are shown in **Table 4**.

Maturation of Megakaryocytes

As these MKs mature, they develop an intricate network of membrane system known as invaginated membrane system (IMS). The IMS retains contact with the extracellular space and divides the cytoplasm into small territories. Actin fibers provide the force for the formation of IMS via WASp/WAVE pathway. Recently, a *CDC42*-interacting protein 4 (CIP4) has also been found to play important role in cytoskeletal and membrane remodeling.

Figure 11 Megakaryocyte (MK) development

Abbreviations: PHSC, pluripotent hematopoietic stem cell; CFU-GEMM, colony-forming unit-granulocyte, erythroid, megakaryocyte, monocyte; BFU, burst-forming unit; CFU-Mk, colony forming unit megakaryocyte.

Table 4 Platelet granules: contents and functions

Granules	Content	Function
α granules	Hemostatic factors (e.g., Factor V, VWF, fibrinogen), angiogenic factors (e.g., angiogenin, VEGF), anti-angiogenic factors (e.g., angiostatin, PF4), growth factors (e.g., PDGF, bFGF, SDF1 α), proteases (e.g., MMP2, MMP9), necrotic factors (e.g., TNF- α , TNF- β)	Involved in adhesion of platelets to vessel wall, platelets
Dense granules	ADP, ATP, serotonin, calcium	Involved in platelet activation
Lysosomal granules	Lysosomal enzymes, e.g., glycosidases and proteases	Unclear

Abbreviations: VWF, von Willebrand factor; VEGF, vascular-endothelial growth factor; ADP, adenosine diphosphate; ATP, adenosine triphosphate; TNF, tumor necrosis factor.

Table 5 Differences between neonatal and adult platelets

Characteristic	Neonatal platelets	Adults platelets
TPO concentration	High	Low
Response to TPO	Highly sensitive	Less sensitive as compared to platelets of a neonate
Megakaryocyte progenitors	Increased number of CFU-MK and BFU-MK	Lesser number
Megakaryocytes	Small, lower ploidy Cytoplasmically mature Increased expression of GATA-1 and surface GP-1	Larger, higher ploidy Decreased expression
Platelets	Reticulated platelets present	Absent

Abbreviations: TPO, thrombopoietin; CFU-MK, colony-forming unit megakaryocyte; BFU-MK, burst forming unit megakaryocyte.

Release of Platelets

Once mature, MKs form proplatelets from its membrane. The microtubules containing polymers of $\alpha\beta$ tubulin are important for formation of the proplatelets. MKs extend pseudopods, which taper and elongate to form proplatelets shaft measuring 2–4 μ m. Whole of the MK cell body transforms into proplatelets, the nucleus is then extruded and degraded. These proplatelets are then released into the sinusoidal blood vessels in the bone marrow and form platelets.

The fetal thrombopoiesis differs from adult thrombopoiesis. Fetal thrombopoiesis is characterized by a higher number of reticulated platelets, higher level of TPO and increased sensitivity to TPO. Fetal MKs are smaller, have lower ploidy and more cytoplasmically mature than adult MKs. Also, the fetal MKs have increased expression of GATA-1 and surface glycoprotein-1. The BFU-MK and CFU-MK are present in greater numbers in fetal life and decrease gradually after birth (**Table 5**). These differences between the fetal and adult platelets resolve in the 1st postnatal month.

FETAL MYELOPOIESIS

Macrophages are the first myeloid cells seen in the developing embryo. Macrophages are produced along with erythroid progenitors during the primitive wave of hematopoiesis. Neutrophils are first observed during the 5th week of postconception life. Both macrophages and neutrophils arise from a common myeloid progenitor. Granulocyte colony-stimulating factors (G-CSF) and macrophage colony-stimulating factors (M-CSF) have also been detected at 6 weeks of gestation and are expressed by the fetal liver from 8 weeks of gestation.

Fetal blood contains only a few neutrophils till the 3rd trimester due to sterile intrauterine environment. The earliest identifiable progenitor of granulocyte series is a myeloblast. A myeloblast contains large nucleus with prominent nucleoli and

little cytoplasm. The myeloblast undergoes a series of stages over 7–10 days to result in a mature neutrophil (**Fig. 12**). The myeloblast transforms into a promyelocyte with accumulation of primary granules, which are rich in proteins, like myeloperoxidase, cathepsins and defensins. These primary granules are involved in intracellular microbe killing. The promyelocyte then matures into a myelocyte and subsequently a metamyelocyte by accumulation of secondary and tertiary granules respectively (**Table 6**). The metamyelocyte stage loses the capacity to proliferate and matures into a neutrophil. A mature neutrophil circulates in the peripheral blood for 3–12 hours before migrating to the lymphoid tissue where it survives for 2–3 days.

FETAL LYMPHOPOIESIS

The human lymphoid tissue is composed of primary lymphoid organs (thymus and bone marrow) and secondary lymphoid organs (spleen, lymph node, tonsils and Peyer's patches, etc). The primary lymphoid organs develop during the 1st trimester. These lymphoid organs serve as sites of differentiation and maturation of B, T and natural killer (NK) cells from a common lymphoid progenitor.

Table 6 Different types of granules present in myeloid cells

Granules	Cells in which these are present	Content
1°	Granulocytes and monocytes	Myeloperoxidase, defensins, cathepsins, neutrophil elastase
2°	Neutrophils, eosinophils, basophils	Lactoferrin, transcobalamin I, neutrophil collagenase and gelatinase, NGAL
3°	Neutrophils	Gelatinase

Abbreviation: NGAL, neutrophil gelatinase-associated lipocalin.

Figure 12 Myelopoiesis

Figure 13 B-cell development; The CD markers in red denote the new ones acquired during development at each stage

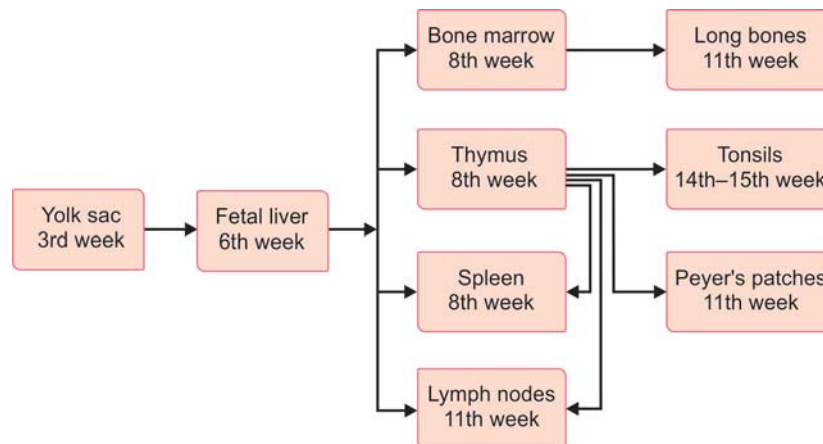

Figure 14 Development of primary and secondary lymphoid organs

B-cells

B-cell development begins in the fetus at about 7 weeks of gestation. The omentum and fetal liver are the main sites of B-cell development. B-cells undergo maturation in two phases: an antigen independent and another antigen-dependent one to form antibody-secreting plasma cells. The development in the antigen independent phase is described in **Figure 13**, the precursor B-cells

undergo immunoglobulin gene rearrangement and acquire new surface markers as they form mature B-cells. During the antigen-dependent phase, the mature B-cells are exposed to a wide array of antigens. The mature B-cells differentiate into a memory cell and an antibody-secreting plasma cell. The development of various primary and secondary lymphoid organs is shown in **Figure 14**.

T-cells

The common lymphoid progenitor in the fetal liver migrates to the thymus probably under the effect of a chemotactic factor. Pro-T-cells bearing surface CD-7 and CD-34 have been detected in fetal liver by 7th week of gestation. Between 8 weeks and 10 weeks of gestation, these pro-T-cells move to thymus and acquire surface T-cell receptors (TCRs) to become pre-T-cells. Human thymic tissue is derived from the 3rd branchial pouch around 4th week of gestation and differentiates into subcapsular, cortical and medullary regions between 9 weeks and 15 weeks of gestation.

The precursor T-cells colonizing the thymus undergo intra-thymic maturation by the process of positive and negative selection from the 2nd trimester onwards till 1–2 years of postnatal life.

The T-cells interact with the major histocompatibility antigens present on the cortical thymocytes via TCRs present on their surface. The T-cells after interaction with these antigens develop the capability to identify the foreign antigens and mature (*positive selection*). Mature T-cells express on their surface either CD-4 or CD-8 receptor which interact with human leukocyte antigen (HLA) class II and class I antigens respectively. The T-cells bearing TCRs capable of interacting with self-antigens undergo programmed cell death (*negative selection*).

Natural Killer Cells

The NK cells are the large granular lymphocytes capable of interacting with the major histocompatibility complex (MHC) antigens and act against various tumors and viruses. NK cells have been detected by 6th week of postnatal life.

ROLE OF CYTOKINES AND GROWTH FACTORS IN HEMATOPOIESIS

The fate of the HSCs depends on various proteins which act on various stages of development. These are called cytokines. Hematopoietic growth factors send out different signals, like proliferation, maturation, differentiation and self-renewal. The actions of various cytokines are described in **Table 7**.

IN A NUTSHELL

1. Hematopoiesis begins in the human as early as 3rd week of gestation. The hematopoietic system is derived from mesodermal cell aggregates in extraembryonic yolk sac.
2. All the cellular components of hematopoietic system are derived from a pluripotent HSC.
3. The site of hematopoiesis shifts sequentially from yolk sac to AGM region to liver, before finally settling in the bone marrow. The change in site of hematopoiesis is accompanied by switch in hemoglobin chains.
4. Stem cell niche provides the optimal microenvironment for the growth and differentiation of hematopoietic stem cells.
5. The MCV and MCH decreases with the gestation age. MCHC remains constant.
6. The platelet production begins by 5th week of gestation. The earliest committed cell is a burst forming unit MK.
7. The platelet production occurs in following steps: production of thrombopoietic factor, proliferation of MK precursors, maturation of MKs and release of platelets.
8. Macrophages are the first cells of the myeloid series to be produced during development followed by neutrophils. Both are derived from a common myeloid progenitor.
9. The development of B-cells begins in the omentum and liver by 7th week of gestation. T-cells mature in the thymus by positive and negative selection from 2nd trimester to 1–2 years of life.
10. The hematopoiesis is regulated by different growth factors and transcription factors which are outside the marrow.

Table 7 Role of cytokines and hematopoietic growth factors in hematopoiesis

IL-1	Induces production of other cytokines from many cells
IL-2	T-cell growth factor
IL-3	Regulates the stem cell growth
IL-4	Regulates mast cell development
IL-5	Eosinophil growth factor
IL-6	Stimulates B-lymphocyte growth
IL-7	Principal regulator of B- and T-lymphocyte growth
IL-8	Promotes survival of cells in response to hematopoietic cytokines
IL-9	Produced by Th-2 lymphocytes Promotes growth of myeloid cells
IL-11	Shares activities with IL-6 increases platelet count in patients with chemotherapy induced thrombocytopenia
IL-15	Stimulates NK cell proliferation
IL-21	Affects growth and maturation of B-, T-, and NK-cells
SCF	Affects primitive hematopoietic cells of all lineages
EPO	Stimulates the proliferation of erythroid progenitors
M-CSF	Promotes the proliferation of monocytic progenitors
G-CSF	Stimulates growth of neutrophilic progenitors
GM-CSF	Affects granulocyte and macrophage progenitors and activates macrophages
TPO	Affects hematopoietic stem cells and megakaryocytic progenitors

Abbreviations: IL, interleukin; NK, natural killer; GM-CSF, granulocyte-macrophage colony-stimulating factor; TPO, thrombopoietin; EPO, erythropoietin.

Chapter 38.2

Approach to Diagnosis of Anemia

MR Lokeshwar, Swati Gupta, Swati Kanakia

Anemia refers to reduction in the oxygen carrying capacity of blood, as observed by reduced levels of hemoglobin (Hb) concentration and red cell mass [hematocrit (HCT)] leading to tissue hypoxia. For practical purpose, anemia is defined as red blood cell (RBC) mass or Hb measurement less than 2 SD below the mean for normal population. Age appropriate cut-off levels of Hb and blood indices are shown in **Table 1**.

Table 1 WHO cut-off values for diagnosis of anemia

Age/Sex group	Hb (g/dL)
6 months–6 years	< 11
6–14 years	< 12
Adult males	< 13
Adult females (nonpregnant)	< 12
Adult females (pregnant)	< 11

The average life span of RBCs is between 100 days and 120 days. The aged cells are removed from circulation by the reticuloendothelial system, particularly in the splenic pulp where the flow of blood is slow. The cells destroyed each day are replaced by new cells released from marrow, with the result the red cell population in the blood consists of cells ranging in the age from 1 day to 120 days. Approximately 1% of the red cells are destroyed and replaced each day. Any congenital or acquired imbalance in erythrocyte loss relative to the marrow's capacity for erythrocyte production—such as reduced production or increased destruction—leads to anemia.

POINTERS FOR ANEMIA

Growth retardation There is a marked reduction in weight in iron deficient children though height seems to be unaffected.

Exercise intolerance Maximum work capacity, work output and endurance are impaired in iron deficiency state.

Behavioral changes Reduced attention span, irritability, decreased scholastic performance, poor academic achievement and conduct disorders occur in these iron deficient children. Child is usually irritable, resentful, crying excessively, holds breath and throws temper tantrums. The cognitive function also suffers in iron deficient children, at times permanently demonstrated impairment of cognitive function in iron deficient children and significant improvement in Mental Development Index (MDI) and Psychomotor Development Index (PDI) after iron therapy have been reported.

Altered host response Iron deficiency affects both cell mediated as well as humoral immunity. However, oral iron therapy only minimally changes saturation of transferrin and hence practically it does not have any adverse effect on incidence of infection.

APPROACH TO A CHILD WITH ANEMIA

It is pertinent to answer three basic questions while approaching a child with suspected anemia. Is the child anemic? What is the cause of anemia? What is the type of anemia?

Is the Child Anemic?

Lower limit of Hb in the newborn period is 13–14 g/dL; at 3 months, 9 g/dL; 6 months to 6 years, 11 g/dL; and 7–12 years, 12 g/dL. A Hb of 9 g/dL is thus normal for a 3 months old infant and needs no treatment; the same level in a older child may call for hematinic therapy. Hence age appropriate cut-off levels are important to interpret the Hb levels. **Table 2** categorizes the severity of anemia according to Hb levels.

Table 2 Grades of severity of anemia

Grades of anemia severity	Hb%
Mild	10 g% And < normal for the age
Moderate	Between 7 g/dL and 10 g/dL
Severe	Below 7 g/dL and > 5 g/dL
Very severe	< 5 g/dL

Clinical Presentation

The common signs and symptoms of anemia are pallor, tiredness, lassitude, easy fatigability, weakness, and shortness of breath. However, these symptoms are nonspecific and can also be seen in various other conditions including a respiratory illnesses, congestive cardiac failure, renal diseases, or myxedema. Pallor (**Figs 1A and B**) is the most common sign of anemia. The color of skin not only depends upon the Hb content of blood but also on the state of blood vessels in the skin, amount of fluid in the subcutaneous tissue and on the degree of skin pigmentation, associated jaundice and cyanosis and hence pallor out of proportion to actual anemia may be noticed in nephrotic syndrome, renal disorders, hypoproteinemia, and congestive cardiac failure. In simple vasovagal syncope, pallor results from cutaneous vasoconstriction and is not a sign of anemia. Hence it is always prudent to rely on hemoglobin or hematocrit estimation to detect anemia.

What is the Cause and Type of Anemia?

Anemia can be caused due to blood loss; due to decreased (inadequate) production; or due to increased destruction. Detailed history, thorough head to toe examination, screening laboratory tests and confirmatory tests are required in a stepwise approach to establish the etiology of anemia.

Anemia can be typed based on the etiology or the morphology of the red cells. These classifications are discussed in the next chapter. A peripheral blood smear and complete blood counts are

Figures 1A and B Pallor: pale tongue and pale nails. Most common sign of anemia

essential to understand the nature of anemia. Though arriving at a correct diagnosis is important before starting any therapy, doing battery of tests is neither possible nor desirable or cost effective in every case of anemia. Interpretation of laboratory findings for typing of anemia is discussed later in this chapter.

HISTORY TAKING FOR ANEMIA

Time Taken to Develop Anemia

Symptoms depend upon not only upon severity of anemia but also time taken to develop anemia (rate of drop in Hb).

Acute Anemia

Acute anemia at any age usually suggests the possibility of acute external or internal *hemorrhage*; or *hemolysis*. Acute hemolysis usually occurs due to red cell enzyme deficiency or immune destruction. Presence of significant icterus may suggest hemolysis or internal hemorrhage as the cause of anemia. There is no icterus in children with obvious external hemorrhage such as a gastrointestinal (GI) bleed, bleeding following vitamin K deficiency or coagulation factor deficiency or platelet disorder. Child may present with signs of congestive cardiac failure, breathlessness, and restlessness.

Chronic Anemia

Chronic blood loss can be either obvious (recurrent hematemesis) or occult (occult blood in stools). Children may remain asymptomatic for long duration if the onset of anemia is insidious. Child with chronic anemia may be brought walking, with minimal symptoms, even though Hb level may be as low as 3–6 g/dL. In mild anemia there may be no signs and symptoms but a definite sense of well-being and better exercise tolerance is observed following treatment. In severe deficiency, all the symptoms of anemia like fatigue, breathlessness, irritability, anorexia, etc. may be seen. Spleen maybe enlarged, depending on the cause. Depletion of nonheme iron contained in tissue proteins is responsible for various other manifestations.

Age-Specific Causes of Anemia

Newborn Period

Common causes of anemia in the newborn include neonatal blood loss, fetomaternal hemorrhage, and hemolytic disorders. In about 50% of all pregnancies there is some degree of fetomaternal hemorrhage of which 8% are significant (0.5–40 mL fetal blood loss) and 1% severe (> 100 mL fetal blood loss). Approach to neonatal anemia is shown in **Flow chart 1**. It has been discussed in detail in an earlier chapter in the Section on High-risk Newborns.

Anemia in Childhood

Nutritional anemias are usually seen between 6 months and 3 years of age. Alpha thalassemia presents with anemia or hydrops in utero or just after birth. Beta thalassemia usually presents after 6 months of age when fetal hemoglobin (HbF) starts decreasing. A congenital bone marrow hypoplasia will present at or soon after birth.

Family History

G6PD deficiency is more common in *Parsis* and *Sindhis*. Thalassemia is seen more in *Punjabis* and *Sindhis*. Sickle cell anemia (HbS) is more common in Madhya Pradesh and Andhra Pradesh. Family history of *blood transfusions* indicates an inherited cause such as thalassemia, enzyme defects (G6PD deficiency), or membrane defects (hereditary spherocytosis). *Repeated history of blood transfusions* usually indicates a non-nutritional anemia such as hemoglobinopathy, thalassemia, or bone marrow hypofunction.

Pedigree chart including the expired members should be charted meticulously including two generations on each side. Many hemolytic anemias are genetically determined. Certain inherited causes of anemia are transmitted in an X-linked fashion and hence are commonly seen in male children, e.g., G6PD deficiency, phosphoglycerate kinase deficiency. Hereditary spherocytosis are transmitted in an autosomal dominant manner.

Hemoglobinopathies like thalassemia, HbS, etc. are autosomal recessive. A history of consanguineous marriage is also helpful in recessive conditions. A family history of neonatal hyperbilirubinaemia, anemia, jaundice, splenomegaly, splenectomy or gallstones should be asked.

Dietary History

A child with predominantly milk-based diet with minimal or no complimentary feeding is more likely to suffer from nutritional anemia. History of pica suggests an iron deficiency anemia. A child on goat's milk is predisposed to folic acid deficiency due to its poor folate content. Breastmilk, the primary source of infant nutrition is poor in iron, containing 0.28–0.73 mg/L. However, the iron in breastmilk has a very high bioavailability (20–80%) and hence iron deficiency rarely occurs in exclusively breastfed infants till the age of 4–6 months. Breastmilk does not protect against iron deficiency after the age of 6 months unless iron containing weaning foods are introduced.

Iron deficiency in older infants and children occurs due to inadequate dietary intake. Anemia is associated with poor dietary intake of iron, folic acid, B₁₂, proteins and Vitamin E and C in the diet. Non-introduction of iron containing weaning foods or continuation of only milk feeds leads to iron-deficiency anemia (IDA) in infants. Food fads may be responsible for anemia in adolescent period. During adolescence, false concerns about the body figure, food fads, ignorance, particularly in girls lead to iron deficiency.

History of Bleeding

History of skin bleeds (petechiae or ecchymosis) or *bleeding from any other sites* suggests platelets or a hepatic involvement. Chronic liver disease could be a cause of anemia that will also affect the coagulation factors and lead to bleeding manifestations. Skin bleeds associated with anemia suggests hypoplasia or infiltration of the bone marrow. The chronic loss of few milliliters of blood daily is sufficient to deplete iron stores and leads to iron deficiency. Stool examination for occult blood is helpful. Trauma, GI bleeding, chronic occult blood loss often occurs in inflammatory bowel disease, Meckel diverticulum, parasitic infestation particularly hookworm infestation are important cause of intestinal blood.

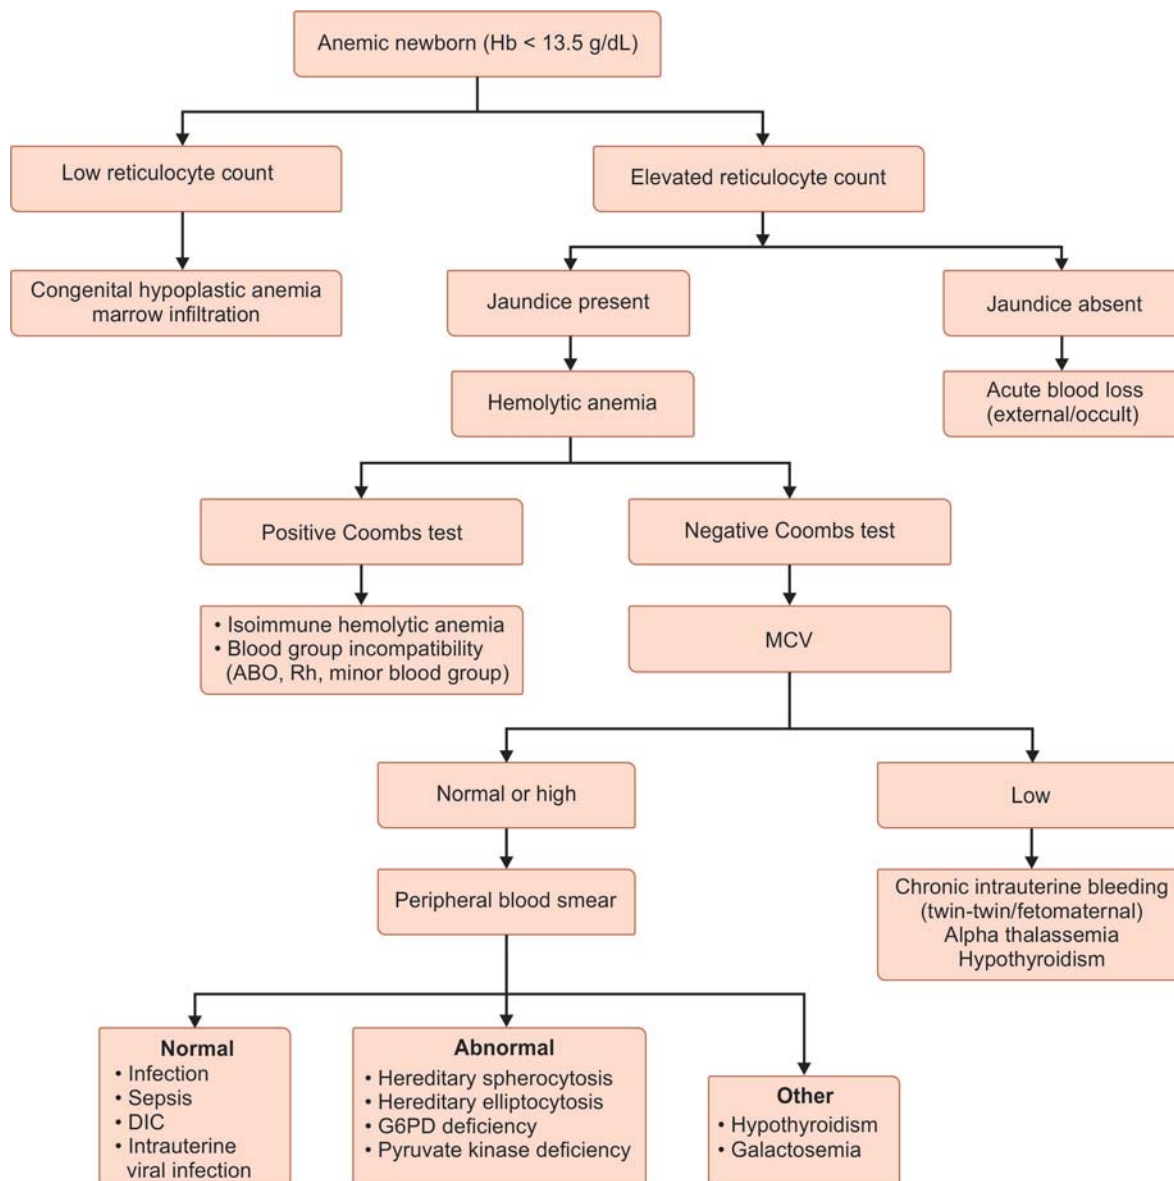

History of Drug Ingestion

Certain drugs can lead to decreased production due to hypoplasia or aplasia of the bone marrow, e.g., chloramphenicol, salicylates, analgesics and nonsteroidal anti-inflammatory drug (NSAID) group of drugs. Some drugs can lead to increased destruction of the RBCs, as is seen in drug-induced hemolytic anemias (penicillin and cephalosporin group, alpha-methyldopa, stibophen, etc.).

Anti-infective drugs like sulfa drugs, nalidixic acid, nitrofurantoin, antimalarials like primaquine, quinine, mefloquine, furazolidone, can lead to hemolysis in individuals with G6PD deficiency. Drugs can also produce megaloblastic anemia, e.g., phenytoin, folate antagonists, etc.

History of Infections

History of fever with sudden appearance of pallor suggests malaria. Bacterial or viral infection leading to cytokine-mediated decrease in iron utilization and RBC production—anemia of chronic infection.

Flow chart 1 Approach to anemia in neonates

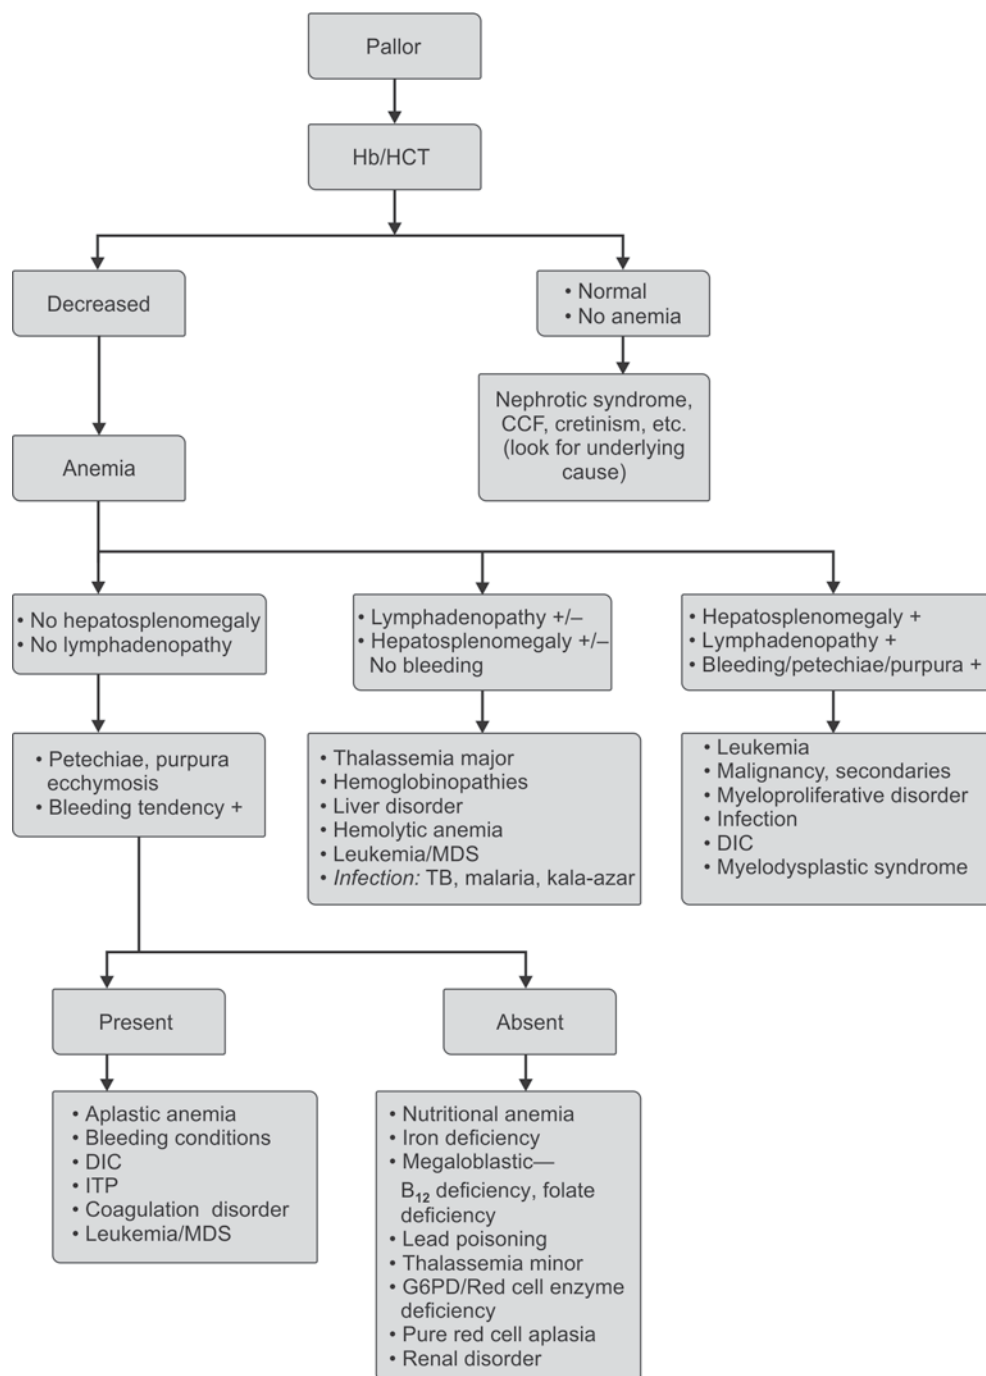

PHYSICAL EXAMINATION

Some physical signs help clinch the diagnosis. To ascertain severity, pulse, blood pressure and respiratory rate should be recorded. Look for puffiness, edema feet, sacral edema, jugulovenous pulse, tenderness, hepatojugular reflux and basal crepitations. All these will help to diagnose congestive cardiac failure as, such children need urgent treatment. Hypertension may be seen in anemia due to renal diseases. Clinical approach to anemia is shown in **Flow chart 2**.

Facies

Hemolytic facies (**Fig. 2**) will have frontal and parietal bossing, large head, depressed bridge of nose, malar prominence, sallow complexion, irregular maxillary teeth with anterior overbite. Hypothyroidism will have typical cretin facies and may be missed. Hemolytic facies suggests chronic hemolysis and extramedullary hematopoiesis as in thalassemia major. This can be confirmed by hair on end appearance in X-ray of the skull (**Fig. 3**).

**Figure 2** Hemolytic facies

Flow chart 2 Clinical approach to anemia

Abbreviations: Hct, hematocrit; CCF, congestive cardiac failure; DIC, disseminated intravascular coagulation; MDS, myelodysplastic syndrome.

Diamond-Blackfan syndrome (DBA) (Figs 4A and B) is characterized by box like face, high arched palate, and triphalangeal thumb. Diagnosis is confirmed by bone marrow examination which shows conspicuous absence of red cell precursors. They have persistent low retic count, macrocytosis, elevated fetal Hb1 antigen and elevated adenosine deaminase levels in the RBCs and usually diagnosed in early infancy in the first 2 years of life.

Eyes Fanconi anemia will have microcornea. Conjunctival vessels tortuosity is seen in HbS and so is the presence of retinal hemorrhage or microaneurysms. Presence of mild jaundice without passage of

high colored urine indicates a process of hemolysis. Osteopetrosis child will develop blindness as time passes by.

Oral cavity Look for glossitis, angular stomatitis, bald tongue which will suggest nutritional anemia. Look for teeth abnormality for hemolytic anemia.

Nail Changes

Platonychia, koilonychia, brittle nails are suggestive of iron deficiency. They are less common in children than in adults, but when present are pathognomonic of iron deficiency anemia (IDA). Dyskeratotic nails will be seen in dyskeratosis congenita.

Figure 3 Hair on end appearance in thalassemia

Lymphadenopathy

Significant lymphadenopathy may suggest tuberculosis, HIV, infectious mononucleosis, leukemia, or lymphoma as the cause of anemia.

Hepatosplenomegaly

Presence of significant hepatosplenomegaly with lymphadenopathy is highly suggestive of malignancy (leukemia and lymphoma). Significant hepatosplenomegaly without lymphadenopathy suggests hemolytic anemia, e.g., thalassemia, or infective pathology (malaria). HIV-AIDS should also be ruled out in presence of hepatosplenomegaly. Hepatosplenomegaly with fever and anemia may be suggestive of malaria and kala-azar. Storage disorders should also be considered in a child with hepatosplenomegaly with systemic manifestations. Isolated splenomegaly favors enteric fever, malaria, portal hypertension, lymphoma, chronic myelogenous leukemia (CML), tropical splenomegaly or hypersplenism, immune hemolytic anemia, or congenital spherocytosis as the cause of anemia.

Bleeding Manifestation

Presence of bleeding tendencies with petechiae, purpura will suggest thrombocytopenia which can be seen in benign diseases like immune thrombocytopenic purpura (ITP) or in serious diseases like aplastic anemia, malignancies or marrow infiltration. Child with ITP is usually a well child without fever, hepatosplenomegaly,

lymphadenopathy, weight loss or bony tenderness as compared to a child with bone marrow failure or leukemia who will be a sick child with fever, weight loss, bony tenderness, lymphadenopathy and hepatosplenomegaly.

Mucosal Changes

Glossitis, angular stomatitis and bald tongue are rarely seen in deficiency of B₁₂, folic acid and iron in small children. Atrophic gastritis and achlorhydria and small bowel changes leading to esophageal mucosal web as seen in Plummer-Vilson syndrome, also called Paterson-Kelly syndrome are rare in children and are more common in adolescent and adults with nutritional anemia.

Skeletal Changes

Childs with Fanconi anemia and thrombocytopenia-absent radius (TAR) syndrome, etc. have skeletal malformations like absent radius, absent or bifid thumb, triphalangeal thumb, polydactyly, syndactyly, short stature, microcephaly. Look for associated anomalies like mental retardation, skin hyperpigmentation, hypogonadism, and renal anomalies (**Figs 5A and B**).

Skin Changes

Hyperpigmentation is seen in Fanconi anemia. Icterus is seen in liver diseases as well as hemolytic anemia. Nonhealing ulcers over lower limbs are seen in any chronic hemolytic anemia especially in HbS and hemoglobin C (HbC) disease (**Fig. 6**). Disseminated intravascular coagulation (DIC) like picture with anemia and thrombocytopenia in a child with giant cavernous hemangioma suggests Kasabach-Merritt syndrome (**Fig. 7**).

Kasabach-Merritt Syndrome

Also known as hemangioma with thrombocytopenia, this disorder was first described in 1940. It is a rare disease usually of infants in which vascular tumor leads to decreased platelet count often presenting at birth. It is usually caused by hemangioendothelioma or other vascular tumor. The condition may progress to disseminated intravascular coagulation. Microangiopathic hemolytic anemia of RBC is often associated. Peripheral smear reveals helmet cells, broken cells, crenated RBCs. Tumors may be found over the trunk upper and lower extremities, retroperitoneum and in the cervical and fascial area.

LABORATORY APPROACH TO CHILDHOOD ANEMIA

Though arriving at a correct diagnosis is very important before starting any therapy, doing battery of tests is neither possible

Figures 4A and B (A) Diamond-Blackfan syndrome (DBA); (B) Bone marrow showing absence of normoblasts in BM

Figures 5A and B Skeletal changes in Fanconi anemia. (A) Absent radius; (B) Bifid thumb, hyperpigmentation, hypogonadism, renal anomalies in such cases

Figure 6 Nonhealing ulcers in sickle cell anemia (HbS) disease

nor desirable or cost effective in every case of anemia. Hence the investigations needed to be done are classified into two categories viz. screening tests and confirmatory tests.

Figure 7 Kasabach-Merritt syndrome

Screening Tests

These include Hb, complete blood count, reticulocyte count, HCT, blood indices, mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), mean corpuscular hemoglobin concentration (MCHC) and red cell width (RDW) and thorough examination of peripheral smear which must be done in all cases for diagnosing anemia. It not only suggests the type of anemia but also gives the clue to the underlying disease and indicates specialized investigations needed further, thus minimising the number of tests and expenses. It also gives direction for further management.

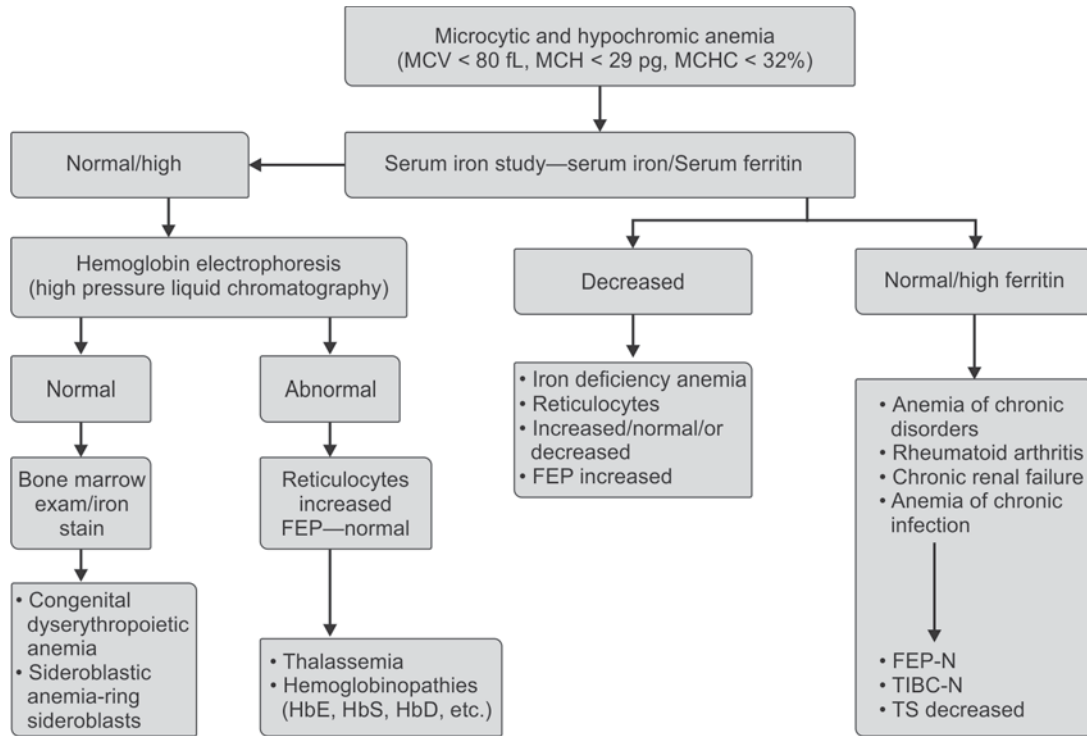

Peripheral smear examination should be done on fresh smears taken from finger prick. It is ideally done on particle cell counter which gives accurate and reproducible results as compared to manual methods. Based on erythrocyte size anemia is further classified as microcytic, normocytic and macrocytic (**Figs 8A to C**). Approach to anemia based upon morphologic classification is provided in **Flow charts 3 to 5**. For details refer to the next chapter on classification on anemia.

Red Cell Width

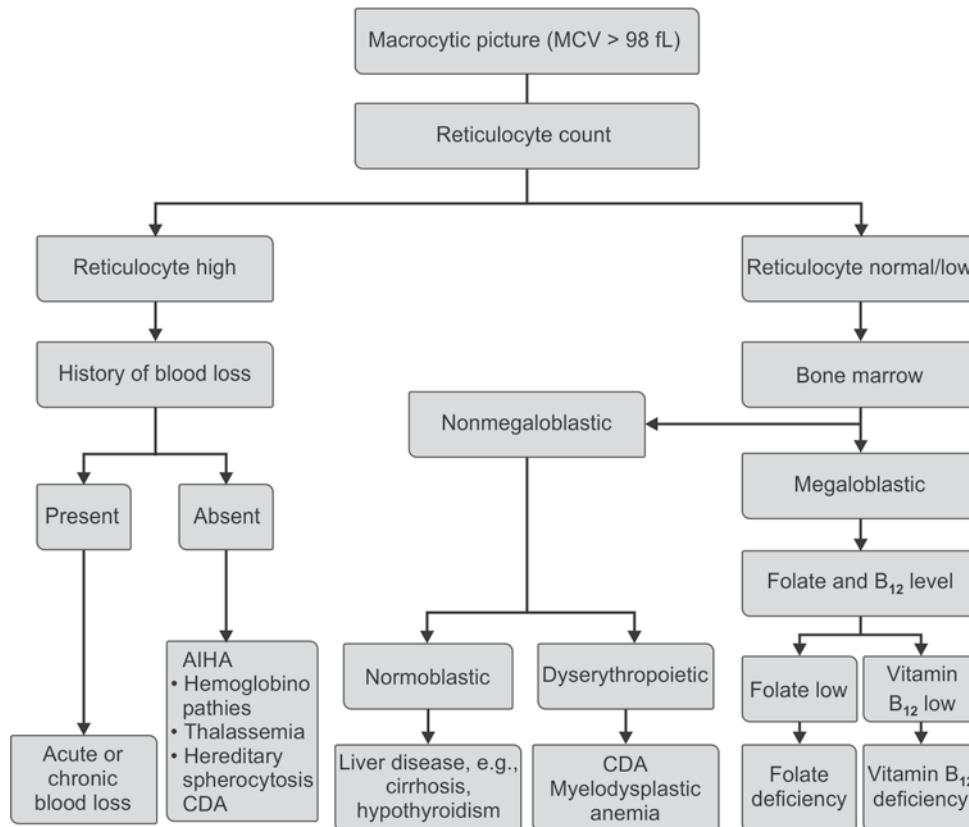

Red cell width indicates the variation in RBC size. Increased RDW indicates presence of anisocytosis as seen in iron deficiency anemia and a normal value (12–14) indicates not much variation in size of the RBCs as in thalassemia.

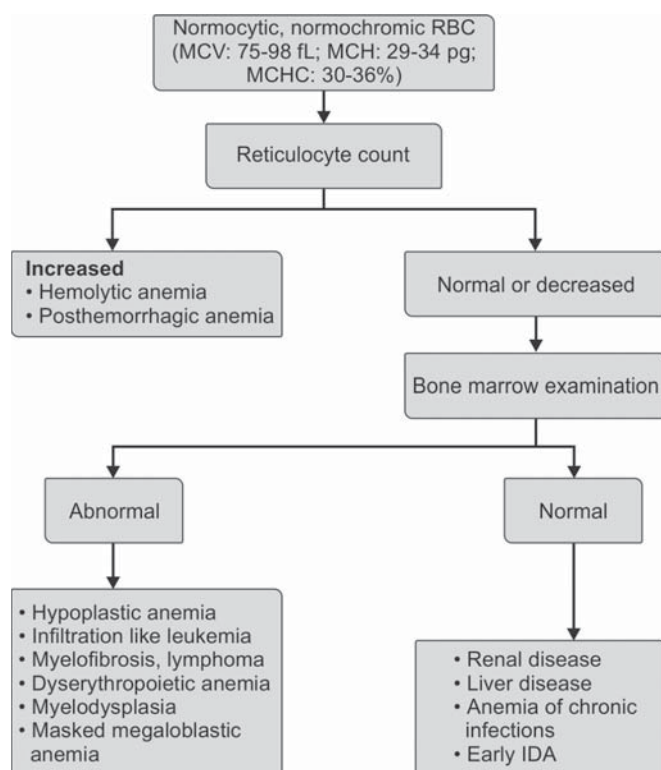

Figures 8A to C (A) Microcytic anemia; (B) Normocytic anemia; and (C) Macrocytic anemia

Flow chart 3 Microcytic and hypochromic picture on peripheral blood smear

Abbreviations: MCV, mean corpuscular volume; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; FEP, free erythrocyte protoporphyrins; TIBC, total iron-binding capacity.

Flow chart 4 Macrocytic picture on peripheral blood smear

Abbreviations: MCV, mean corpuscular volume; AIHA, autoimmune hemolytic anemia; CDA, congenital dyserythropoietic anemias.

Flow chart 5 Normocytic, normochromic anemia**Reticulocyte Count**

Number of reticulocytes in the blood reflects the bone marrow activity and is expressed as the percentage of the total RBC count. If the bone marrow is hyperactive as in cases of hemolytic anemia, the reticulocyte count increases. The reticulocyte count is decreased in patients with bone marrow hypoplasia or aplasia.

Anemia per se results in increased bone marrow activity to compensate for decreased Hb, leading to falsely high reticulocyte count. Therefore, correction should be made for the existing severity of anemia. This is done as follows:

$$\text{Corrected reticulocyte count} = \frac{\text{Actual reticulocyte count} \times \text{Packed cell volume (PCV)}}{0.45 \text{ (normal PCV)}}$$

Bone Marrow

Bone marrow examination is very helpful in making a diagnosis as many times the peripheral blood examination may not reveal the true picture. A peripheral pancytopenia may not be associated with

bone marrow aplasia suggesting an alternate diagnosis. Similarly a peripheral macrocytic picture may not be associated with megaloblastosis in bone marrow suggesting towards a diagnosis other than vitamin B₁₂ or folic acid deficiency. Bone marrow examination can be diagnostic in aplastic anemia and leukemia. Bone marrow examination will show hyperplasia in patients with hemolytic syndrome and hypersplenism.

Special Investigations

Specific investigations for etiological diagnosis include serum iron studies, serum folate and vitamin B₁₂ levels for deficiency anemias; and Hb electrophoresis for hemoglobinopathies and thalassemia.

IN A NUTSHELL

1. Detailed history, clinical examination and complete blood counts along with a peripheral blood smear examination and various algorithms aid in reaching a diagnosis.
2. Detailed peripheral smear examination is of utmost importance. Its examination not only helps in classification of anemia but presence of other red cell abnormalities, gives clue to the underlying diagnosis.
3. These children may be subjected to few additional, specific tests for confirmation of etiology of anemia.

Chapter 38.3

Anemia: Etiology and Classification

Nitin Shah, Sunil Udgire

When faced with a child with anemia, one needs to establish the severity of anemia for immediate action, type of anemia to ask for necessary diagnostic tests and identify the etiology of anemia to understand the basis behind. This section will help you understand these principles.

HISTORICAL ASPECTS

Anemia was described as pallor, breathlessness and edema in about 1500 BC in Papyrus Ebers, an Egyptian manual of therapeutics, which is believed to be the first complete description of iron deficiency. Pernicious anemia was described by Thomas Addison in 1855 which also suggested role of cobalamin deficiency as the cause. Subsequently in 1880 Ehrlich described the term megaloblast for the abnormal normoblast seen in megaloblastic anemia. Cooley described what is now known as thalassemia in 1925. First case of thalassemia from India was probably reported in 1938 from Calcutta. Sydenstricker described the first case of sickle-cell anemia in children and the first case of sickle-cell disease in an Indian immigrant was reported from Cape Town by Berye and Bull in 1943 and from within India by Lehmann and Catbush in 1952 among Veddoids aboriginal tribes of Nilgiri Hills in South India.

EPIDEMIOLOGY

Anemia is a global public health problem affecting both developing and developed countries with major consequences for human health as well as social and economic development. According to an estimate carried out between 1993 and 2005 by World Health Organization (WHO), prevalence of anemia in preschool aged children was 47.4% and school aged children 25.4%, while that of preschool children from South-East Asia as per WHO-region was 65.5%.

Iron deficiency is the most common and widespread nutritional disorder in the world. In nonmalaria endemic regions, 60% of cases of anemia are due to iron-deficiency anemia (IDA). For malaria endemic regions, approximately 50% of anemia is attributable to iron deficiency. In India prevalence of IDA in children was estimated to be 70% in 1990 by Chakraborty and not much has changed in recent time as studies done since 2000 show prevalence of 60–90% at different age in children. Modern *zero figure trends* and the resultant increase in the followers of vegan diet have led to a surge in the number of anemia cases in the Western world too. Over the last few decades, cobalamin and folic acid deficiency have emerged as equally big problems.

According to WHO, about 5% of the world population is carrier for different inherited disorders of hemoglobin (Hb) and about 370,000 severely affected homozygote or compound heterozygote cases of thalassemia are born every year. The United Nations Children's Fund (UNICEF) in 1996 estimated that there were 29.7 million carriers of beta-thalassemia trait in India and about 10,000 infants with homozygous beta-thalassemia born every year. The general incidence of thalassemia trait and sickle-cell hemoglobinopathies in India varies between 3–17% and 1–44% respectively. It is estimated that there are about 65,000–67,000 beta-thalassemia patients in India with around 9,000–10,000 cases being added every year. The carrier rate for beta-thalassemia gene varies from 1–3% in Southern India to 3–15% in Northern India.

DEFINITION

Derived from the Greek term which means *bloodlessness*, anemia is defined as decreased red blood cell (RBC) volume (reflected by RBC count and Hb concentration per RBC and hematocrit) or reduced Hb concentration below the age-appropriate normal values. Main function of RBCs is to carry oxygen to and carbon dioxide from the tissues. Anemia therefore will lead to tissue hypoxia at cellular levels which is difficult to measure in day-to-day clinical practice. Child is said to be anemic when the Hb and/or hematocrit is two standard deviations below mean for that particular age and sex. The normal Hb levels along with normal red cell values at different ages, i.e., from newborn to adulthood are given in **Table 1**. WHO cut-offs for defining anemia at various ages have been listed in the previous chapter.

CLINICAL MANIFESTATIONS

The manifestations of anemia depend on five factors, viz.: (1) reduction in oxygen-carrying capacity of blood, (2) degree of change in total blood volume, (3) speed at which the previous two factors developed, (4) capacity of the cardiovascular and pulmonary systems to compensate for the anemia and (5) associated manifestations of the underlying disorder that resulted in the development of anemia. Clinical presentation has been covered in the previous chapter on approach to anemia.

ETIOLOGY AND CLASSIFICATION OF ANEMIA

Anemia can be classified on the basis of etiology which helps us understand the pathophysiology of anemia. Morphological classification based on size and shape of red cells helps us investigate a case of anemia and zero down on close differentials. Classification based on severity of anemia helps us decide the plan of management of a case and need of transfusion. A combined approach will help us understand, investigate and manage a case of anemia, especially when the child is sick.

Etiological Classification

There are four basic causes of anemia: (1) decreased production, (2) increased losses in form hemorrhage or (3) hemolysis and (4) sequestration. We can separate the causes of anemia into two broad categories: (1) Disorders of red cell production, in which net red cell production is depressed. This can be due to either ineffective erythropoiesis (disorders of erythroid maturation) or absolute failure of erythropoiesis. (2) Disorders in which rapid destruction of red cells occur due to hemorrhage or hemolysis. In some cases of anemia, more than one mechanism may be involved but one functional disorder is generally the major reason responsible for anemia. Etiological classification of anemia is given in **Table 2**.

Classification Based on Severity and Onset

Anemia can be classified based on severity as per WHO guidelines:

- Mild, when Hb concentrations are above 10 g/dL but below the cut-off value
- Moderate when the concentration is between 7 g/dL and 10 g/dL
- Severe when it is below 7 g/dL.

Anemia can also be classified based on its onset into *acute anemia* which develops over days to weeks and *chronic anemia* which develops over months. This was also discussed in the previous chapter. Severity of anemia along with clinical condition of patient, especially status of compensation, will help clinician make treatment plan. For example, a 2-year-old child with Hb of 3 g/dL due to iron deficiency would have developed anemia over months and hence will be stable and would not need transfusion unless in occult or overt congestive cardiac failure. Whereas in the

Table 1 Red cell values at various ages: mean and lower limit of normal (-2 SD)*

Age	Hemoglobin (g/dL)		Hematocrit (%)		Red cell count ($10^{12}/L$)		MCV (fL)		MCH (pg)		MCHC (g/dL)		Reticulocytes

From: Dallman PR. Blood and blood-forming tissue. In: Rudolph A. Pediatrics. 16th ed. E Norwalk, CT: Appleton-Cernuary-Croles; 1977.

*These data have been compiled from sources. Emphasis is given to studies employing electronic counters and to the selection of populations that are likely to exclude individuals with iron deficiency. The mean \pm 2 SD can be expected to include 95% of the observations in a normal population.

Abbreviations: SD, standard deviation; MCV, mean corpuscular volume; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration.

same child if the anemia is due to acute hemolysis say following glucose-6-phosphate dehydrogenase (G6PD) deficiency will be grossly sick and will certainly need transfusion. Also in a sick child with severe anemia, which is acute in onset the treatment, gets priority rather than wasting time in elaborate investigations. One can always investigate the child later.

Morphological Classification

This approach helps us narrow down the differential diagnosis and at times even clinches a diagnosis. Anemia is classified morphologically based on red cell indices as well as evaluation of peripheral smear for red cell size, shape and other abnormalities. It shows whether the anemia is microcytic, normocytic, or macrocytic; hypochromic or normochromic; shows specific morphologic abnormalities suggestive of red cell membrane disorders (e.g., spherocytosis, stomatocytosis or elliptocytosis) or hemoglobinopathies (e.g., sickle-cell disease, thalassemia). This classification is also arbitrary, and categories are not mutually exclusive. Classification based on red cell size and reticulocyte count is shown in **Table 3**.

Fully automated techniques are available for determination of Hb, hematocrit and red cell indices to precisely classify anemia. Steps to follow in investigation of anemia are detailed clinical history and physical examination, complete blood examination to determine whether the abnormality is isolated to a single cell line (RBCs only) or whether it is part of a multiple cell line abnormality; determine morphological type of anemia depending on blood smear and red cell indices, mean corpuscular volume (MCV), and red cell volume distribution width (RDW); reticulocyte count

for degree of erythropoiesis; and look for evidence of hemolytic process, clinical and laboratory features. Bessman and associates have provided a classification of anemia based on MCV and RDW. An updated version that includes mean corpuscular hemoglobin concentration (MCHC) is shown in the **Table 4**. Red cell disorders can be classified according to their predominant morphology. An approach to such a classification is presented in **Table 5**.

IN A NUTSHELL

1. Iron deficiency is the most common and widespread nutritional disorder in the world.
2. Anemia can be classified on the basis of etiology which helps us understand the pathophysiology of anemia.
3. Morphological classification based on size and shape of red cells helps us investigate a case of anemia and zero down on close differentials.
4. Classification based on severity of anemia helps us decide the plan of management of a case and need of transfusion.
5. Blood smear is very useful tool in diagnosis of anemia, and it should not be overlooked in busy practice.
6. Steps to follow in investigation of anemia are detailed clinical history and physical examination, complete blood examination, determine morphological type of anemia; reticulocyte count for degree of erythropoiesis; and look for evidence of hemolytic process, clinical and laboratory features.

Table 2 Etiological classification of anemia

I. Impaired red cell production due to deficiency	
<ul style="list-style-type: none"> • <i>Decreased dietary intake:</i> Iron, B₁₂ • <i>Increased demand:</i> Growth (iron), chronic hemolysis (folic acid) • <i>Decreased absorption:</i> Malabsorption, intrinsic factor deficiency (B₁₂) • Iron deficiency • Vitamin B₁₂ deficiency • Folic acid deficiency • Protein malnutrition • Vitamin B₆ deficiency • <i>Impaired erythropoietin production:</i> CRF, hypothyroidism, hypopituitarism 	
II. Impaired red cell production due to bone marrow failure	
<ul style="list-style-type: none"> • <i>Aplastic anemia:</i> Congenital or acquired • <i>Pure red cell aplasia:</i> Congenital (Diamond-Blackfan syndrome), acquired (TEC) • <i>Marrow infiltration:</i> Malignancies, osteopetrosis, myelofibrosis (CRF, vitamin D deficiency) • Pearson syndrome 	
III. Blood loss

<ul style="list-style-type: none"> • Cellular defects: <ul style="list-style-type: none"> – <i>Membrane defects:</i> Spherocytosis, elliptocytosis, stomatocytosis – <i>Enzyme defects:</i> Pyruvate kinase, G6PD deficiency – <i>Hemoglobin defects:</i> Thalassemia syndromes, sickle-cell anemia • Extracellular defects: <ul style="list-style-type: none"> – <i>Autoimmune:</i> Warm, cold antibody – <i>Fragmentation hemolysis:</i> DIC, TTP, HUS, ECMO, prosthetic heart valves, burns – Hypersplenism – <i>Plasma factors:</i> Liver disease, abetalipoproteinemia, infections, Wilson disease 	

Abbreviations: TEC, transient erythroblastopenia of childhood; CRF, chronic renal failure; G6PD, glucose-6-phosphate dehydrogenase; DIC, disseminated intravascular coagulation; TTP, thrombotic thrombocytopenic purpura; HUS, hemolytic-uremic syndrome; ECMO, extracorporeal membrane oxygenation.

Table 3 Classification of anemia based on red cell size

I. Microcytic anemia (MCV low):	
<ul style="list-style-type: none"> • <i>Low or inadequate reticulocyte count</i> <ul style="list-style-type: none"> – Iron deficiency – Thalassemia trait – Chronic disease – Lead poisoning – Copper deficiency – Sideroblastic anemia • <i>High reticulocyte count</i> <ul style="list-style-type: none"> – Thalassemia syndromes – Pyropoikilocytosis – Hemoglobin C and E disease 	
II. Macrocytic anemia (MCV high):	
<ul style="list-style-type: none"> • <i>Low or inadequate reticulocyte count</i> <ul style="list-style-type: none"> – Vitamin B₁₂ deficiency – Folic acid deficiency – Congenital and acquired aplastic anemia – Hypothyroidism – Orotic aciduria – Drug induced • <i>High reticulocyte count</i> <ul style="list-style-type: none"> – Dyserythropoietic anemia type I and III – Active hemolysis 	
III. Normocytic anemia (MCV normal):	
<ul style="list-style-type: none"> • <i>Low or inadequate reticulocyte count</i> <ul style="list-style-type: none"> – Chronic disease – Malignancy – RBC aplasia (TEC) – Renal failure – Endocrinopathies – Hypersplenism – Dyserythropoietic anemia type II – Hemophagocytic anemia • <i>High reticulocyte count</i> <ul style="list-style-type: none"> – <i>Antibody-mediated hemolysis:</i> Warm, cold – <i>Microangiopathy:</i> DIC, HUS, TTP – <i>Membranopathies:</i> Spherocytosis, elliptocytosis – <i>Enzymopathies:</i> Pyruvate kinase, G6PD deficiency – <i>Hemoglobinopathies:</i> HBSS, SC 	

Abbreviations: MCV, mean corpuscular volume; RBC, red blood cell; TEC, transient erythroblastopenia of childhood; DIC, disseminated intravascular coagulation; HUS, hemolytic-uremic syndrome; TTP, thrombotic thrombocytopenic purpura; G6PD, glucose-6-phosphate dehydrogenase.

Table 4 Relationship of MCV and red cell distribution width (RDW) in a variety of red cell disorder

RDW	Mean corpuscular volume (MCV)		
	Low	Normal	High
Normal	Heterozygous α - and β -thalassemia	Normal Lead poisoning Early iron deficiency Liver disease	Aplastic anemia
High	Iron deficiency Hemoglobin H disease S β -thalassemia		Newborns, prematurity Vitamin B ₁₂ deficiency or folate deficiency
		High MCHC	High MCHC
		Immune hemolytic anemia SS and SC disease Hereditary spherocytosis	Immune hemolytic anemia

Adapted from Bessman JD, Gilmer PR, Gardner FH. Improved classification of anemias by MCV and RDW. *Am J Clin Pathol.* 1983;80(3):322-6.

Abbreviations: MCV, mean corpuscular volume; RDW, red cell volume distribution width; MCHC, mean corpuscular hemoglobin concentration; SC, sickle cell.

Table 5 Classification of red cell hemolytic disorders by predominant morphology and specific red cell morphologic abnormalities

- *Acanthocytes (spur cells)*: Because of changes in membrane lipid content, these red cells have several irregularly distributed, sharp projections of unequal length. Most of the affected erythrocytes are also small and lack central pallor:
 - Spur-cell anemia
 - Liver disease
 - Uremia
 - Abetalipoproteinemia
 - Hypothyroidism
 - Heat stroke
 - DIC
 - After splenectomy or hyposplenic state
 - Vitamin E deficiency
- *Echinocytes (burr cells)*: Burr cells usually have 10–30 blunt and fairly symmetrical projections:
 - Renal failure
 - Dehydration
 - Storage artifact
 - Liver disease
- *Elliptocytes*: Elliptical cells, normochromic:
 - Hereditary elliptocytosis
 - Thalassemias
 - Megaloblastic anemias
 - IDA
- *Spherocytes*: Inherited or acquired defect in the erythrocyte membrane decreases the surface area to volume ratio:
 - Hereditary spherocytosis
 - Transfused erythrocytes
 - Autoimmune hemolytic anemia
 - Severe burns, other red cell thermal injury
 - *Clostridium welchii* septicemia
 - *Enzyme deficiency*: G6PD, pyruvate kinase deficiency
 - Hemolytic transfusion reactions
 - ABO incompatibility in neonates
 - Microangiopathic hemolytic anemia
 - Hypersplenism
- *Target cells*: Erythrocyte's center contains a circle of Hb pigment surrounded by a ring of pallor:
 - Iron deficiency
 - Hemoglobinopathies, like S, C, D and E
 - Thalassemias
 - Liver disease, like hepatitis, obstructive jaundice
 - After splenectomy

Contd...

Contd...

- *Stomatocytes*: Have a slit-like area of central pallor:
 - Hereditary stomatocytosis
 - Rh_{null} blood group
 - Malignancies
 - Liver disease, especially acute alcoholism
- *Schistocytes*: Helmet, triangular shapes, or small fragments:
 - Microangiopathic hemolytic anemia
 - DIC
 - Chemotherapy (mitomycin C)
 - Malignant hypertension
 - Hemolytic uremic syndrome
 - G6PD deficiency
 - Burns
 - Liver disease
 - Uremia
- *Heinz bodies*: Aggregated denatured Hb:
 - Thalassemia
 - Heinz body hemolytic anemia
 - Asplenia
 - Chronic liver disease
- *Teardrop cells (dacryocyte)*: Shape of drop, usually microcytic:
 - Thalassemia major
 - Bone marrow malignancy
 - Myeloproliferative syndromes
 - Newborn
- *Cabot's ring bodies*: Nuclear remnant ring configuration inclusions:
 - Lead poisoning
 - Pernicious anemia
- *Basophilic stippling*: Basophilic stippling is the presence of numerous small, purplish inclusions within erythrocytes that represent aggregates of ribosomal RNA:
 - Lead poisoning
 - Thalassemia
 - Unstable Hbs
 - Pyrimidine 5'-nucleotidase deficiency
- *Howell-Jolly bodies*: Round, purple inclusions in erythrocytes that represent DNA fragments that were once part of the nucleus of immature red cells:
 - Absent or hypofunctioning spleen
 - Macrocytic or hemolytic anemia
 - Dyserythropoietic anemia

Abbreviations: IDA, iron-deficiency anemia; Hb, hemoglobin; G6PD, glucose-6-phosphate dehydrogenase; DIC, disseminated intravascular coagulation; RNA, ribonucleic acid; DNA, deoxyribonucleic acid.

Chapter 38.4

Congenital Bone Marrow Failure

Maitryee Bhattacharya, Meet Kumar

Inherited bone marrow failure syndromes (IBMFS) are a heterogeneous group of disorders characterized by bone marrow failure (BMF) along with one or more structural abnormality. Of all the aplastic anemia patients diagnosed in children and adolescents, approximately 25% of pediatric and 10% of adolescents have an inherited etiology. Identification of such patients is of utmost importance, as inherited and acquired disorders differ significantly in treatment options, outcomes and prognosis. IBMFS can be classified into those with unilineage cytopenia or those with bilineage or multilineage cytopenia.

FANCONI ANEMIA

Fanconi anemia (FA) was first described by Dr Guido Fanconi in 1927 when he noted macrocytic anemia in a family of three brothers along with varying skeletal abnormalities. FA constitutes the most common type of IBMFS (constituting almost 50%). However, reported frequency of FA of all aplastic anemia in children varies from 10% to 25% in different Indian studies.

Etiopathogenesis

Fanconi anemia is identified as a multigenic disorder. Currently 13 genes are identified and dissected.

These FA proteins function in coordination in the repair of DNA crosslinks (**Fig. 1**). There are three discrete steps in the FA DNA damage response pathway core complex. Eight wild-type FANC proteins (FANCA-C, FANCE-G, FANCL and FANCM) and few other proteins form a single large nuclear protein *core complex*, that functions as an ubiquitin ligase of which FANCL is the catalytic subunit ID complex. The activated core complex results in conversion of two downstream protein targets, FANCI and FANCD2 (called the *ID complex*), from unubiquitinated isoforms to monoubiquitinated isoforms downstream effector complexes. In normal cells after monoubiquitination of the

ID complex, the wild-type core complex translocates the monoubiquitinated ID complex to chromatin and localizes the ID complex to nuclear foci to complete the final step of the DNA repair response. Additional factors also operate in FA BMF, including telomere shortening.

Clinical Features

It is reported in larger series that 39% of FA patients have aplastic anemia and anomalies (**Figs 2A to D**), 30% have aplastic anemia without anomalies, 24% have anomalies without aplastic anemia, and 7% have neither. Frequency of common structural anomalies is shown in **Table 1**.

Table 1 Common structural anomalies in Fanconi anemia

Anomalies	Associated frequency (%)
Skin pigment changes or café-au-lait spots	40–65
Short stature	40–65
Skeletal (thumbs, hands, head, face, trunk)	40–70
Hypogonadal and genitalia changes (mostly male)	20–30
Eye, eyelid, or epicanthal fold anomalies	20–40
Renal malformations	20–35
Gastrointestinal or cardiopulmonary malformations	10–15
Ear anomalies (external and internal), deafness	~10
CNS imaging anomalies	3–10

Approach to Diagnosis

A child should be tested for FA if presents with aplastic anemia, any of the structural anomalies listed above, primary myelodysplastic syndrome (MDS) or acute myelogenous leukemia (AML) (at a young age), cancer typical of FA at an atypical age. On initial suspicion for FA, a stress cytogenetic test is usually done for diagnosis. However, if stress test is negative, but suspicion is still high, second level tests may be done for definitive diagnosis (fibroblast culture for mosaicism, complementation analysis, western blot for FANCD2 determination, flow cytometry for studying cell cycle kinetics, etc.). However, if those tests come negative, an alternative diagnosis should be considered.

Investigations

Peripheral blood and bone marrow The RBCs are macrocytic with mean corpuscular volume (MCV) often above 100 fL even before the onset of anemia. In the early stages, there is usually erythroid hyperplasia in the bone marrow (BM), with varying dyserythropoiesis and dysmyelopoiesis. As the disease progresses, the marrow becomes progressively more hypocellular.

Stress cytogenetics This test evaluates the oversensitivity of T lymphocytes of FA patients to various cell mitogens and cross-linking agents like mitomycin-C (MMC) or diepoxybutane (DEB). The stressed chromosomes show evidence of chromosomal breakage or aberrations (in the form of breaks, gaps, rearrangements, radials, triradials, quadriradials) (**Fig. 3**). There are rare disorders, such as Nijmegen breakage syndrome, in which chromosome breakage may be positive but the patient does not have FA. The blood result may also be normal in cases of mosaicism, when the test may need to be done from fibroblast.

Complementation analysis Definitive proof of FA is accomplished by identification of the gene complementation group, followed by demonstration of the disease-causing mutation.

Figure 1 Fanconi anemia/BRCA DNA damage response pathway. Following DNA damage, the proteins represented by A, B, C, E, F, G, L, and M form the core complex, which is required for ubiquitination of the I and D2 proteins, which are in turn required for the downstream complex to form foci for DNA repair

Figures 2A to D Facial similarities between unrelated patients with a triangular face and micrognathia (A to C) and triphalangeal thumb abnormality (D)

Figure 3 Patterns of chromosomes in blood treated with DNA cross-linking agents. Left, Mitomycin C, arrows show radial figures. Right, Diepoxybutane, arrows show breaks, gaps, and rearrangement figures. Source: Dr Mayur Parihar, Consultant, Department of Cytogenetics, Tata Medical Center, Kolkata.

Management and Outcome

Management of patients with FA begins with a thorough history and physical examination, laboratory tests and cancer screening. A surveillance program for solid cancers should be initiated at least annually. Dentists, oral surgeons, or head and neck surgeons should be consulted starting 10 years of age to screen for head and neck squamous cell carcinomas. At 13 years of age, all women with Fanconi phenotype should have annual gynecologic screening. Growth should be serially documented, and when growth velocity or stature is less than expected, endocrine evaluation should be done and growth hormone deficiency addressed. Recommended hematologic monitoring is to monitor blood counts every 3–4 months, with annual BM aspirates and biopsies including cytogenetics.

Treatment of BMF should be initiated as the hemoglobin falls less than 8 g/dL, platelets fall less than 30,000/ μ L, and absolute neutrophil count is less than 500/ μ L (or there are symptoms from anemia, bleeding, or infection).

Androgens

Androgen therapy has been used to treat FA for decades. The overall response rate is about 50%. Reticulocytosis occurs initially, followed by a rise in hemoglobin within 1–2 months. When an adequate response has been attained, the androgens should be slowly tapered but not stopped. Oxymetholone, an oral 17- α -alkylated androgen,

is used most frequently at 1–5 mg/kg once a day. Some prefer to add corticosteroids to control androgen-induced growth acceleration and to prevent thrombocytopenic bleeding by promoting vascular stability. Almost all patients relapse when androgens are stopped. A few noteworthy complications associated with androgen therapy include peliosis hepatis, cholestatic jaundice or elevated liver enzymes, hepatocellular adenomas, hepatocellular carcinoma (characteristically does not produce α -fetoprotein in serum) and prostatic carcinoma. Those receiving androgens should be monitored for liver enzymes periodically.

Hematopoietic Stem Cell Transplantation

Hematopoietic stem cell transplantation is the only curative therapy for the hematologic abnormalities of FA: aplastic anemia, AML, and MDS. The best donor source is an human leukocyte antigen (HLA)-matched sibling. Special precaution need be taken so as to exclude the possibility of FA phenotype in the sibling. Owing to high-risk of severe cytotoxicity from chemotherapy and irradiation and exaggerated graft versus host disease (GVHD) in these patients with the use of conventional conditioning regimens, reduced-intensity hematopoietic stem cell transplantation (HSCT) protocols have been introduced and improved outcomes achieved. Absolute indications for a matched sibling donor HSCT include severe under productive cytopenias and transfusion dependency, high-risk MDS with chromosomal clonal abnormalities or an overt AML.

DYSKERATOSIS CONGENITA

Originally it was considered a dermatologic disease and was termed Zinsser-Cole-Engman syndrome, manifesting as a diagnostic ectodermal triad of reticulate skin pigmentation of upper body, mucosal leukoplakia, and nail dystrophy. Hematologic manifestations constitute an important part and cause substantial morbidity and mortality. Dyskeratosis congenita (DKC) patients also have a predisposition to develop cancer and MDS. DKC constitutes approximately 5% of all inherited marrow failures.

Pathophysiology

Dyskeratosis congenita shows many modes of inheritance including X-linked recessive, autosomal dominant and autosomal recessive. Six DKC genes (*DKC1*, *TERC*, *TERT*, *NOP10*, *NHP2*, *TINF2*) have been identified till date. These gene products are involved in a highly conserved process of telomere maintenance pathway by which the ends of chromosomes are prevented from shortening substantially with each cell replication (**Fig. 4**). DKC with mutations in the *DKC1* (X-linked recessive DKC) or *TINF2*

Figure 4 Telomere biology pathway with mutations in patients with Dyskeratosis congenita. Mutations in any of the proteins in telomerase complex can cause Dyskeratosis congenita. These proteins are associated with maintenance of telomere length with help of shelterin-dyskerin pathway

and biallelic *TERT* mutations (autosomal recessive DKC) can result in a severe form of DKC called *Hoyeraal-Hreidarsson syndrome*, characterized by hematologic and dermatologic manifestations of DKC in addition to cerebellar hypoplasia. *Revesz syndrome* is a combination of classical manifestations of DKC and exudative retinopathy. It is caused by mutations in *TINF2* and is an autosomal dominant form of the disease. Most studies of the pathogenesis of the aplastic anemia in DKC have shown a marked reduction or absence of colony growth factors CFU-GEMM, CFU-E, etc.

Clinical Features

Clinical manifestations often appear during childhood. Lacy reticulated skin pigmentation affecting the face and trunk is a common finding (89%) and usually appear first. Nail dystrophy of the hands and feet is the second most common finding (88%), that usually starts with longitudinal ridging and may eventually cause

nail loss. Leukoplakia is found in ~75% that usually involves oral cavity (**Figs 5A and B**). Epiphora (excessive tearing) secondary to nasolacrimal duct obstruction is common and occurs in approximately 50%.

Abnormalities of the teeth, particularly an increased rate of dental decay and early loss of teeth, are common. Skeletal abnormalities such as osteoporosis with recurrent long bone fractures and vascular necrosis are seen in approximately 20% of cases. Genitourinary abnormalities and gastrointestinal abnormalities have been reported. BMF develops in about 80% of patients by the age of 20 years. These patients are particularly prone to develop cancers usually in the 3rd and 4th decades of life. They have increased risks for MDS, AML and solid tumors with a cumulative incidence of approximately 10–30%.

Laboratory Findings

Peripheral blood and bone marrow The incidence of cytopenias caused by BMF has been reported in up to 90% of the patients. The RBCs are often macrocytic, and the fetal hemoglobin can be elevated.

Telomere length is a useful screening testing for DKC with majority showing very short telomeres, examined in leukocyte subsets using flow cytometry with fluorescence in situ hybridization. The presence of short telomeres in peripheral blood lymphocytes is suggestive for DC to be the cause of BMF but is not specific. Although patients with acquired aplastic anemia may have short telomeres in granulocytes, patients with DC have short telomeres in all leukocyte subsets and this is an important distinguishing feature.

Management

Androgens Androgens improve BM function in about 50% of patients. If a response is achieved, the androgen dose may be slowly tapered but should not be stopped. As in FA, patients typically become refractory to androgens as aplastic anemia progresses. A small number of patients may respond to G-CSF therapy.

Hematopoietic stem cell transplantation DKC is a disorder with chromosomal instability caused by defective telomere maintenance. This explains the hypersensitivity to irradiation and chemotherapy and transplantation. Further, because of the high degree of mucocutaneous involvement, DKC patients may be expected to be more susceptible to endothelial damage, which occurs after HSCT as a result of various factors. Limited data is available with HSCT due to rarity of disease.

Figures 5A and B Dyskeratosis congenita. (A) Dystrophic nails; (B) Oral leukoplakia

SHWACHMAN-DIAMOND SYNDROME

Shwachman-Diamond syndrome (SDS) is an autosomal recessive disorder characterized by exocrine pancreatic insufficiency, BMF and other somatic abnormalities (particularly metaphyseal dysostosis). It constitutes around 2% of all IBMFS.

Pathophysiology

The mutant gene responsible for this complex pleiotropic phenotype, termed Shwachman-Bodian-Diamond syndrome (SBDS), has been identified and has been confirmed in 90% of patients with the classic presentation. SBDS seems to be multifunctional and promotes cell survival, ribosome biogenesis, mitotic spindle stability, and chemotaxis. No unifying pathogenesis has been able to account for all of the multisystem features of SDS.

Clinical Features

The most common hematologic abnormality affecting 88–100% of patients with SDS is neutropenia. Roughly 10–65% of patients have pancytopenia with some patients developing aplastic anemia. Patients with SDS have an increased risk for myelodysplasia and AML. Chromosome 7 and 20q deletion abnormalities are the most common chromosomal changes in patients with SDS. Exocrine pancreatic dysfunction is hallmarks of SDS, caused by absence of acinar cells. Clinical presentation is an infant presenting with symptoms of malabsorption, steatorrhea, failure to thrive, and low blood levels of fat soluble vitamins (vitamin A, D, E, and K). For reasons that remain unclear, exocrine pancreatic function spontaneously improves over time in roughly 50% of patients. Skeletal abnormalities are also commonly reported in patients with SDS, related to abnormal development of the growth plates. Other abnormalities as neonatal cardiac manifestations and various endocrine abnormalities have also been reported including insulin-dependent diabetes, growth hormone deficiency, hypogonadotropic hypogonadism and hypothyroidism.

Approach to Diagnosis

The diagnosis of SDS is largely based on clinical phenotype, with pancreatic exocrine and BM dysfunction being the main features. Exocrine pancreatic insufficiency may be demonstrated by elevated fecal fat excretion following a 72-hour collection in the absence of concomitant intestinal or cholestatic liver disease with imaging studies showing a small or fatty pancreas. Signs of marrow failure may include intermittent or persistent neutropenia (absolute neutrophil count $< 1,500/\mu\text{L}$) documented at least 3 times over a minimum of 3 months without an apparent cause; hypoproliferative anemia with a hemoglobin concentration below the age-related normal; unexplained macrocytosis; platelet count less than $150,000/\mu\text{L}$ without alternative etiology; or hypocellular BM. Definitive evidence is provided by sodium dodecylbenzenesulfonate (SDBS) genetic testing, however 10% of patients with clinical features of SDS may lack these mutations.

Management

General Peripheral blood counts should be monitored for cytopenias every 3–4 months. Marrow evaluation with aspirate and biopsy to assess for marrow cellularity and progression should be done yearly. For exocrine pancreatic insufficiency, most patients require oral pancreatic enzyme supplementation. However, since steatorrhea resolves in 50% of patients; assessment of continued need for pancreatic enzyme supplementation should be routinely done.

Supportive care Steroids and androgens have been shown to be effective in inducing hematologic improvement in 50%. Anemia

and thrombocytopenia should be managed with transfusions of RBCs or platelets.

Hematopoietic cell transplantation The only definitive therapy for marrow failure, MDS or leukemia is hematopoietic cell transplantation (HCT). In a large HCT registry for SDS patients for varied indications (severe aplastic anemia, MDS/AML, or other diagnosis), overall survival was 65%, with a median follow-up of 1.1 years.

CONGENITAL AMEGAKARYOCYTIC THROMBOCYTOPENIA (CAMT)

Patients with amegakaryocytic thrombocytopenia lack any characteristic birth defects. Patient usually present with platelet-type bleeding tendency from early infancy, however, serious bleeding may also be associated. Sometimes, a fraction of patients may tend to evolve to aplastic anemia, MDS or even acute myeloid leukemia without developing thrombocytopenia. It has been estimated that approximately 50% of patients develop aplastic anemia by the age of 5 years. The underlying genetic defect identified in these patients is a bi-allelic mutation in the *MPL* gene that encodes for thrombopoietin (TPO) receptor. TPO is an essential integral master regulator of megakaryocytopoiesis and platelet production. Hematopoietic stem cell transplant remains the only curative therapy for this disorder. Importantly, severe toxicity associated with conditioning regimens has not been found in patients suffering from these disorders. No increased rate of transplant-related toxicity has been reported in these patients.

UNILINEAGE CYTOPENIAS

Diamond-Blackfan Anemia

Diamond-Blackfan anemia (DBA) is a rare group of IBMFS, characterized by failure to produce red cell, presence of congenital anomalies, and cancer predisposition. DBA is now long recognized and being established as belonging to the class of disorders known as ribosomopathies. It constitutes around 15% of all IBMFS.

Pathophysiology Mutations in *RPS19*, *S24*, *S17*, *RPL5*, *L11* and *L35A* have been identified in approximately one-third of patients with DBA. These are critical for normal maturation of rRNA because its deficiency causes defective cleavage of the pre-rRNA and abnormal maturation of the 40S subunit. This leads to accumulation of faulty pre-40S ribosome subunits.

Clinical features About 30–45% of patients present with one or more congenital anomalies. Most of these phenotypic abnormalities can be divided as either craniofacial dysmorphism (hypertelorism, microcephaly, microphthalmos); prenatal or postnatal growth failure; neck anomalies (pterygium colli or Klippel-Feil syndrome or Sprengel deformity); and thumb malformations (bifid thumb, duplication, subluxation). A typical DBA facies has been described and consists of two-colored hair, snub nose, wide-set eyes, a thick upper lip, and an intelligent facial expression. Rare anomalies include urogenital malformations (dysplastic or horseshoe kidneys, duplication of ureters), congenital heart disease (ventricular and atrial septal defects), or hypogonadism, and ear malformations.

Diagnosis The diagnostic criteria for DBA, presented first in 1976 by Diamond et al., are still followed. These include presentation with anemia (before first birthday), with near normal neutrophil and/or platelet counts, reticulocytopenia, macrocytosis and normal marrow cellularity with a paucity of red cell precursors. Progression to pancytopenia is rare but may occur. Majority of patients have an increased level of red cell adenosine deaminase (ADA) enzyme levels, and signify fetal red-cell phenotype. It is a sensitive test as up to 10% patients may have normal levels. Hemoglobin F levels are often elevated, although this is a nonspecific finding.

Management Current mainstays of treatment are red cell transfusions, corticosteroid therapy, and HSCT. A majority of DBA patients will respond to steroid therapy, although a few 20% of patients might not respond and will require prolonged red cell transfusions for recurrent anemia. Such patients need to be monitored for side effects of chronic transfusion like infection transmission, alloimmunization and iron overload. Iron chelation therapy need to be resorted to if serum ferritin levels increase beyond 1,000 ng/mL. One fourth of patients have been reported to undergo what is known as *spontaneous remission*, and may not require any therapy. It may be advisable to transfuse during initial growth years to maintain adequate growth spurt, but the side effects of transfusion therapy need to be balanced against the benefits.

Corticosteroid may be started at 2 mg/kg/day, for a maximum trial of 4 weeks. An adequate response is considered as a hemoglobin level greater than 9 g/dL independent of transfusion. In case of response, steroid taper should ensue. Definitive therapy for DBA, like other IBMFS, is stem cell transplantation. Allogeneic matched sibling HSCT has been very successful. The data from the Diamond-Blackfan Anemia Registry of North America (DBAR) reveal an overall survival of 77% for sibling HSCT and 31% for alternative donor HSCT. After HSCT, periodic phlebotomy should be done, when the hemoglobin permits, to eliminate residual iron burden.

Congenital Dyserythropoietic Anemia

The designation congenital dyserythropoietic anemia (CDA) refers to a family of inherited refractory anemia characterized by BM erythroid multinuclearity, ineffective erythropoiesis, and secondary hemosiderosis. The ineffective erythropoiesis is reflected by BM erythroid hyperplasia, inappropriately low reticulocyte counts for the degree of anemia, and intramedullary RBC destruction. Splenomegaly and chronic or intermittent jaundice are additional features. Granulopoiesis and thrombopoiesis are normal. Three classical forms of CDA have been described (**Table 2**).

There are additional, less common groups (and not types) of CDA that are identified when classification into the above groups is not possible (CDA groups IV to VII). These are classified on the basis of morphology rather than genotypic features, and can vary in presentation from severe macrocytosis with no anemia (as in CDA group VI) to severe transfusion dependent anemia since birth with normocytic normochromic indices (as in CDA group VII).

Kostmann Syndrome

Patients with severe congenital neutropenia (SCN) typically present with recurrent life-threatening infections in the first few months of life. Diagnosis is established by persistent low neutrophil counts of less than 500/ μ L for at least 3 months after exclusion of acquired causes of neutropenia. Most common genetic mutation identified in these patients is the heterozygous ELANE mutations found in 30% of patients. BM examination shows a maturation arrest in the neutrophilic and myeloid lineage. Rarely, the disease can progress to myelodysplasia and leukemia. It constitutes roughly 17% of

all IBMFS. Other gene mutations have been identified including mutations in *G-CSF*, *GFI1*, *WASP* and *HAX1*. The importance of identifying ELANE mutations lies in the tendency to progress to acute leukemia at a much higher rate than in other mutations. The treatment of neutropenia in patients with SCN is G-CSF, to which most respond with improved neutrophil counts. The aim is to raise the count to above 1,500/ μ L.

Thrombocytopenia Absent Radii

As the name suggests, patients present with bleeding manifestation due to thrombocytopenia and typically bilaterally absent radii (although in less than 5% cases, radii may be absent unilaterally). An important distinguishing feature from FA is that in thrombocytopenia absent radii (TAR) thumbs are usually present, while they will be absent in FA if the radii are absent. The genetics of TAR is not clear. A few studies have identified interstitial deletion of 200 kb on chromosome 1q21.1, although the incriminating gene is not the only gene involved and search for other affected genes is still an active research area. Patients may have other birth defects like hypoplastic ulnae, hypoplastic humeri, phocomelia, bowed legs, hip dysplasias, abnormal facies, renal malformations, etc. Marrow examination usually reveals absent or small and abnormal megakaryocytes; other lineages being normal. Few patients may require platelet transfusions, and a very occasional patient may also require red cell transfusion support, however, the usual clinical course is a trend of increase in platelet counts by 1 year of age. Stem cell transplantation is a very rare requirement.

IN A NUTSHELL

1. Marrow failure syndromes are a rare group of diseases that need high index of suspicion for early diagnosis and intervention.
2. Most of these syndromes are associated with some genetic predisposition.
3. History should include evaluation regarding symptoms of malabsorption, GI symptoms, pulmonary symptoms, frequent infections, developmental delays, drug intake and exposure to other marrow toxins.
4. A clinical exam should focus on facial features, skeletal abnormalities such as thumb and radius, hair loss, skin pigmentation changes, leukoplakia, nail dystrophy and structural cardiac, pulmonary and genitourinary abnormalities.
5. A laboratory examination should aim confirmation of diagnosis with blood counts and peripheral smear examination, reticulocyte count, bone marrow aspiration and biopsy, cytogenetics including stress cytogenetics, flow cytometry for CD55/CD59, routine biochemistries and HLA-typing.
6. Although steroids and androgens show efficacy in few patients, definitive therapy for most patients remains bone marrow transplantation.

Table 2 Congenital dyserythropoietic anemia types

	Type I	Type II	Type III
Inheritance	AR	AR	AD, AR
RBCs	Macrocytic	Normocytic	Macrocytic
Erythroblast LM	Megaloblastic, internuclear bridges	Normoblastic, binuclearity	Megaloblastic, up to 12 nuclei per cell
Ham test	Negative	Usually positive	Negative
Gene location	15q15	20q11	15q21

Chapter 38.5

Aplastic Anemia

Amita Mahajan

Aplastic anemia (AA) refers to bone marrow (BM) failure leading to pancytopenia. It is characterized by a hypocellular marrow without fibrosis or dysplasia. This includes congenital BM failure syndromes, which together to represent about 10–30% of all patients with AA. The vast majority of children with AA, however, have acquired AA which is being covered in this chapter. We have already discussed the congenital BM failure syndrome in the previous chapter. With current management strategies, the outcome in acquired AA has improved dramatically.

EPIDEMIOLOGY

The incidence of acquired AA from North America and Europe is 2 in 1 million children per year. The reported incidence in Asia is at least two to three times higher and incidence as high as 14 per million has been reported from Japan. Data available from India is largely hospital based rather than being population based but is again consistent with the incidence being much higher than that reported from the developed world.

ETIOLOGY

A number of drugs, toxins, infectious agents, radiation and immune disorders are linked to AA. **Box 1** lists the common offending agents. The most common identifiable preceding event in India is seronegative hepatitis. However, most patients do not have a well-defined precipitating factor and are referred to as idiopathic AA. A careful history for known offending agents should always be taken. Even in the absence of classical physical findings, inherited BM failure syndromes should always be considered and excluded by appropriate tests before initiating the treatment.

BOX 1 Etiology associated with acquired aplastic anemia

- Hepatitis B, C, seronegative hepatitis
- Human immunodeficiency virus (HIV)
- Cytomegalovirus
- Epstein-Barr virus (EBV)
- Parvovirus
- Mycobacterial infections
- Human herpesvirus 6 (HHV-6)
- Varicella zoster virus
- Measles, adenovirus

PATHOPHYSIOLOGY

It is now well established that the pathogenesis of acquired AA is immune mediated. The pathophysiology responsible for marrow destruction has been inferred from the results of immunosuppressive therapy (IST). Hematological improvement after IST implicated the immune system in the destruction of progenitor stem cells. Results from numerous studies have

demonstrated increased cytokine expression, low CD4 regulatory T-cells, oligoclonal CD8 cytotoxic T-cells, and expansion of specific CD4 cell populations in the BM of AA patients. The antigens inciting the aberrant immune response have not been identified. However, recently a likely genetic signature of immune escape has been identified in the form of acquired number-neutral loss of heterozygosity of the short arm of chromosome 6 (6pLOH). These findings have strengthened the belief that BM aplasia in acquired AA is immune mediated. Indeed, the terminology should be *immune-mediated AA* but as convention it is being termed as idiopathic AA.

CLINICAL FEATURES

Most children present with signs and symptoms related to pancytopenia. Thrombocytopenia may manifest as easy bruising or petechiae or occasionally as epistaxis or menorrhagia. Pallor, lethargy, and weakness secondary to anemia are the other common presenting features. Overt infection at presentation is infrequent even in the presence of severe neutropenia. There may be history of single lineage cytopenia, for a length of time prior to development of pancytopenia. Mean corpuscular volume is normal or increased. The reticulocyte count is markedly reduced. In addition, routine workup for a child with pancytopenia should include liver and kidney function tests. Also, megaloblastic anemia should be ruled out as this continues to be the most common cause of pancytopenia in India because of the dietary habits of large sections of the Indian population.

DIAGNOSIS AND SEVERITY

Diagnosis is established on BM biopsy which reveals a markedly hypocellular BM with increased fat spaces (**Fig. 1**). Ideally paroxysmal nocturnal hemoglobinuria (PNH) should be ruled out by doing the Ham test or preferably by flow cytometric studies. In selected cases, workup for autoimmune diseases may be indicated if clinical features suggest an underlying autoimmune disorder. Appropriate test should be undertaken to determine the etiology as and when indicated. The severity of AA is graded on the basis of BM cellularity, absolute neutrophil count (ANC) and platelet count. Patients with ANC less than 500/ μ L, platelet count less than 20,000/ μ L, corrected reticulocyte count less than 1% and BM cellularity less than 25% are classified as having severe AA. Patients with these features but an even lower ANC of less than 200/ μ L are classified as very severe AA. **Table 1** shows the classification based on severity.

Figure 1 Markedly hypocellular bone marrow in aplastic anemia

Table 1 Definition of severity of aplastic anemia (AA)

Moderate or nonsevere AA (NSAA)	Decreased BM cellularity and peripheral blood cytopenia not fulfilling the criteria for SAA
Severe AA (SAA)	BM cellularity < 25% and at least two of the following: <ul style="list-style-type: none"> • Absolute neutrophil count (ANC) < 500/μL • Platelet count < 20,000/μL • Corrected reticulocyte count < 1%
Very severe AA (vSAA)	Fulfilling criteria for SAA but ANC < 200/ μ L

DIFFERENTIAL DIAGNOSIS

Acquired AA should be differentiated from inherited BM failure syndromes. All children with AA should have a chromosomal breakage analysis at least a few weeks after a transfusion to avoid a falsely negative result. Acquired AA also needs to be differentiated from hypoplastic myelodysplastic syndrome (MDS). Telomere length analysis is the test of choice to rule out dyskeratosis congenita but is not widely available. Megaloblastic anemia should always be considered in children with pancytopenia but in these patients, the BM is, in fact, hypercellular. Transient BM suppression following viral illness may also manifest as pancytopenia but this is usually self-limited and recovers spontaneously.

MANAGEMENT

Mild to Moderate Aplastic Anemia

The vast majority of children with acquired AA actually have severe AA. A proportion may, however, have mild to moderate AA. Though the clinical course of these patients is variable, most of these will eventually progress to develop severe AA. A small proportion may achieve remission and therefore management should be judicious. Mild to moderate AA is usually seen in inheritable marrow failure syndromes and these must be ruled out in this clinical situation. In the short term, some of them may respond to milder therapies in the form of androgenic steroids if there is residual hematopoietic function, cyclosporine alone, or thrombopoietic agents. At least in some patients, moderate AA results from telomere gene mutations and stem cell exhaustion and androgens have been shown to increase telomerase activity through estradiol receptors and this may explain their mechanism of action in stimulating marrow function.

In the past, colony stimulating factors were tried in this situation. This however carries the serious risk of developing myelodysplasia and therefore they are no longer routinely recommended but used sparingly to overcome acute infective episodes. Daclizumab, a humanized monoclonal antibody to the interleukin-2 receptor, has shown some success in this setting with relatively little toxicity.

The use of immunosuppression with agents such as cyclosporine is not entirely without side effects. Patients may experience hirsutism, nephrotoxicity, or hypertension. If the patient is asymptomatic, it may be prudent to keep them under close observation. The definitive treatment is however, identical to that of severe AA.

Severe Acquired Aplastic Anemia

The primary treatment options for children with AA are allogeneic hematopoietic stem cell transplantation (HSCT) or immunosuppressive therapy (IST). Allogeneic HSCT with a matched family donor if feasible is currently the treatment of choice for these patients. If done early in the course of disease before the onset of infectious complications, the survival is as high as 90%. The preferred conditioning regimen is cyclophosphamide

and antithymocyte globulin (ATG). This conditioning regimen results in decreased graft versus host disease and improved long-term survival in comparison with regimens that include total body irradiation. Another conditioning regimen being increasingly used is fludarabine and cyclophosphamide with good results.

Patients, for whom, a matched family donor is not available, IST with horse-ATG (hATG) with cyclosporine is the preferred treatment. A short course of steroids is given to prevent serum sickness. There is now ample data that the response rate is superior if hATG is used in comparison to rabbit-ATG (rATG). Cyclosporine is given for 12 months and then tapered slowly over a few months. The response rate in children is better than that seen in adults and reported to be in excess of 60%. Some recent studies have reported response rates of 70–80%. This includes complete response, i.e., normalization of blood counts and partial response wherein patients may continue to have relatively low counts but are transfusion independent. **Table 2** enumerates definitions of response to IST. The major concerns with regards to IST are the risk of clonal evolution and development of myelodysplasia and leukemia. Algorithm for treatment of AA is given in **Flow chart 1**.

With improved results from matched unrelated donor (MUD) transplants and increased availability of unrelated donors from various registries, this is another option that can be actively considered in these patients and may eventually become frontline therapy. Recently, favorable results have been reported from haploidentical transplants in patients who have failed to IST. This is an exciting development, especially for countries where BM donor registries are not fully developed, as potentially this could mean that every patient has a potential donor.

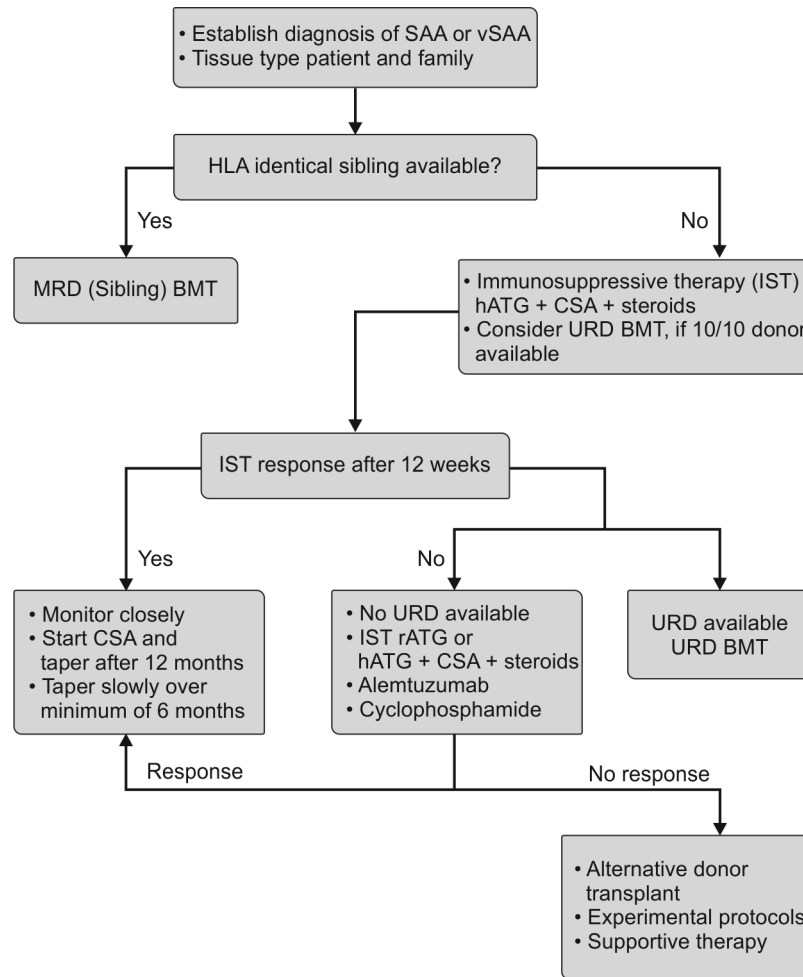

For those, wherein unrelated transplant is not feasible, a second course of IST with hATG or rATG may achieve a response in a proportion of patients. A second course may also be warranted in those who relapse after a length of time. Both allogeneic bone marrow transplant (BMT) and IST are highly myelosuppressive and immunosuppressive and need to be carried out in specialized centers. Allogeneic BMT carries with it the risk of graft rejection, severe infections and graft versus host disease which may be potentially fatal. IST, with cyclosporine, usually needs to be continued for 6–12 months. IST with cyclosporine can be associated with severe infusional reactions, anaphylaxis, severe infections and serum sickness in the short term. Patients undergoing both these treatments are also susceptible to severe viral infections, e.g., cytomegalovirus (CMV), and are also at risk of Epstein-Barr virus-associated lymphoproliferative disease.

Other immunosuppressive agents such as mycophenolate mofetil, sirolimus and alemtuzumab have been tried but have not demonstrated superior responses or reduced incidence of clonal evolution. Cyclosporine alone has been tried and may show a response rate in a small proportion of patients. High-dose cyclophosphamide without stem cell support has been used by some centers with good response rates. However, this is associated with prolonged neutropenia and morbidity and is usually considered only as second- or third-line therapy.

Table 2 Definitions of response after immunosuppressive therapy (IST)

Complete response (CR)	ANC > 1,500, platelet > 100,000, Hb > 11 g/dL
Partial response (PR) in SAA	ANC > 500, platelet > 20,000, Hb > 8 g/dL
PR in moderate AA	ANC > 1,000, platelet > 30,000, Hb > 8 g/dL
Overall response	CR or PR 6 months after IST

Abbreviations: ANC, absolute neutrophil count; SAA, severe aplastic anemia; AA, aplastic anemia.

Flow chart 1 Treatment algorithm for acquired aplastic anemia

Abbreviations: SAA, severe aplastic anemia; vSAA, very severe aplastic anemia; HLA, human leukocyte antigen; MRD, matched-related donor; hATG, human antithymocyte globulin; CSA, cyclosporine; URD BMT, unrelated donor bone marrow transplantation; rATG, recombinant antithymocyte globulin.

Recently, eltrombopag, a thrombopoietic agent has been shown to improve hematopoiesis in a proportion of patients with adult AA who were refractory to IST and is currently being evaluated in this setting.

Supportive Care

The significant improvement in the overall survival of children with AA is at least partly attributable to marked improvements in supportive care. Infections and bleeding are the major cause of morbidity and mortality in this cohort.

Transfusions

The transfusion policy in AA is generally restrictive. Most centers transfuse packed red cells if hemoglobin is less than 10 g/dL or if child is symptomatic. Leukodepleted and irradiated blood products should be given to reduce the risk of transfusion-associated graft-versus-host disease and human leukocyte antigen (HLA) sensitization. Also, immediate family members should be avoided as donors if an allogeneic stem cell transplant from a matched family donor is being contemplated. Platelet transfusions are considered, if platelets are less than 10,000/ μ L or there is symptomatic bleed. Higher thresholds (i.e., < 20,000/ μ L) may be considered for those being managed for sepsis or undergoing IST.

In life-threatening situations, granulocyte transfusions may be considered to provide a bridge between treatment response and neutrophil recovery.

Prophylaxis from Infections

There is no evidence to support the role of antibiotics for prophylaxis in this patient population. However, a number of precautions are routinely prescribed for these patients. **Table 3** lists the precautions that are commonly recommended for these patients. Prompt administration of intravenous antibiotics in the event of fever or other signs of infection is the cornerstone of management of neutropenic fever in this population. The choice of first-line antibiotics is usually a third-generation cephalosporin with or without an aminoglycoside. The choice of first-line antibiotic depends on the known sensitivity pattern in a given hospital. Subsequent management is as for other patients with neutropenic fever as per pre-established hospital guidelines.

Prophylactic antifungals are however routinely used for patients with prolonged neutropenia on immunosuppressive treatment. Posaconazole is considered to be the drug of choice for antifungal prophylaxis. For patients with suspected fungal infection or persistent fever, computed tomography of chest and galactomannan testing are recommended and empiric treatment

Table 3 Principles of neutropenic precautions for pediatric aplastic anemia (AA) patients

Avoid	Construction areas, compost, potted plants, unpasteurized dairy products, uncooked meat products, unwashed raw fruits or vegetables, crowded areas, live vaccines
Recommended	Frequent hand washing, guidelines for body hygiene, prophylactic antifungals, G-CSF when on IST
In hospital	Air quality control, barrier isolation

Abbreviations: G-CSF, granulocyte-colony stimulating factor; IST, immunosuppressive therapy.

is started. Antifungal treatment is largely directed at *Aspergillus* and possible strategies include use of voriconazole/amphotericin B/caspofungin.

Pneumocystis prophylaxis is to be considered for those with severe lymphopenia [absolute lymphocyte count (ALC) < 500/ μ L] especially following IST. The drug of choice for pneumocystis prophylaxis is cotrimoxazole but is difficult to use in view of myelosuppressive effect. The options are pentamidine nebulization or dapsone.

Granulocyte-colony stimulating factor (G-CSF) is not routinely recommended in AA. However, it may be considered in patients with active infection and is routinely used by some centers following IST. Prolonged use may increase the chances of clonal hematopoiesis and malignant transformation to MDS/acute myeloid leukemia and is discouraged.

LONG-TERM OUTCOME

As the numbers of children with AA that are successfully being treated with BMT or IST are increasing, there are concerns regarding long-term outcome and late effects of successful therapy. For patients undergoing BMT, these include growth failure, infertility, and chronic graft-versus-host disease. For those undergoing IST, the biggest concern is the development of PNH, MDS and leukemia which can develop after many months to years. The cumulative long-term rate of clonal evolution is about 15% and this risk is highest in those who receive chronic G-CSF therapy.

One of the key concerns following treatment of AA with BMT is development of late malignancies. In a series from Japan, of 329 children who underwent allogeneic BMT, 5 (2.5%) developed a malignancy over a 20-year follow-up period (malignant peripheral nerve sheath tumor, thyroid carcinoma, colon carcinoma, MDS and hepatoblastoma). Essentially all children who undergo treatment for AA need to be on ongoing follow-up even if cured of AA.

PROGNOSIS

The outcome of patients with inherited BM failure syndromes is variable depending on presentation, treatment strategies employed and the eventual development of malignancy in a proportion of patients. Prognosis has, however, improved significantly with improved supportive care, improved access to transplant and active surveillance for possible malignancies.

The prognosis of acquired AA has improved dramatically with current management strategies. If a matched donor is available and an HSCT is done at appropriate time, the overall survival is in excess of 80–90%. For those who receive IST, over 60% can be

expected to be long-term survivors. In fact, a number of studies report response rates as high as 75%. The success rate for MUD and haploidentical transplants has also offered potentially curative options to these patients.

There is however the concern regarding clonal evolution of hematopoiesis and development of PNH in about 10–20% of AA patients especially in patients who receive IST and this may develop several years after treatment. There is also increased risk of development of autoimmune disease (10%) and solid tumors (11%). Thus, children with AA should be followed up indefinitely irrespective of the treatment modality used.

Long-term survival rates among children diagnosed with severe AA are excellent due to the success of HLA-identical related HSCT, concurrent advances in IST, and improved supportive care. The challenge in making treatment recommendations for children with severe AA, therefore, is to balance the apparent chronicity and morbidity following IST, with the potential up-front toxicity and complications of HSCT.

IN A NUTSHELL

1. Though a number of triggering events are known, the majority of children with acquired AA have idiopathic immune-mediated AA.
2. With current treatment strategies, the long-term outcome of aplastic anemia has improved dramatically.
3. The treatment of choice for all patients with AA is matched related HSCT.
4. For patients with acquired AA who do not have a matched related donor, IST is the treatment of choice.
5. For patients refractory to IST, MUD transplantation or haploidentical transplantation are potentially curative options.
6. Optimal supportive care remains a cornerstone of therapy prior to, during and following definitive therapy.
7. Irrespective of the treatment modality used, these patients need to be followed for life.

Chapter 38.6

Iron Deficiency Anemia

Mamta Manglani

Iron is required for multiple cell functions, including DNA synthesis, oxygen transport and cellular energy production. Various iron-containing proteins are hemoglobin (Hb), myoglobin, cytochrome c, cytochrome P-450, catalase, myeloperoxidase, cyclooxygenase, and ferritin lipoygenase. Certain enzymes are iron-dependent, viz., aldehyde oxidase, nicotinamide adenine dinucleotide phosphate (NADP) dehydrogenase, tyrosine hydroxylase, succinate dehydrogenase, tryptophan hydrolase, xanthine oxidase, ribonucleotide reductase, NADPH ubiquinone oxidoreductase, NADPH succinate oxidoreductase, and *cis*-aconitase. Of the various nutrient deficiencies, iron deficiency is the most common cause of anemia worldwide.

IRON METABOLISM

Factors Affecting Iron Absorption in the Gut

Heme iron is not affected by presence of any factors in the gut. The absorption of nonheme iron is retarded by an alkaline pH, presence of phosphates, phytates, bran, starch, tannins, calcium, antacids, other metals (Co, Pb), etc. It is enhanced by ascorbic acid, free hydrochloric acid, presence of sugars and amino acids in the diet, presence of heme iron (nonvegetarian source of iron) and ethylenediaminetetraacetic acid (EDTA). Phytates, which constitute 1–2% of many cereals, nuts and legumes, play a major role in the causation of nutritional anemia in the developing world (Fig. 1).

Bioavailability of Iron in the Food

The bioavailability of iron from a particular dietary source affects the amount absorbed. Ferrous iron is better absorbed compared to ferric iron. It is estimated that in wheat-based diet, iron absorption is around 2% and in rice-based diet, it is 5–13%. Poor bioavailability of iron in largely cereal-based diet is a major cause of iron deficiency anemia (IDA) in most developing countries. Fish, meat and poultry are good sources of iron and bioavailability is around 20–30%. Increasing the dietary intake to meet the caloric needs will also increase the dietary intake of iron by one-third. Calcium in the form of milk, cheese or calcium added to the bread depresses iron absorption.

Absorption: Mucosal Cell Control Theory

The major regulation of iron cycle occurs through control of absorption since there is hardly any excretion via a physiological

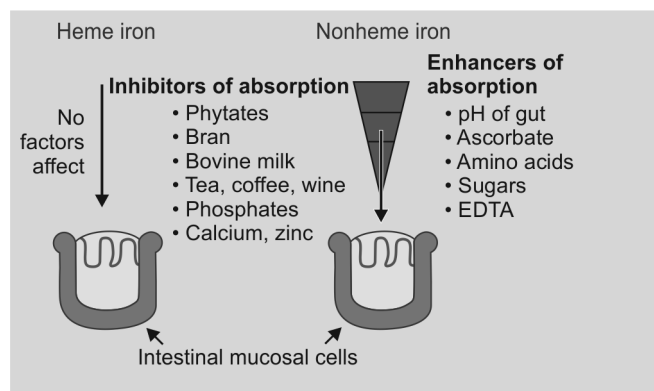

Figure 1 Factors affecting iron absorption

mechanism. Iron is available in the ferric form in diet. This is reduced to ferrous form by duodenal cytochrome b reductase (Dcytb) in the lumen of the proximal small intestine. The iron molecule that is taken into the mucosal cell across the brush border binds either with the apoferritin molecule (when iron status is adequate) or with the transferrin (when iron is required by the body). The transferrin bound iron is then released to the ferroportin at the basolateral membrane to be transported across into the circulation. Also, simultaneously, ferrous iron has to be oxidized to ferric state again during basolateral membrane transfer and this occurs through the multicopper ferroxidase hephaestin. It again binds to transferrin in circulation to be transported to various sites of synthesis of iron-containing proteins and enzymes. Iron bound to apoferritin remains in the mucosal cell and gets denuded with the cell within 3–4 days. If iron is required in the body, it is bound to the ferroportin, which is then transferred to the transferrin (produced in the liver), which carries it across the mucosa (Fig. 2). It is then utilized in the bone marrow for Hb production, in the muscle tissue for myoglobin and in the body for various other enzymes. Any excess iron is stored in the form of ferritin in the liver.

Role of Hepcidin

Since there is no excretory mechanism for iron in the body, absorption is regulated at the cellular and systemic level hepcidin, a 25 amino acid hormone synthesized in the liver, is responsible in balancing the enterocyte as well as the macrophage release of iron to maintain iron homeostasis. Hepcidin inhibits the absorption of iron at the intestinal level through internalizing ferroportin, the key molecule for transporting the iron in the ferrous form across the brush border of the intestinal villi. Thus, it blocks the binding of ferroportin to the iron molecule and prevents absorption. Also, it prevents release of iron through the same mechanism at the storage level in the macrophages. TMPRSS6 (liver-expressed type 2 transmembrane serine protease) normally inhibits hepcidin through cleaving of bone morphogenetic protein (BMP) coreceptor hemojuvelin. In vitro, TMPRSS6 expression is upregulated by hypoxia and iron deficiency. However, one of the genetic variants of TMPRSS6 leads to the downregulation of the inhibition of hepcidin. This causes an overexpression of hepcidin and therefore inhibition of iron absorption causing a refractory iron deficiency state. Role of hepcidin in iron absorption is summarized in Box 1.

Iron Cycle in Body

The RBCs circulate for their life span of approximately 120 days and are then destroyed in the spleen, liberating free iron, which is then retransported to the bone marrow and other tissues for its

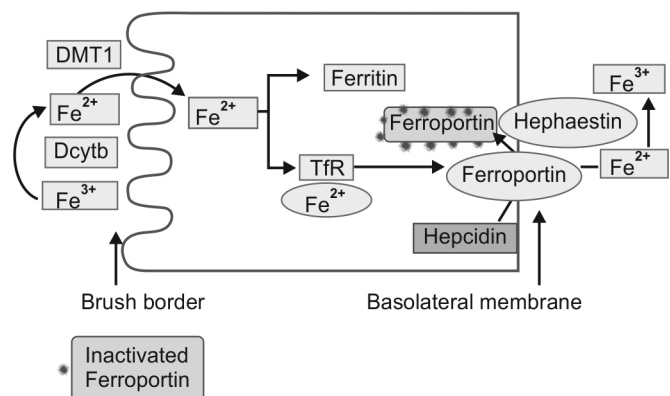

Figure 2 Mucosal cell control of iron absorption

Abbreviations: DMT, divalent metal transporter; Dcytb, duodenal cytochrome b reductase; TfR, transferrin receptor.

BOX 1 Role of hepcidin in iron metabolism

- Increased hepcidin production
 - Reduced iron absorption through internalizing ferroportin, preventing transfer of iron across the basolateral membrane and preventing mobilization of iron from stores
- Decreased hepcidin production
 - Increased dietary iron absorption
 - Increased mobilization of iron from stores

reutilization. Thus, most of the iron is cycled continuously in the body, with only 1–1.5 mg/day of iron being excreted through the intestinal epithelial cells after completion of their life span (**Fig. 3**). Since 10% of ingested iron is absorbed and the daily loss is only 1–1.5 mg, one needs to ingest about 10 mg of iron daily, except during periods of extra needs.

Foods Containing Iron

Foods rich in iron are green leafy vegetables, jaggery, cereals especially ragi, dates, almonds, nuts, sprouts, nonvegetarian sources such as pork, veal and other red meats, especially

liver. Though breastmilk contains small amount of iron, the bioavailability of this iron (lactoferrin) is about 50–70% and hence, it is adequate for the first 4–6 months of life.

EPIDEMIOLOGY OF IRON DEFICIENCY ANEMIA

It is estimated that iron deficiency affects about 30% of the world population and about 70–90% in the developing countries, including India (**Tables 1 to 4**). IDA is most common in the age group of 6 months to 3 years and 12–17 years (adolescence). It is also significantly common among pregnant and lactating women, thus compromising the iron stores in their infants. IDA can occur due to decreased absorption, increased demand or high losses from body (**Box 2**).

CLINICAL MANIFESTATIONS

Clinical features of IDA are similar to those due to anemia of any etiology. However, besides anemia, iron deficiency affects a number of other systems in the body. These include neurotransmitters (cognitive dysfunction), epithelial tissues, etc. Children with IDA generally present with symptoms depending on the rate of fall of

*National Nutrition Monitoring Bureau Survey (NNMBS), 2006

BOX 2 Causes of iron deficiency anemia*Reduced absorption*

- Nonbreastfed infants on cow's milk
- Inadequate intake of iron-containing foods
- Diet containing low iron or nonbioavailable iron
- *Malabsorption of iron*: Chronic diarrhea, celiac disease, cow's milk allergy, gastrointestinal (GI) surgery, giardiasis, etc.
- TMPRSS6 genetic variant leading to reduced inhibition of hepcidin and therefore overexpression of hepcidin

Increased requirement

- During periods of growth—preterm infants, toddlers, puberty
- During reproductive age in females
- Pregnancy and lactation

Increased losses

- Blood loss due to any cause
 - Gastrointestinal bleeding
 - Diverticulitis (polyps, fetomaternal hemorrhage, etc.)
 - Repeated blood sampling
 - *Menstruating women*: It is estimated that about 20% of women require ≥ 2 mg of iron per day
 - Intestinal parasites—hookworm infestation

Inadequate transport

- Atransferrinemia
- Antitransferrin receptor antibodies

Hb and homeostatic adjustment of various systems in the body. As the fall of Hb is very gradual, the onset of symptoms is insidious. Initially, pallor (**Fig. 4**) noticed over tongue, lips, conjunctiva, palms, nails, etc., easy fatigability, anorexia and irritability may be noticed.

Hyperdynamic circulation may lead to palpitations, shortness of breath, decreased exercise tolerance and congestive heart failure. Mild degree of hepatosplenomegaly is also not uncommon. Pedal

Table 3 Prevalence of anemia among children aged 6–35 months (%), India

Anemia level	NFHS-2			NFHS-3		
	Urban	Rural	Total	Urban	Rural	Total
Mild (10.0–10.9 g/dL)	23.7	22.7	22.9	25.8	25.7	25.7
Moderate (7.0–9.9 g/dL)	42.0	47.1	45.9	42.0	51.7	49.4
Severe (< 7.0 g/dL)	5.1	5.5	5.4	4.4	3.5	3.7
Any anemia (< 11.0 g/dL)	70.8	75.3	74.3	72.2	80.9	78.9

Figure 4 Pallor of the palm

edema in IDA may be due to congestive heart failure, impaired renal function or associated protein deficiency. Rarely increased intracranial tension with papilledema may occur. Skull changes with caput quadratum appearance (frontoparietal bossing) similar to that seen in congenital hemolytic anemia may be seen in children with chronic long-standing iron deficiency occurring since early life. These skeletal changes do not reverse with iron therapy.

Nonhematologic Consequences of Iron Deficiency

It has been shown that iron deficiency per se even in the absence of anemia leads to several morphological and biochemical changes at tissue level with deleterious effects on various systems.

Koilonychia and platynychia (**Fig. 5**), glossitis, stomatitis, and angular cheilosis are the other common features, not commonly seen in children. Formation of mucosal webs at the pharyngoesophageal junction causes dysphagia mainly for solids. The triad of dysphagia due to esophageal webs, koilonychia and splenomegaly in a patient with IDA is known as the Plummer-Vinson or Patterson-Kelly syndrome.

Pica is a well-documented feature of anemia in children. Craving to eat unusual substances such as dirt, clay (geophagia), ice (pagophagia), laundry starch (amylphagia), salt, cardboard, etc., is seen in almost 70–80% of patients and is usually cured by prompt iron therapy.

Functional impairments of various tissues such as the myocardium, peripheral nerves, intestinal mucosa, cerebral cortex, kidney and liver, etc., have been demonstrated in patients of iron deficiency, which have been corrected by iron therapy before a significant rise in the Hb level.

There are studies to suggest that children with iron deficiency have lower intelligence quotient (IQ) scores, lack of concentration, distractibility, short attention span and impaired mental and motor development. These changes lead to scholastic backwardness too and may be irreversible if the onset is in infancy.

Iron deficiency also adversely affects the immune system, thus increasing susceptibility to infection. Another area of special significance is poor endurance and physical fitness even with mild anemia, probably due to lower myoglobin production.

INVESTIGATIONS

Complete Blood Count and Peripheral Smear

There is low Hb/low hematocrit (Hct) with reduced red cell count; red cell indices may not be altered in mild IDA, however, with ongoing

Figure 5 Koilonychia in iron deficiency anemia

deficiency, these are reduced as follows: mean corpuscular volume (MCV) less than 80 fL, mean corpuscular hemoglobin (MCH) less than 27 pg and mean corpuscular hemoglobin concentration (MCHC) less than 32%, increased red cell distribution width (RDW) [$> 14\%$ by coefficient of variation (CV)] (normal $13.4 \pm 1.2\%$); white cell counts are normal, and platelet count may be increased or normal. Peripheral smear shows microcytic, hypochromic anemia with significant anisocytosis and poikilocytosis (**Fig. 6**).

Serum Iron Studies

Normal serum iron level varies considerably. It has a diurnal variation with a peak in the morning and trough in the evening. Dietary intake also can alter the iron levels in the plasma and hence they are unreliable by themselves. Serum iron concentration may also be affected by chronic infection, malignancies and chemotherapy as well as iron medication. Values below 40 $\mu\text{g/dL}$ are considered significantly low and suggestive of iron deficiency (in absence of infection or other disorders which affect iron metabolism).

Total Iron Binding Capacity and Transferrin Saturation

Total iron binding capacity (TIBC) is the measure of plasma transferrin, which is free, not bound to iron. The normal value of TIBC is 250–350 $\mu\text{g/dL}$. In iron deficiency states, TIBC is

Figure 6 Peripheral blood smear with hypochromic, microcytic red cells with anisocytosis and poikilocytosis in iron deficiency anemia

increased ($> 350 \mu\text{g/dL}$) and transferrin saturation (TS) is reduced to below 16% ($< 12\%$ for children). TIBC less than $200 \mu\text{g/dL}$ is characteristic of inflammatory disease. Factors that affect serum iron concentration do not alter values of TIBC.

Serum Ferritin

Serum ferritin is a sensitive laboratory index of iron status. It is the best noninvasive test (gold standard with a high specificity and adequate sensitivity) for evaluating iron status in the body. A serum ferritin value of less than 12 ng/mL is highly specific for iron deficiency, but gives no information about its magnitude. Serum ferritin is increased in chronic disorders, e.g., chronic infection and inflammation, malignancies, chronic liver disorders. In presence of any of these, a coexisting IDA can be missed.

Soluble Plasma Transferrin Receptor

In IDA, transferrin receptors (TfRs) are increased due to an increased turnover associated with ineffective erythropoiesis and, an increase in cellular TfR expression produced by iron starvation. Unlike the serum ferritin, which only identifies iron deficiency, the serum TfRs measure its severity.

Content of Hemoglobin in Reticulocytes

Content of Hb in reticulocytes (CHR) at a cut-off of 27.5 pg has a sensitivity of 83% and a specificity of 72% for diagnosis of IDA and can be used as a corroborative investigation.

Bone Marrow Examination

Bone marrow aspiration is not recommended for the diagnosis of IDA, as there are simpler, noninvasive and relatively inexpensive tests, which diagnosis of IDA. In contrast, bone marrow iron staining, though a gold standard, is very painful, expensive and cumbersome to perform. However, bone marrow when done shows increased cellularity with micronormoblastic erythroid hyperplasia. On staining with Prussian blue (Perls' reaction), there is little or no stainable iron seen.

TREATMENT

Basic principles of management include correction of anemia and treatment of underlying cause. Treatment of IDA depends upon the severity and associated complications. Those with very severe anemia and/or congestive heart failure, with Hb less than 5 g/dL require hospitalization. Oral iron therapy with monitoring is adequate for those without evidence of congestive heart failure. Packed red cell transfusion is required for those in congestive heart failure irrespective of the level of Hb. Packed red cells at 5 mL/kg should be slowly administered over 2–3 hours to avoid volume overload.

Medicinal Iron Therapy

Oral iron therapy is the ideal treatment for IDA. It is safe, economical and as effective as parenteral therapy. For infants and children, the recommended therapeutic dose is 3–6 mg of elemental iron/kg body weight/day. Higher doses are unnecessary and may increase side effects, reducing patient compliance. Although the desired Hb level is usually reached in 2–3 months, iron therapy should continue for another 2–3 months to build up iron stores.

Ferrous compounds are better absorbed than ferric iron, and are therefore the recommended form of iron for treatment. Amongst ferrous compounds, ferrous sulfate (20% elemental iron), gluconate (30% elemental iron) and fumarate (33% elemental iron) compounds are the most commonly used preparations. A ferrous sulfate preparation microencapsulated with phospholipids was found to have equivalent bioavailability

to ferrous sulfate. Other ferrous compounds used include ferrous ascorbate, succinate, lactate, glycine sulfate, glutamate, citrate, tartrate and pyrophosphate. Ferrous salts have a high incidence of gastrointestinal (GI) side effects ($\sim 23\%$).

The ferric compounds offer no additional advantage over ferrous fumarate, gluconate or sulfate and are more expensive. Ferric ammonium citrate (18% elemental iron) is the most commonly used of these salts. There has been no significant difference demonstrated in the toxicity profile of ferrous and ferric compounds.

Iron amino acid chelates are conjugates of the ferrous or ferric ion with amino acids. Although numerous conjugates have been formulated the most studied of these are ferrous bis-glycinate (20% elemental iron content), ferric tris-glycinate and ferrous glycine sulfate. They have no effect on the color or taste of food products. Comparison of ferrous sulfate with ferrous bis-glycinate in infants of 6–36 months of age showed equivalent rise in Hb in the two groups.

Iron polymaltose complex (IPC) is a novel iron preparation, which contains nonionic iron and polymaltose in a stable complex. IPC compounds have, however, not been found to be as efficacious as the traditional ferrous compounds in the treatment of IDA.

Carbonyl iron is a small particle preparation of highly purified metallic iron. This preparation has been found to be variably effective and safe in prevention and treatment of iron deficiency with lesser side effects compared to ferrous sulfate. Carbonyl iron is much less toxic than other ionized forms of iron.

Colloidal iron is a readily available iron preparation; however, there is hardly any data on colloidal iron. Iron acetyl transferrin in infants has been shown to be efficacious for treatment of IDA. Iron protein succinylate is another compound which has been tried in children in some studies and has been found more efficacious than IPC preparations. Iron in the form of Hb has little advantage over other iron preparations, and fails to provide the daily therapeutic requirement in the recommended doses. Large volumes need to be ingested to produce therapeutic effect.

Folic acid can be combined with iron at negligible extra cost. Addition of vitamin C (200 mg) increases the absorption of iron by about 30%. But addition of vitamin C may add to the cost significantly. Vitamin B_{12} may need to be given in nonresponders or with evidence of megaloblastic anemia.

Uncoated or sugar-coated tablets are not only cheapest but also disintegrate easily in stomach. However, they are oxidized in humid environment, making the compound less stable. Enteric-coated tablets are more expensive and may not disintegrate in the stomach, and hence absorption may not be adequate. In slow release preparations, only a small amount of iron comes into contact with the duodenal mucosa at a given time, thus improving absorption and reducing GI side effects. Though liquid preparations are very useful in children, but they deteriorate on storage.

In 1996, a group of consultants from the United Nations Children's Fund (UNICEF) devised a new technology called *sprinkles* through which encapsulated micronutrients in powder form could be added directly to food at the household level. The micronutrients are encapsulated in a thin coating of a soy-based hydrogenated lipid, which prevents the micronutrients from oxidizing the food. Thus, the color or taste of food to which sprinkles are added does not change. The encapsulated micronutrients are packaged in single-dose sachets to ensure that the correct amount of iron is given. The contents of the sachets are then sprinkled onto whatever food is served in the household, including typical complementary and family foods. This has been useful both for treatment and prevention of IDA. As the iron in *sprinkles* is microencapsulated, other micronutrients, such as vitamin A, folic acid, vitamin B_{12} and ascorbic acid, can be included without significant loss of nutrient stability.

Side Effects

Side effects are mild and have been reported in about 14% of patients and not related to any particular iron compound. Intolerance to oral iron is basically related to the amount of iron in the gut. Usual side effects are nausea, vomiting, constipation, diarrhea, and abdominal discomfort. Iron absorption is maximum during the initial phase of therapy and is inversely proportionate to the level of Hb. It declines from 14% in the 1st week to 7% in the 4th week to 2% after 4 months.

Parenteral Iron Therapy

Parenteral route should be used only in definite indications like severe intolerance to oral iron, GI bleeding aggravated by oral iron therapy, bleeding more than the increase in Hb with oral iron, preoperative in urgent surgeries, and malabsorption syndromes.

There is no evidence that the rate of Hb response is different in oral or parenteral therapy. Iron dextran complex was the most commonly used preparation in the past. However, with availability of the newer preparations with much lesser side effects, (such as ferric carboxymaltose, sodium iron gluconate, ferumoxytol and iron sucrose). Iron dextran is no longer the first choice for parenteral therapy. Experience with the newer compounds has been encouraging, though ferric carboxymaltose is not yet approved for use in children. The total dose required may be calculated using one of the following formulae:

$$\text{Iron (mg)} = \text{Weight (kg)} \times \text{Hb deficit (g/dL)} \times 80/100 \times 3.4 \times 1.5$$

Or

$$\text{Weight (kg)} \times \text{Hb deficit (g/dL)} \times 4$$

The response can be predicted. Adverse reactions include skin rash, arthralgia, myalgia, and rarely anaphylaxis.

Response to Therapy

In uncomplicated IDA, administration of iron shows a predictable reticulocytosis and a rise in Hb. Hb concentration remains the most dominant predictor of response to therapy in uncomplicated iron deficiency. A positive response to therapy can be defined as a daily increase in Hb concentration of 0.1 g/dL (0.3% or 1% rise in Hct) from the 4th day onwards. Lower the initial Hb greater is the rise in the Hb following iron therapy. A reticulocyte response is generally seen in 7–10 days whereas a very early rise is observed in CHR (within 2–4 days).

Effect of Maternal Iron Deficiency on Fetus and Infant

It has been adequately shown through extensive studies that mild maternal anemia due to iron deficiency does not compromise the Hb levels in the fetus or newborn, though it reduces the storage iron. However, severe IDA in the pregnant woman definitely causes significant adverse effects in the unborn fetus as well as in the newborn. It leads to lower Hb as well as lower ferritin. It may cause placental insufficiency, prematurity, low birthweight, asphyxia, subnormal brain development, etc. Addressing the iron deficiency state of the adolescent girl who is the future pregnant and lactating woman is crucial to have an iron replete future population too!

PREVENTION

Food-based approach constitutes the most desirable and sustainable method of preventing iron deficiency. Supplementation of iron should be done in vulnerable age

groups including pregnant women, toddlers, adolescent girls, etc. Once the child has been weaned, dietary modification can help to increase iron intake through iron-rich foods. Avoid limiting factors—the poor bioavailability of iron due to presence of inhibitors like phytates in cereal-based diet and phenolic compounds including tannin present in tea and coffee. Absorption promoter of iron like vitamin C has been shown to be deficient in Indian diet. Therefore, inclusion of vitamin C containing diet prevents iron deficiency. Fruits (uncooked as heat destroys vitamin C) with lunch and dinner for 1 month have shown to raise Hb level by 2.2 g/dL. Fermentation and germination can enhance iron absorption by increasing vitamin C content and lowering phytic acid content. Heme iron present in meat is not only better absorbed, but increases absorption of nonheme iron of vegetable foods. Fortification of foods with iron is a cost effective, long-term measure for improving the iron status of the entire population. Using sprinkles in routine food preparations is a feasible option. A formula for double-fortified salt, i.e., salt fortified with iodine and iron has been developed and which was found to be effective in controlling nutritional anemia.

IN A NUTSHELL

1. Iron deficiency anemia is the most common nutritional deficiency and occurs primarily due to poor intake of iron or diet having low iron content.
2. Various factors which affect iron absorption have been reviewed.
3. Iron metabolism has been described in simplified way for better understanding.
4. Iron deficiency anemia has many adverse effects.
5. It can be managed with iron supplementation.
6. Correction of underlying factors is important to prevent recurrence of IDA.
7. Iron deficiency anemia can be prevented by fortification of food items.

Chapter 38.7

Megaloblastic Anemia

Sangeeta Mudaliar, Bharat Agarwal

Megaloblastic anemia is characterized by the presence of macrocytes in the blood and megaloblasts in the bone marrow. The common causes of megaloblastic anemia in childhood are folate or vitamin B₁₂ [cobalamin (Cbl)] deficiency or defects in their metabolism. Deficiencies of thiamine, ascorbic acid and tocopherol may also be related to megaloblastic anemia.

EPIDEMIOLOGY

In tropical and subtropical regions like South Asia, Mexico, Africa, Central and South America, nutritional megaloblastic anemia is more prevalent. In these populations, it is commonly seen in age group of 3–18 months and is associated with prolonged breastfeeding and maternal deficiencies.

Over the last three decades, due to dietary supplementation during pregnancy to prevent neural tube defects, the prevalence of folate deficiency has fallen to 2–10% from 70% to 75%. Cbl deficiency is now emerging as a significant cause of nutritional megaloblastic anemia.

ETIOLOGY

Tables 1 to 3 enlist the causes of megaloblastic anemia, vitamin B₁₂ deficiency and folate deficiency, respectively.

Folate Deficiency

Exclusive goat milk feeding can cause megaloblastic anemia due to lack of folate in goat milk. Maternal folate deficiency with prolonged breastfeeding is another important causative factor in infants. Ascorbate (vitamin C) is important to preserve intrinsic folates from dietary sources. Vitamin C deficiencies have been reported to be associated with folate deficiency. In conditions with increased cell turnover such as leukemia, chronic hemolytic anemia and sideroblastic anemia, there is increased demand which if unmet leads to folate deficiency anemia.

Impaired absorption as in tropical sprue, gluten enteropathy and other intractable diarrheas leads to folate deficiency. Relative folate deficiency is caused by induction of microsomal enzyme in folate metabolism. When used on a long-term basis sulfonamide antibiotics may interfere with folate metabolism causing megaloblastic changes. Antineoplastic agents such as methotrexate which are inhibitors of human dihydrofolate reductase (DHFR), also cause megaloblastic changes.

Hereditary folate malabsorption (congenital malabsorption of folate) may present in early infancy with megaloblastic anemia, mouth ulcers, failure to thrive, chronic or recurrent diarrhea, seizures, and progressive neurological deterioration. Low red cell, serum and cerebrospinal fluid folate levels with classic clinical features are diagnostic. It is a rare disease, with autosomal recessive inheritance.

Methylenetetrahydrofolate reductase deficiency is rare and may present as severe form in first few months of life or as late as 16 years of age in a much milder form. Megaloblastic anemia is not common in these patients because reduced folates are available for purine and pyrimidine synthesis. The most common presentation is developmental delay. Other features may be motor and gait abnormalities, seizures, mental retardation, strokes, psychiatric manifestations, microcephaly and vasculopathy.

Vitamin B₁₂ Deficiency

Nutritional deficiency occurs in breastfed babies of B₁₂ deficient mothers and in strict vegans, and lacto vegetarians. Absorption of vitamin B₁₂ is impaired in congenital absence of intrinsic factor (IF), juvenile pernicious anemia, fish tapeworm infestation, postgastric surgery and ileal malabsorptive states. Therapy with para-aminosalicylic acid, colchicine and zidovudine may lead to B₁₂ deficiency. Inherited disorders like Imerslund-Gräsbeck syndrome (proteinuria with renal tubular defect), inborn errors of Cbl metabolism (methylmalonic aciduria, homocystinuria), and IF/Cbl receptor defect are rare disorders leading to B₁₂ deficiency.

VITAMIN B₁₂ TRANSPORT AND INBORN ERRORS OF METABOLISM

Transport Disorders

Food Cobalamin Malabsorption

The release of Cbl from the food in stomach is mediated by acidic pH and peptic activity. This release may be compromised in patients with impaired gastric function due to gastrectomy or atrophic gastritis. These patients have normal Schilling test but low serum Cbl and mild elevated methylmalonic acid and homocysteine.

Intrinsic Factor Deficiency

This form of pernicious anemia resulting either due to production of immunologically active but nonfunctional IF or total lack of IF production is autosomal recessively inherited. Clinical features include megaloblastic anemia, developmental delay and myelopathy. It usually presents in early childhood after the first year of life, but may not appear until adolescence or adulthood. These patients have normal gastric cytology and gastric acid secretion. Absorption of Cbl is abnormal in these patients but gets normalized when the vitamin is mixed with a source of normal IF.

Imerslund-Gräsbeck Syndrome (Defective Vitamin B₁₂ Transport by Enterocytes)

Imerslund-Gräsbeck syndrome causes clinical manifestations of vitamin B₁₂ deficiency usually within the first 2 years, later presentation may also occur in some. Clinical features include pallor, weakness, anorexia, failure to thrive and recurrent infections. They also have proteinuria of tubular type as a common feature. These

Excess excretion, e.g., vitamin B₁₂ deficiency, chronic dialysis, hepatic disorder.

patients have normal intestinal morphology and normal IF. There is no evidence of antibodies to IF. Their selective defect in vitamin B₁₂ absorption does not correct by treatment with IF. Treatment with systemic vitamin B₁₂ corrects the anemia but not the proteinuria.

Partial Deficiency of Transcobalamin I (R-Binder or Haptocorrin Deficiency)

Partial deficiency of transcobalamin I (TC I) with TC I concentrations of 25–54% of the mean normal concentration has been reported. Clinically this syndrome is characterized by a myelopathy not explained by any other cause. Though serum vitamin B₁₂ concentrations are persistently low but patients are asymptomatic of vitamin B₁₂ deficiency since they have normal TC II-Cbl levels.

Transcobalamin II Deficiency

Transcobalamin II deficiency is a rare autosomal recessive disorder. The defect in TC II may be due to lack of protein causing an inability to bind or facilitate uptake of Cbl into cells. The Schilling test is usually abnormal in these patients suggesting that the TC II molecule may play a role in the transport of Cbl across the ileal cell mediated by IF.

Severe megaloblastic anemia occurs usually in the first few months of life. Other symptoms include diarrhea, weakness and failure to thrive. Some patients may present with isolated erythroid hypoplasia or decreased production of all the hematopoietic cell lines. Untreated or undertreated patients may present with neurologic symptoms later in life. And despite adequate treatment, neurologic deficits persist. Severe immunologic deficiency with defective humoral and cellular immunity has been reported.

Laboratory findings show hyperhomocysteinemia, macrocytic anemia, and raised methylmalonic acid levels.

Disorders of Metabolism

Acquired

Impaired utilization of Cbl occurs in protein energy malnutrition and hepatic dysfunction. Few drugs like colchicine, neomycin, ethanol, etc. are associated with defective absorption or utilization of vitamin B₁₂.

Congenital

All the congenital defects of Cbl metabolism are autosomal recessively inherited. The patients may have either methylmalonic acidemia or hyperhomocysteinemia or both. Methylmalonic acidemia results from defective mitochondrial methylmalonyl-CoA mutase or its cofactor adenosylcobalamin. Hyperhomocysteinemia occurs as a result of abnormality in the cytoplasmic methionine synthase or its cofactor methylcobalamin.

Patients have severe metabolic acidosis and large amounts of methylmalonic acid in urine, cerebrospinal fluid and blood.

Adenosylcobalamin Deficiency: CblA and CblB Diseases

Cells in these patients fail to synthesize adenosylcobalamin. Deficiency of a mitochondrial nicotinamide adenine dinucleotide phosphate (NADPH)-linked aquacobalamin reductase results in CblA disease. In CblB, final step in adenosylcobalamin synthesis is affected due to defect in adenosyltransferase.

These defects in turn cause impaired methylmalonyl-CoA mutase activity resulting in to methylmalonic acidemia.

Infants present in the first few weeks or months of life with severe ketoacidosis, hypoglycemia and hyperglycinemia. Ketoacidosis results in developmental delays and failure to thrive. With the relief of ketoacidosis, normal growth ensues. Serum Cbl levels are normal.

Deficiency of Methylmalonyl-CoA Mutase

Life threatening or fatal ketoacidosis may occur due to defects in methylmalonyl-CoA mutase apoenzyme. It results in methylmalonic aciduria. Symptoms include failure to thrive, lethargy, muscular hypotonia, respiratory distress, vomiting and dehydration. High levels of ammonia, glycine and ketones in the blood and urine may be present. Many also have hypoglycemia, low WBC and platelets. This defect does not respond to vitamin B₁₂ therapy. On a protein diet, the symptoms get rapidly induced.

Methylcobalamin Synthesis Deficiency: CblE and CblG Diseases

Functional methionine synthase deficiency (CblE, CblG) is characterized by homocystinuria and hypomethioninemia without methylmalonic aciduria. Usually symptoms like megaloblastic anemia, developmental delay, ataxia, cerebral atrophy, EEG changes, tone abnormalities, seizures, blindness, nystagmus and failure to thrive occur within the first 2 years of life, but a few patients have been diagnosed in adulthood.

Combined Adenosylcobalamin and Methylcobalamin Deficiency: CblC, CblD, and CblF Diseases

In these disorders, failure to synthesize both adenosylcobalamin (resulting in methylmalonic aciduria) and methylcobalamin (resulting in hypomethioninemia and homocystinuria) occurs resulting in deficient activity of methylmalonyl-CoA mutase and N⁵-methyltetrahydrofolate (N⁵-MTHF): homocysteine methyltransferase.

In CblF, the exit of Cbl from the lysosome is defective while in CblC and CblD, the defect is in Cbl reductase. These patients are symptomatic in the first year of life. Clinical features include poor feeding, failure to thrive, lethargy, megaloblastic anemia, spasticity, psychosis, developmental retardation. Usually it is fatal in patients who present in the first month of life. Those who present later have a better prognosis. Chorionic villus biopsy can help in prenatal diagnosis in CblC disease.

Other Inherited Disorders with Megaloblastic Anemia

- Diabetes insipidus, diabetes mellitus, optic atrophy, deafness (DIDMOAD) syndrome (thiamine responsive)
- Refractory sideroblastic anemia
- Congenital disorders of DNA synthesis
- Orotic aciduria
- Lesch-Nyhan syndrome.

Thiamine-Responsive Megaloblastic Anemia

Diabetes insipidus, diabetes mellitus, optic atrophy, deafness (DIDMOAD) syndrome is a rare autosomal recessive disorder. The characteristic features are diabetes mellitus, diabetes insipidus, sensorineural deafness and megaloblastic anemia which respond to pharmacologic doses of thiamine. Additional clinical findings include optic atrophy, cardiomyopathy, and stroke like episodes.

Orotic Aciduria

Orotic aciduria is an autosomal recessive defect of pyrimidine synthesis which results from defective conversion of orotic acid to uridine. Large amount of orotic acid is excreted in the urine. It is associated with severe megaloblastic anemia, neutropenia, failure to thrive and physical and mental retardation.

Lesch-Nyhan Syndrome

In this disorder, purine synthesis is impaired due to lack of hypoxanthine phosphoribosyltransferase. Clinical characteristics

include mental retardation, self-mutilation and choreoathetosis. Megaloblastic anemia is present in some patients.

PATHOPHYSIOLOGY

Folate Deficiency

Folate and B₁₂ deficiency and defect in their metabolism result in defective DNA synthesis resulting in megaloblastic anemia. The first phase in the absorption of natural folates involves digestion of polyglutamates to monoglutamates. Absorption of folates occurs in the small intestine through a saturable carrier process for relatively low intestinal concentrations of folate and by diffusion for high concentrations of folate.

Folic acid is essential for purine biosynthesis. Folic acid absorbed from the diet gets activated to produce active tetrahydrofolic acid (THF). THF is necessary for single carbon transfers in the synthesis of pyrimidine nucleotides. With less amount of biologically active THF, the ability to repair and replicate DNA is decreased. Vitamin B₁₂ is a cofactor for the activation of folic acid in a step that also converts homocysteine to methionine.

In folate deficiency, THF production is depleted causing slowing of DNA synthesis. This results in pancytopenia due to defective hematopoiesis. The cells that are produced have immature nuclei compared with the degree of maturation of the cytoplasm due to arrest of nuclear maturity.

Vitamin B₁₂ Deficiency

Cobalamin is synthesized by microorganisms and is present only in foods of animal origin (meat or fish) such as milk, dairy products, liver, muscle and eggs. It remains stable with cooking at high temperature but is inactivated by ascorbic acid.

In the acidic pH of stomach, Cbl is released by enzymatic digestion from protein complexes in food. It binds to R binder (haptocorrin) present in saliva and gastric juice (**Table 4**). After release from R binder in the duodenum by pancreatic proteases, Cbl binds to IF (synthesized by gastric parietal cells, it is a 45 kDa glycoprotein). In bile also Cbl is attached to R binder, it forms a complex with IF in the duodenum. The complex of IF-Cbl gets attached to the ileal brush border through its receptor cubilin. Usually a limited absorption of 1.5–2.5 µm of Cbl occurs through ileal receptors from a single meal; rarely larger amounts have also been documented. Also a small fraction (< 1%) of a large oral dose gets absorbed passively from the oral, gastric and small intestinal mucosa. The IF-Cbl complex is digested within the enterocyte and the Cbl appears in portal blood attached to TC II (a 38 kDa polypeptide). The Cbl-TC II complex has a rapid metabolic turnover with a half-life of about 6 min. Cbl can bind to either TC I or TC II in the plasma.

Cobalamins are stored in tissues in its coenzyme forms. One-third of body stores are found in the liver. Because of well stored Cbls in tissues, it takes time for deficiency to manifest. Cbl acts

as a coenzyme in propionic acid metabolism for conversion of methylmalonyl-CoA and in the synthesis of methionine from homocysteine. Synthesis of methionine from homocysteine also requires a folate coenzyme N⁵-MTHF.

In vitamin B₁₂ deficiency, propionic acid metabolism is slowed resulting in accumulation of methylmalonic acid. Also in vitamin B₁₂ deficiency folate becomes trapped in its methyl form causing a deficient synthesis of methylene THF. Methylene THF is a coenzyme for thymidyl acid synthesis. Thus, the folate trap occurring as a result of deficiency vitamin B₁₂, slows down DNA synthesis.

CLINICAL FEATURES

Older children present with pallor, easy fatigability, irritability and lethargy. Infants may have regression of milestones and infantile tremor syndrome. On examination, most patients have pallor and sallow yellow complexion. They may have hyperpigmentation of knuckles and nail bed. Patients with pernicious anemia present with anemia, diarrhea, paresthesia, anorexia, recurrent glossitis, and neuropsychiatric symptoms. Vitamin B₁₂ deficiency frequently affects vibratory sensation in the extremities. These changes reflect neurotoxicity occurring because of deficient B₁₂ levels. Once the child is B₁₂ replete, these symptoms can be monitored to determine the degree of resolution.

APPROACH TO DIAGNOSIS

A careful and detailed dietary history is important to diagnose megaloblastic anemia. Dietary faddism, family-induced dietary restriction, exclusive goat's milk should be enquired for. In the case of a breastfed infant with megaloblastic anemia, the maternal dietary history should also be obtained. In infants, dietary vitamin B₁₂ deficiency is quite rare, it may occur in breastfed infants whose mothers are B₁₂ deficient. A careful history of the mother's diet, including the current diet, her diet during and before pregnancy is extremely important.

Document the presence or absence of sprue, malabsorption syndromes and conditions such as intestinal blind-loop syndrome or bowel resection, Crohn's disease, or tuberculosis as potential causes of B₁₂ malabsorption. History of surgery involving the stomach, jejunum, or ileum is important as these may lead to megaloblastic anemia due to impaired absorption of B₁₂. Also, evaluate for other acquired disorders like parasitic infestation.

Leukemia and other malignancies should be ruled out if bone and joint pain are present; marrow replacement may cause pancytopenia in these patients. Bleeding and bruising may rarely be observed due to thrombocytopenia associated with vitamin B₁₂ deficiency; these symptoms should also raise suspicion of leukemia or other marrow replacement disorders.

Careful drug history is important. History of sulfa exposure or use of chemotherapeutic agents, such as methotrexate or azathioprine, anticonvulsants should be considered. Obtaining detailed family history and enquiring about members of extended family is necessary to detect congenital absence or deficiency of carrier proteins which is a common cause of vitamin B₁₂ deficiency occurring in families. These conditions often manifest during infancy and early childhood. Evaluate for Imerslund-Gräsbeck syndrome of proteinuria and excretion of Cbl and IF where appropriate.

Differential Diagnosis

Aplastic anemia, leukemia, myelodysplastic syndrome, malabsorptive diseases and lymphoproliferative states may present with macrocytosis, megaloblastoid marrow anomalies, pancytopenia or high-serum lactate dehydrogenase (LDH) and thus need to be differentiated from megaloblastic anemia.

Table 4 Steps in absorption of cobalamin

1. Release of food-bound cobalamin (in stomach)
↓
2. Binds to R binder (in stomach)
↓
3. Released from R binder (in the proximal small intestine)
↓
4. Binds to intrinsic factor (IF)—produced by gastric parietal cells
↓
5. Transport of IF-cobalamin complex intracellularly through the cubilin receptor (in the ileum)
↓
6. Bound to transcobalamin II (released into plasma)

INVESTIGATIONS

The goal is to confirm the diagnosis of megaloblastic anemia, distinguish between folate or Cbl or combined deficiency, and to determine the underlying cause—dietary, sociocultural or disease related.

Peripheral Blood Examination

There is anemia with low reticulocyte count and macrocytosis [mean corpuscular volume (MCV) 110–130 fL]. In presence of concurrent iron deficiency or thalassemia trait, macrocytosis may get masked. Hypersegmented neutrophils (defined as the presence of one or more six-lobed neutrophils or five or more neutrophils with five well-separated lobes among 100 segmented neutrophils) (**Fig. 1**) are present. There is leukopenia or normal WBC and platelet counts may be reduced.

Bone Marrow Examination

Bone marrow evaluation should be considered for any child with more than one abnormal cell line. It can help to rule out other disorders such as aplastic anemia, leukemia and myelodysplasia. Bone marrow in patients with megaloblastic anemia demonstrates the RBC precursor nuclear/cytoplasmic asynchrony and abnormal granulocyte precursors.

Marrow is hypercellular, myeloid:erythroid ratio changing from 3:1 to 1:1 due to increased erythropoiesis. Megaloblastic erythropoiesis with intermediate and orthochromatic features with a sieve like nucleus and hemoglobinized cytoplasm and mitotic figures is seen (**Fig. 2**). Dyserythropoiesis is evidenced by nuclear remnants, bi- and trinucleated cells, Howell-Jolly

bodies and dying cells. Band cells and giant metamyelocytes are present. Megakaryocytes are either normal or increased with pseudohyperdiploidy.

Erythroid precursors have a normal DNA content with an elevated RNA content. Because of the increased RNA per unit of DNA erythroid precursors are larger than normal cells at the same level of maturation. The nuclear chromatin of the erythroid precursors appears loose giving the characteristic appearance of the megaloblast. There is asynchronicity in maturation of the nucleus and cytoplasm leading to nucleus appearing less mature than the cytoplasm.

Vitamin B₁₂ and Folate Assessment

Serum homocysteine and serum methylmalonic acid levels are useful in differentiating between folate and Cbl deficiency. In folate deficiency, only homocysteine is raised with normal methylmalonic acid levels while in Cbl deficiency, levels of both are significantly raised.

Methylmalonic acid and total homocysteine levels are sensitive indicators of vitamin B₁₂ deficiency and correlate with clinical abnormalities and therapeutic response. However, care should be taken in interpreting these results as they are not specific to vitamin B₁₂ deficiency.

Serum folate and cobalamin levels are easily available tests but have high-false positivity and negativity. Also, the levels normalize fairly rapidly with replacement therapy or even with normal hospital diet. For folate assessment, the RBC folate level is the best measure of metabolically active folate and includes 5-MTHF in the assay. Serum folate measures the circulating pool of folate but does not accurately reflect the amount of THF present in the tissues.

Serum vitamin B₁₂ level Normal values 200–800 pg/mL, vitamin B₁₂ deficiency levels less than 80 pg/mL.

Serum and red cell folate levels Red cell folate normal levels: 74–640 ng/mL; serum folate: normal levels: greater than 5–6 ng/mL; borderline: 3–5 ng/mL; low: less than 3 ng/mL.

Serum and Urine Assessment

Serum LDH is elevated to range of 2,000–5,000 IU/dL. It reflects increased turnover of cells in the marrow due to ineffective erythropoiesis. Measurement of IF and urine proteins, if possible, detects Imerslund-Gräsbeck syndrome. Serum chemistries allow assessment of protein loss and nutritional status. For excluding orotic aciduria, urinary excretion of orotic acid should be assessed. Schilling test and formiminoglutamic acid (FIGLU) test were used in the past to diagnose vitamin B₁₂ and folic acid deficiency. However, these tests are not used currently.

TREATMENT

Signs of heart failure should be carefully monitored in patients with severe anemia to avoid worsening of the cardiovascular status. Blood transfusion should be given very slowly. Successful treatment of patients with folate and Cbl deficiency involves replacement of the deficient vitamins, identification of the underlying cause and appropriate therapy for that, improvement of the diet and regular follow-ups to evaluate and monitor the patient's clinical status.

Folate Deficiency

With 100–200 µg folic acid per day, optimal response may be seen in most patients. With administration of high-dose folate, the hematologic features of Cbl deficiency may reverse, but the neurologic manifestations can progress. So, it is important to rule out Cbl deficiency before treating solely with folate.

The appetite improves and a sense of well-being returns within 1–2 days of the treatment. There is a fall in serum iron

Figure 1 Hypersegmented neutrophil

Figure 2 Bone marrow with megaloblast

in 24–48 hours and reticulocytes rise in 2–4 days with peak at 4–7 days. The hemoglobin levels become normal in 2–6 weeks. The WBCs and platelets increase with reticulocytes. Within the marrow, megaloblastic changes diminish in 24–48 hours, but large myelocytes, metamyelocytes, and band forms may be present for several days. Folic acid is usually given for several months till a new population of red cells has been formed. Folinic acid is used only for treating the toxic effects of DHFR inhibitors (e.g., pyrimethamine, methotrexate).

Etiology should be determined to prevent recurrence, for example, improved diet in nutritional deficiency, a gluten-free diet in gluten enteropathy, or treatment of underlying inflammatory disease such as Crohn's disease or tuberculosis. If the underlying disease is treated appropriately, there is no need to continue folic acid for life. In some situations, it is advisable to continue the folic acid to prevent recurrence, for example, in chronic hemolytic anemia such as thalassemia or in patients with malabsorption who do not respond to a gluten-free diet. Cases of hereditary DHFR deficiency respond to *N*5-formyltetrahydrofolic acid and not to folic acid.

For treating nutritional folate deficiency, an improved diet or a folate supplement, or both may be required. For patients who have folate malabsorption, 5–15 mg/day of folate should yield normal or high serum and erythrocyte folate levels.

Cobalamin Deficiency

Daily dose of 25–100 µg may be used to start therapy along with potassium supplements. Hypokalemia has been documented during B₁₂ initiation treatment in adults. In view of the ability of the body to store vitamin B₁₂ for long periods, monthly intramuscular (IM) injections in doses between 200 µg and 1,000 µg can be started as maintenance therapy. Lifelong treatment may be required in most cases of vitamin B₁₂ deficiency. Parenteral B₁₂ is needed for patients with defects affecting the intestinal absorption of vitamin B₁₂ (abnormalities of IF or of ileal uptake) to bypass the defective step.

Conventional therapy in megaloblastic anemia due to vitamin B₁₂ deficiency has been 1,000 µg of cyanoCbl or hydroxyCbl by injection daily for 1 week, followed by 100 µg of cyanoCbl weekly for 1 month and then monthly thereafter. Patients with complete TC II deficiency respond only to large amounts of vitamin B₁₂ and the serum Cbl level must be kept very high. Doses of 1,000 µg IM two or three times weekly are required to maintain adequate control.

Patients with methylmalonic aciduria with defects in the synthesis of Cbl coenzymes are likely to benefit from massive doses of vitamin B₁₂. These children may require 1–2 mg vitamin B₁₂ parenterally daily. However, not all patients in this group benefit from administration of vitamin B₁₂. Congenital methylmalonic aciduria can be diagnosed in utero by measurements of methylmalonate in amniotic fluid or maternal urine. It may be possible to treat vitamin B₁₂-responsive patients in utero.

In vitamin B₁₂-responsive megaloblastic anemia, the reticulocytes start to rise on the 3rd or 4th day, peak on the 6th to 8th day, and gradually fall to normal by about the 20th day. There is inverse relation between peak of the reticulocyte count and the degree of anemia. Bone marrow reversal from megaloblastic to normoblastic cells starts as early as 6 hours and is completed in 72 hours.

Permanent neurologic sequelae often occur. But, the level of alertness and responsiveness improves within 48 hours and developmental delays may catch up in several months in young infants. Prompt hematological responses occur with the use of oral folic acid, but it is contraindicated because it has no effect on

neurologic manifestations and may precipitate or accelerate the development of neurological symptoms.

OUTCOME

The degree of compliance with the treatment and the underlying cause predicts the outcome and prognosis of megaloblastic anemia. Folic acid deficiency is relatively easy to treat; added folate in the diet of the patients may be sufficient to treat. In some patients with vitamin B₁₂ deficiency, parenteral therapy may be necessary. Vitamin B₁₂ deficiency may be associated with severe neurologic abnormalities which may be long lasting and may not improve even with appropriate therapy.

IN A NUTSHELL

1. Megaloblastic anemia is characterized by the presence of macrocytes in the blood and megaloblasts in the bone marrow.
2. Common causes of megaloblastic anemia in childhood are deficiency of folate or vitamin B₁₂ (Cbl) or defects in their metabolism.
3. Impairment of DNA synthesis is the basic underlying pathogenetic mechanism resulting from deficiency of folic acid and/or vitamin B₁₂ at the cellular level.
4. Strict vegetarians and vegans are at high risk of vitamin B₁₂ deficiency.
5. Foliates are thermolabile and 50–95% loss may occur during cooking and boiling.
6. With appropriate investigations, underlying cause of the megaloblastic anemia should be established.
7. *Successful treatment of patients with folate and Cbl deficiency involves:* Correction of the deficiency, identifying and treating the causative disorder, improvement of the diet, follow-up evaluations to monitor the clinical status and to prevent the recurrences.

Chapter 38.8

Approach to Hemolytic Anemia

VP Choudhry

Increased red cell destruction resulting in anemia is the hallmark of hemolytic anemia. Normal red blood cells (RBCs) survive for 100–200 days. RBC survival depends upon the severity of hemolytic process. RBC destruction secondary to intracorporeal (intrinsic) or extracorporeal (extrinsic) are the predominant causes for various hemolytic mechanisms. Hematopoietic system undergoes increased erythropoiesis to compensate for excessive hemolysis in an attempt to correct anemia. RBC production may increase by 8- to 10-fold to maintain normal hemoglobin levels. Thus, anemia may not become evident if bone marrow is able to compensate for increased RBC destruction. Compensated hemolytic state is termed when a person has increased reticulocyte count with erythroid hyperplasia in the bone marrow along with decreased RBC survival evident by (1) increased plasma lactate dehydrogenase (LDH) level (2) reduced plasma haptoglobins (3) studies revealing reduced red cell survival, etc. Hemolytic anemia is termed only when the compensatory mechanisms have failed and the individual develops anemia.

In certain conditions, the major defect is impairment of RBC production which plays a major role, e.g., leukemia, aplastic anemia, malignant lymphomas, liver or renal disorders, rheumatoid arthritis, myelodysplastic syndromes, megaloblastic anemias, etc. These conditions may be associated with reduced RBC survival but the clinical features of hemolytic anemia are absent. Sometimes hemolytic process may become evident with the increase in hemoglobin level after packed cell transfusion which is not well sustained. However, all these conditions are not considered as hemolytic anemia.

INTRACORPUSCULAR DEFECTS

Red blood cell has three main components, viz., (1) red cell membrane, (2) hemoglobin molecule and (3) various enzymes involved in red cell metabolism. Defects in any of three can result in hemolytic anemia (**Box 1**). These disorders are inherited congenital disorders which usually present in infancy and early childhood. However, some of the disorders may manifest even during adulthood.

EXTRACORPUSCULAR DEFECTS

These are important causes of hemolytic anemia in which RBCs are normal but their survival is reduced as result of problems in the plasma. These conditions are acquired and hemolysis results from immune or nonimmune mechanisms (**Box 2**). These disorders often present later except hemolytic disease of the newborn which often present in the first few days of life.

DIAGNOSIS OF HEMOLYTIC ANEMIA

Whenever any child is suspected to have hemolytic anemia, effort should be made to get the answer for following questions:

1. Is the anemia hemolytic?
2. Severity of anemia and whether the onset is acute or insidious?
3. Is RBC destruction due to intrinsic or extrinsic etiology?

Reduced survival of RBC is the hallmark of hemolytic anemia but the RBC survival studies for its diagnosis are not practical. Thus, the diagnosis of hemolytic anemia is determined by evidences of increased red cell destruction and increased hematopoietic regeneration. Generally clinical features to all hemolytic anemia

BOX 1 Intracorporeal defects/congenital hemolytic anemia

RBC membrane defects

- Hereditary spherocytosis (HS)
- Hereditary elliptocytosis (HE)
- Hereditary stomatocytosis
- Acanthocytosis (*abetalipoproteinemia*)

Hemoglobin (Hb) defects

- Sickle cell anemia
 - Unstable Hb disease, HbC, HbD, HbE
- *Thalassemia*: α - or β -thalassemia
- Sickle cell β -thalassemia, HbE β -thalassemia, HbD β -thalassemia, etc.
 - Double heterozygous disorders

Enzyme defects

- Glucose-6-phosphate dehydrogenase deficiency
 - Glutathione reductase/synthetase
 - Adenylate kinase deficiency
- Pyruvate kinase deficiency
 - Hexokinase
 - Glucose phosphate isomerase
 - Phosphoglycerate kinase
- Drug-induced hemolytic anemia
- Favism

BOX 2 Extracorporeal defects/acquired hemolytic anemia

Immune causes

- Autoimmune hemolytic anemia
 - Warm antibody
 - Cold antibody
- Incompatible blood transfusion
- Drug induced

Nonimmune

- Paroxysmal nocturnal hemoglobinuria
- Cardiac hemolytic anemia
- Microangiopathic hemolytic anemia
- March hemoglobinuria

Secondary

- Bacterial (cholera, *Salmonella*, clostridial, Gram positive infections, etc.)
- Protozoa (malaria, toxoplasmosis, leishmaniasis)
- Burns
- Lead poisoning
- Thermal injury
- Snake venoms

are common but presence of some features along with evidences for intravascular or extravascular causes for hemolysis are helpful in determining the etiology of anemia.

Intravascular hemolysis is an acute process where RBC destruction releases free hemoglobin which binds with haptoglobin resulting in low haptoglobin levels. Extravascular hemolysis results from increased removal of senescent RBC by process of phagocytosis by the reticuloendothelial system. Hemoglobin released is catabolized by phagocytic cells and thus there is no increase of free hemoglobin in plasma though the serum bilirubin levels are raised in some condition.

Evidence of Hemoglobin Breakdown

Jaundice and hyperbilirubinemia Increase in unconjugated bilirubin and presence of jaundice are often present in several hemolytic disorders. Unconjugated serum bilirubin varies between 3 mg/dL and 5 mg/dL and is evident on the sclera. However, its levels may be high in hemolytic crisis, hemolytic disease of the newborn, hemoglobin E disease, development of hepatitis (A or E) in presence of glucose-6-phosphate dehydrogenase (G6PD) deficiency, etc.

The bilirubin levels depend upon combination of multiple factors, viz., amount and rate of RBC breakdown and the ability of liver to conjugate or excrete the bilirubin. Thus, the serum bilirubin level does not correlate with rate of hemolysis. Jaundice is often present but its absence does not exclude the hemolytic state or anemia if the liver is able to conjugate and excrete the excess of bilirubin efficiently. Hemolytic jaundice is predominantly unconjugated which does not appear in the urine and it does not cause pruritus. However, in presence of complications such as gallstones, liver disease (cirrhosis), conjugated bilirubin levels may be increased.

Plasma haptoglobin Haptoglobins are α_2 -glycoproteins which combine with hemoglobin and its products. They are synthesized in the liver. Hemoglobin molecule is very small when it binds with haptoglobin and its derivatives to form a larger complex which is rapidly removed by the parenchymal cells of the liver. In hemolytic states, there is increased release of hemoglobin and thus the plasma haptoglobin levels get reduced in hemolytic anemia which return to normal levels with 4–6 days. However, in chronic hemolytic condition, its levels continue to remain low.

Plasma hemopexin Hemopexin is a β -glycoprotein and it binds with free heme molecule. In severe hemolytic condition when large amount of hemoglobin is released and haptoglobin gets fully saturated then unbound hemoglobin is converted to methemoglobin. Subsequently methemoglobin breaks into ferriheme and globin. Ferriheme combines with hemopexin to form a complex which is cleared by liver in similar way as haptoglobin. Hemopexin levels are low as it gets utilized in forming a complex with ferriheme in intravascular hemolytic conditions.

Lactate dehydrogenase Plasma levels of LDH are increased in hemolytic anemia and megaloblastic anemia because of ineffective erythropoiesis. LDH levels are also raised in other disorders such as myocardial or pulmonary infarction, muscle diseases, lymphoma, leukemia, etc. Thus, it is not diagnostic only for hemolytic states.

Evidence for Intravascular Hemolysis

Hemoglobinuria and hemosiderinuria Hemoglobin from destroyed RBC is released in the plasma during intravascular hemolysis. If the released hemoglobin levels exceed, the haptoglobin binding capacity in such situations unbound hemoglobin passes through the glomerular membrane which is reabsorbed in the proximal renal tubules. However, if the proximal tubules are unable to absorb because of its excessive load, it appears in the urine as hemoglobinuria. The urine color may vary from pink to black. Hemoglobinuria can be easily distinguished from hematuria by urine microscopic examination. In the renal tubular cells, globin is degraded and heme iron is stored in the tubular cells. Gradual loss of iron-laden tubular cells appears as hemosiderin in the urine. Hemosiderin can be demonstrated in the centrifuged urine sediment by Prussian blue stain as extracellular or intracellular granules. It is often present in chronic hemolytic anemia such as paroxysmal nocturnal hemoglobinuria (PNH).

Urobilinogen The bilirubin breakdown major product is urobilinogen which is mainly excreted through feces and small amounts in the urine. Usually urobilinogen is not measured as it is not practical and the difficulties in its technique and interpretation.

Red Blood Cell Changes

Several hemolytic anemias are characterized by changes in RBC. Presence of spherocytes, sickle cells, red cells fragmentation, Heinz body, increased osmotic fragility (OF) whenever present strongly suggests the presence of hemolytic anemia. Thus, detailed examination of peripheral blood film by an expert is of utmost importance and often provides clue for the underlying condition.

Spherocytes RBCs which are more spheroidal with decreased diameter are termed as spherocytes. Spherocytes have reduced

surface area while their volume may be normal or slightly reduced. These cells appear as small, round, deeply staining cells with hardly any central pallor. Spherocytes are seen in hereditary spherocytosis in which there is intrinsic defect in red cell membrane. Among the acquired conditions such as autoimmune hemolytic anemia, hemolytic disease of the newborn, burns, thermal injury, etc., the spherocytes are present in varying number. Thus, their presence is not diagnostic of underlying etiology. Spherocytes vary between 15% and 20% are present in HS and autoimmune hemolytic anemias while in other disorders the spherocytes are usually around 5%.

Osmotic fragility Spherocytes have increased lysis in hypotonic solution. Percentage of red cell lysis is measured in different concentration of saline solution. Normally 50% of red cell lysis occurs between 4.0 g/L and 4.5 g/L of sodium chloride. Increased OF occurs in presence of spherocytes. OF gets accentuated by incubating RBC for 24 hours. Increased OF only confirms the presence of spherocytes or elliptocytes but is not diagnostic of underlying cause of hemolytic anemia on same lines as presence of spherocytes and elliptocytes.

Sickle cells Red cells acquire the sickle or elongated shape and these cells are present on peripheral blood. In sickle cell disease, the red cells become sickle shaped due to intracellular polymerization of HbS which is reversible upon reoxygenation. Sickling of red cells can be induced by sealing a drop of blood under a coverslip to exclude oxygen by adding 2% sodium metabisulfite. Reducing agent such as sodium dithionite if added to hemolysate it forms deoxy-Hbs complex which is insoluble and renders the solution turbid. The test is termed as solubility test. Presence of sickle cells alone or in combination of positive sickling phenomenon or positive solubility test cannot distinguish sickle cell trait from sickle cell anemia. However, presence of sickle cells on blood smear/sickling phenomenon/positive solubility tests are diagnostic of inherited sickle cell disorder.

Red blood cell fragmentation Fragmented RBCs are irregularly contracted cells having different shapes and sizes appearing as crescent, triangular, comma shaped deeply staining cells. Presence of such cells in significant number is suggestive of hemolytic anemia. These cells are also seen in hemolytic anemia secondary to cardiac diseases, microangiopathic states, e.g., disseminated intravascular hemolysis, chemical hemolytic anemia, etc. Presence of RBC fragmentation is not diagnostic of any specific hemolytic disorder.

Heinz body These are aggregates of denatured globulin and can be demonstrated in RBC by supravital staining. However, significant number of Heinz bodies may be present in various hemolytic anemias such as thalassemia syndromes, hemoglobin H, exposure to oxidant drugs and chemicals and following splenectomy.

Target cells Red cells with hemoglobin in the center with pallor around and peripheral hemoglobinized red cells are termed as target cells. Thus, cells are present in good number in thalassemia, homozygous hemoglobinopathies, following splenectomy and in obstructive jaundice. Presence of these cells supports the diagnosis of hemolytic anemia but further tests are essential to determine the underlying etiology.

Evidence of Erythroid Hyperplasia

Hemolytic anemia results in increase in erythropoietin level in response to chronic hypoxia. Erythropoietin stimulates the erythropoiesis in the bone marrow resulting in reticulocytosis, polychromatic macrocytes in blood and erythroid hyperplasia in the marrow (**Box 3**). Absolute reticulocyte count is now readily available in five part cell counters which are reliable and accurate. Reticulocytosis does not occur proportional to the severity of anemia. However, it varies between 5% and 20%. Its levels are higher in disorders like autoimmune hemolytic anemia and HS as compared with other hemolytic anemias. It may be used as an

index of RBC production. It is desirable to determine corrected reticulocyte count which is proportional to the hematocrit or hemoglobin level. Additional benefit of automated cell counters is that it can identify stress reticulocytes based upon their increased volume and RNA content. Nucleated RBCs (normoblasts) are often present in blood, which are also proportional to the severity of anemia. However, normoblast number is high in hemolytic disease of the newborn and after splenectomy in patients with hemolytic anemia. Reticulocyte count is also high in response to hematinic therapy in nutritional anemia.

Polychromasia macrocytosis Chronic hypoxia results in high levels of erythropoietin production which in turn leads to premature release of reticulocytes, which are larger in size and appear as polychromatic cells. As these cells mature, the polychromasia disappears but the RBC continues to have large size (macrocytosis). Presence of these cells in blood results in higher number results in high mean cell volume (MCV) of RBC. Macrocytosis is more pronounced following acute episodes than chronic hemolytic disorders. However, macrocytosis does not occur in conditions like HS and sickle cell anemia. In addition, leukocytosis and thrombocytosis may be observed in some cases as a part of bone marrow hyperplasia.

Bone marrow hyperplasia Bone marrow aspirations appear more cellular and contain less fat. Bone marrow shows normoblastic erythroid hyperplasia with myeloid erythroid ratio may become 1:1 or less. Megaloblastoid changes may be present secondary to folic acid deficiency. Similarly bone biopsy is hypercellular and may show sheets of erythroid cells.

Bony changes Marrow hyperplasia in thalassemia often results in bony changes. Broadening of diploic spaces and thickening of frontal and parietal bones occur which are seen as *hair-on-end* appearance on X-ray of skull and these changes are more remarkable in frontal and parietal bones. On other hand, thinning of cortex along with widening of marrow cavity occurs in tubular bones of hand (carpal and metacarpals) along with decreased density of the medullary area which may appear as coarse and this has been termed as trabecular pattern. Similar changes may be present in ribs. The vertebral bodies become short and widened. These changes are more marked in thalassemia major while bony changes are mild and infrequent in HS, enzymopathies, etc.

History and Examination

Congenital hemolytic anemia Onset of anemia is usually mild to moderate. Children remain asymptomatic even for years except in cases with thalassemia major. Children with thalassemia intermedia, Hb E/ β -thalassemia often present late. Sometimes these cases present initially with complications of gallstones, growth, retardation or fractures of long bones, leg ulcers, etc. **Table 1** summarizes the difference in clinical features between congenital and acquired hemolytic anemia.

Age of onset Anemia presenting in newborn period has different causes (**Box 4**) as compared with hemolytic anemia presenting

later. Simple algorithm for anemia presenting in newborn is given in **Flow chart 1** which is helpful for diagnosis.

Acute onset Acute onset is often present in patients with acquired hemolytic anemia who present with malaise, weakness, backache, headache, breathlessness. History of black color urine is suggestive of intravascular hemolysis. Jaundice may be present and bilirubin level is usually up to 5 mg/dL.

Jaundice It is usually mild to moderate and is of unconjugated type. It is not associated with pruritus while jaundice in Rh or ABO incompatibility is very high and may cause kernicterus in neonate if not detected early and treated as an emergency. Patients with enzymopathy especially with G6PD present with high bilirubin either following drug exposure or infections. Jaundice in G6PD deficiency is mild but development of hepatitis in G6PD deficiency results in high serum bilirubin level. Splenomegaly is generally mild to moderate in nature and it may increase with advancing age. However, in patients with sickle cell anemia, spleen size decreases due to autoinfarction as the child grows. In patients of HS, splenomegaly may be the only clinical presentation and patients may have mild anemia. Leg ulcers, often present in sickle cell anemia, may also develop in patients with hereditary spherocytosis and non-transfusion-dependent thalassemia.

Table 1 Difference in clinical features of congenital and acquired hemolytic anemia

Features	Congenital	Acquired
Race	Common in certain races and regions	Uncommon
Inheritance	Usually inherited	Acquired
Family history	Positive	Negative
Age	Starts from infancy	Second decade
Onset	Insidious	Acute
Anemia	Mild to moderate	Severe
Jaundice	Mild, moderate or severe	Mild to moderate during acute episode Absent in insidious onset
Bony changes	Often present	Absent
Splenomegaly	Present	Usually absent
Leg ulcer	May occur in sickle cell anemia	Absent
Cholelithiasis	May occur in thalassemia, hereditary spherocytosis, and sickle cell anemia	Absent

BOX 4 Causes of neonatal hemolytic states

Immune hemolytic anemia

- ABO and Rh incompatibility

Nonimmune hemolytic anemia

- **Disorders of red cell membrane:** Hereditary spherocytosis, hereditary elliptocytosis, hereditary stomatocytosis
- **Red cell enzyme deficiencies:** Glucose-6-phosphate dehydrogenase deficiency, pyruvate kinase deficiency, etc.
- **Thalassemias:** α -thalassemia, β -thalassemia, compound double heterozygous
- **Hemoglobinopathies:** Sickle cell anemia
- **Infection/septicemia:** Gram positive and gram-negative, intrauterine infections (TORCH), malaria
- Disseminated intravascular coagulopathy
- Galactosemia
- Drug induced

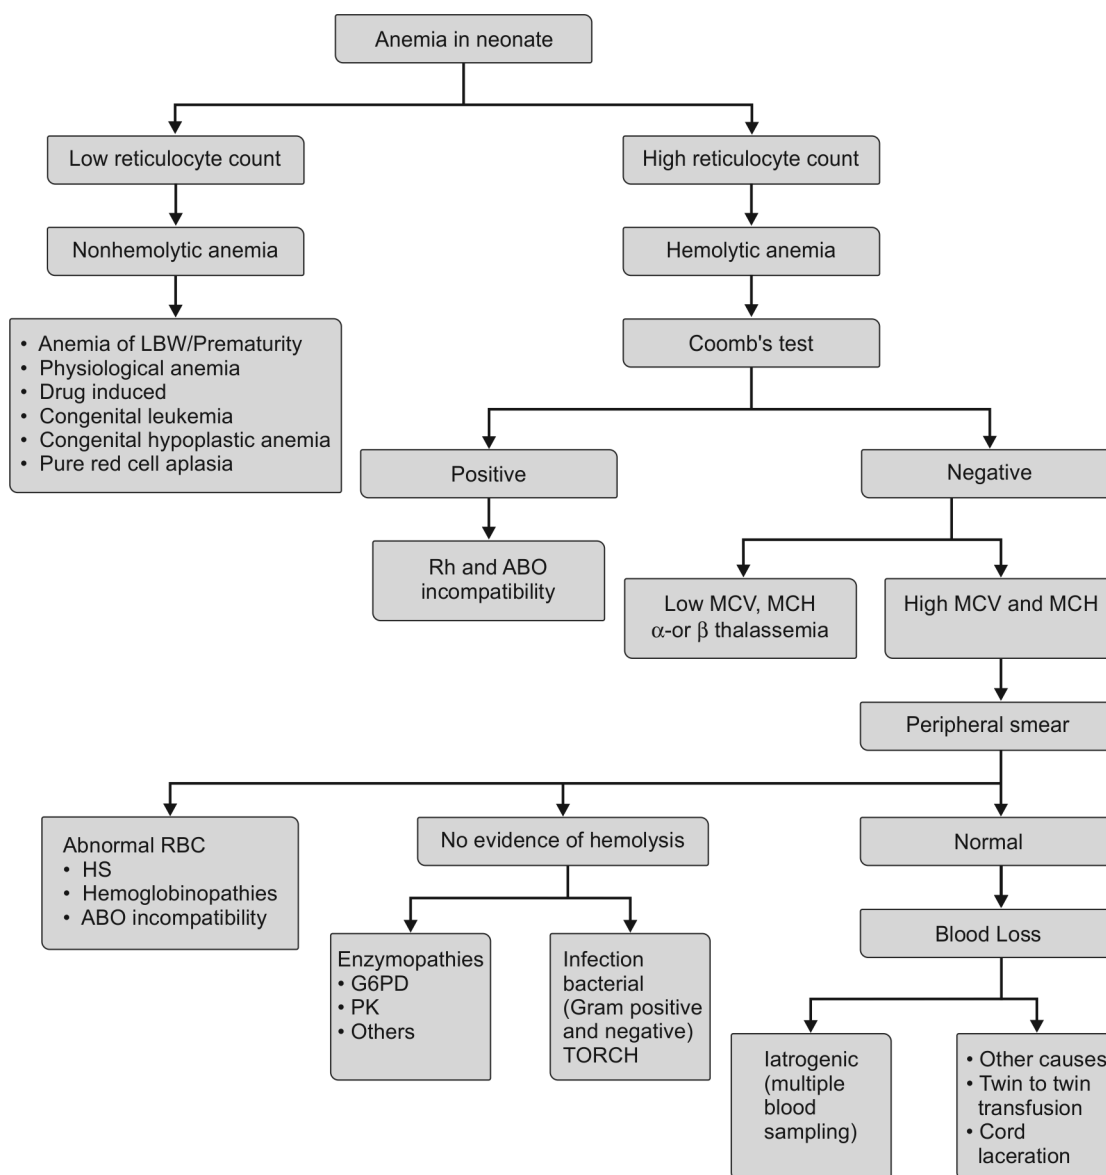

BOX 3 Laboratory evidence of erythroid hyperplasia

Blood

- Reticulocytosis (polychromasia, basophilic stippling), nucleated RBCs
- Macrocytosis
- Leukocytosis and thrombocytosis
- Ferrokinetic studies showing increased plasma iron turnover

Bone marrow

- Normoblastic erythroid hyperplasia
- Myeloid and erythroid ratio 1:1
- Bone biopsy showing hypercellularity with sheets of erythroid cells

Flow chart 1 Algorithm for approach to hemolytic anemia in neonate

Abbreviations: LBW, low birthweight; MCV, mean corpuscular volume; MCH, mean corpuscular hemoglobin; HS, hereditary spherocytosis; PK, pyruvate kinase deficiency; G6PD, glucose-6-phosphate dehydrogenase.

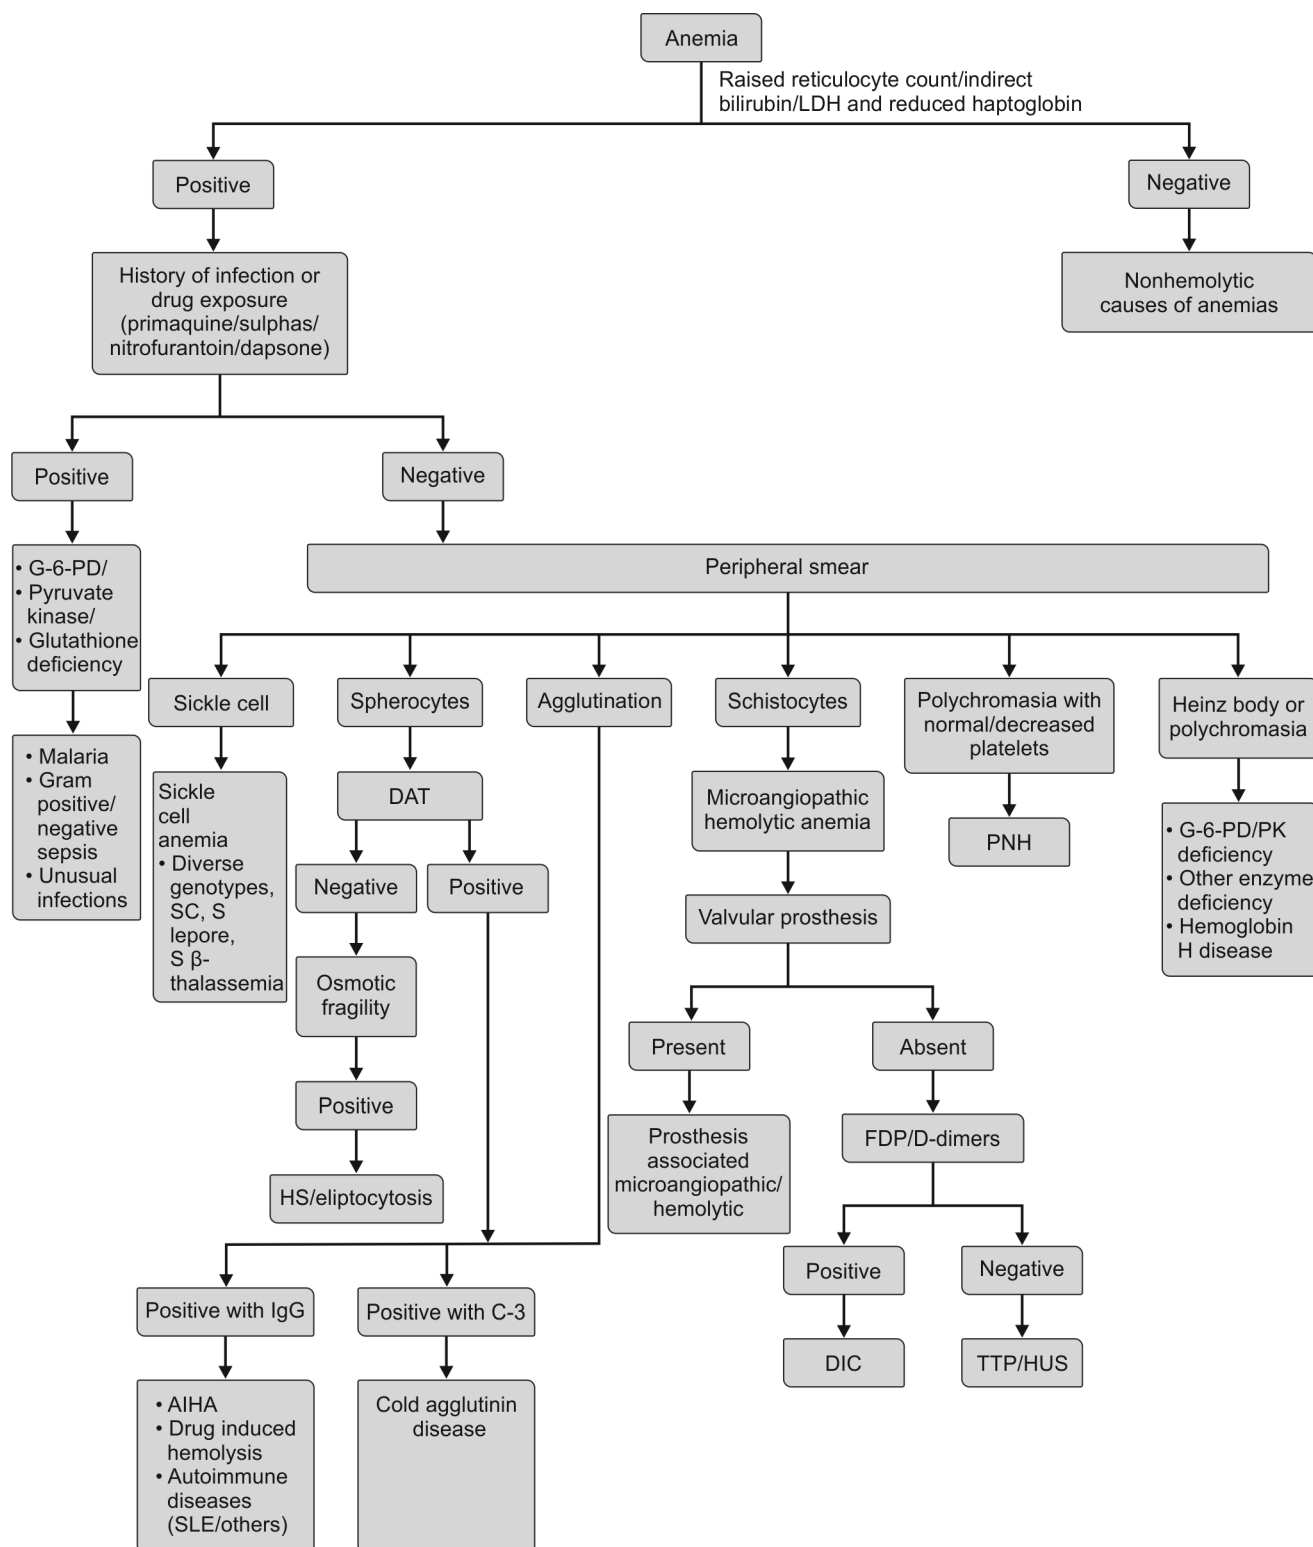

Cholelithiasis Many patients with hemolytic anemia (thalassemia, HS, sickle cell anemia, non-transfusion-dependent thalassemia (NTDT) may develop gallstones because of increased pigment load. The prevalence of cholelithiasis increases with advancing age. The children with cholelithiasis are at higher risk of developing cholecystitis and obstructive jaundice. These children at times may present as acute abdomen.

Features of underlying conditions Patients with lymphomas, immune disorders such as rheumatoid arthritis, systemic lupus erythematosus (SLE), antiphospholipid syndrome may develop acquired hemolytic anemia. These disorders are more common in adults than in children. Clinical manifestations of these disorders provide a clue for presence of hemolytic anemia and underlying etiology.

APPROACH TO A CHILD WITH HEMOLYTIC ANEMIA

Causes of hemolytic anemia are variable from inherited to acquired causes (**Boxes 1 and 2**). A detailed history of onset of symptoms (acute or insidious) along with duration of the illness,

family history of similar disease or history of blood transfusion to the patient and family members, course of the disease are helpful. The origin of the family, its race and region are also of great help as certain hemolytic anemias are widely prevalent in certain region, e.g., HbE in Northeastern states of India, Burma, and Thailand. There is a sickle cell belt across Madhya Pradesh, Maharashtra, Orissa in India while sickle cell anemia is very common in Africa. Inherited disorders often present from early childhood and are of insidious onset. On other hand, acquired causes of hemolytic anemia are generally of acute onset, present late and family history is usually negative (**Table 1**). Examination revealing the presence of anemia, jaundice, hemolytic facies, growth retardation, hepatosplenomegaly evidences of recurrent infection, dactylitis and chronic leg ulcers are helpful for diagnosis of hemolytic anemia. Detailed clinical presentation and diagnostic criteria of various hemolytic anemias are given in respective Chapters. General approach along with algorithms is included which guides the clinicians how to proceed to make a definitive diagnosis with minimal investigations (**Flow charts 1 and 2**).

Many hemolytic disorders are episodic in nature and thus all test may be negative in the absence of active hemolysis

Abbreviations: LDH, lactate dehydrogenase; G6PD, glucose-6-phosphate dehydrogenase; DAT, direct antiglobulin test; AIHA, autoimmune hemolytic anemia; SLE, systemic lupus erythematosus; DIC, disseminated intravascular coagulation; TTP, thrombotic thrombocytopenic purpura; HUS, hemolytic uremic syndrome; FDP, fibrin degradation products; PNH, paroxysmal nocturnal hemoglobinuria; PK, pyruvate kinase deficiency.

Investigations in Hemolytic Anemia

Detailed peripheral examination is of utmost importance which provides clue for various underlying causes. Presence of high reticulocyte count, unconjugated bilirubin, LDH levels and reduced haptoglobin levels are suggestive of hemolytic anemia. It is preferable that blood should be taken prior to blood transfusion for initial peripheral smear, special tests such as Heinz bodies, hemoglobin electrophoresis, osmotic fragility, G6PD and other enzymopathies as all these tests get altered following blood transfusion. List of test which is usually required to confirm the diagnosis is given in **Box 5**. Based upon the detailed history, examination along with

red cell morphology and reticulocyte counts, it is essential to have a clinical diagnosis and minimum number of test should be done to make a correct diagnosis so that appropriate treatment can be initiated.

BOX 5 Investigations for hemolytic anemia

Essential tests

- Full blood examination, with special reference to: Morphology of RBCs—spherocytes, sickle cell, autoagglutination, fragmentation, inclusion bodies, etc. (**Flow chart 2**)
- Reticulocyte count
- Plasma haptoglobin level
- Serum bilirubin level (unconjugated)
- Osmotic fragility test
- Direct antiglobulin test
- Antibody screening
- Sickling test/solubility test
- Tests for abnormal hemoglobin: Hemoglobin electrophoresis, high-pressure liquid chromatography, HbH inclusions, etc.
- Examination of urine for urobilinogen, hemoglobin, hemosiderin

Special investigations

- RBC survival studies (for establishing hemolytic anemia in doubtful cases)
- Bone marrow aspiration and biopsy (evidence of erythroid hyperplasia, folate deficiency, lymphoma and other secondary causes)
- Plasma for hemoglobin and methemalbumin (for confirming intravascular hemolysis)
- X-ray of skull, hands and long bones
- Family studies for hereditary hemolytic anemias
- Heinz body preparation (hereditary hemolytic anemia, chemical hemolytic anemia)
- Enzyme studies G6PD, PK and other enzymes
- Cold agglutinins (AIHA)
- Tests for secondary AIHA - LE cell test, ANA, lymph node biopsy, etc.
- *Paroxysmal nocturnal hemoglobinuria test*: Ham's acid serum test, sucrose hemolysis test, CD55, CD59
- Donath-Landsteiner test for paroxysmal cold hemoglobinuria

IN A NUTSHELL

1. Whenever any child is suspected to have hemolytic anemia, effort should be ascertain if RBC destruction is due to intrinsic or extrinsic etiology?
2. *Hemolytic anemia is characterized by either or more of the following*: Hemoglobin breakdown, intravascular hemolysis, presence of spherocytes, fragmented red cells, and erythroid hyperplasia.
3. Evidence of hemoglobin breakdown includes jaundice and hyperbilirubinemia, increased plasma haptoglobin and hemopexin, and increased plasma LDH.
4. Evidence for intravascular hemolysis includes anemia, hemoglobinuria, and hemosiderinuria.
5. Red blood cell changes suggesting hemolysis includes presence of spherocytes, fragmented red cells, target cells, Heinz bodies, or increased OF.
6. Erythroid hyperplasia is suggested by reticulocytosis, presence of normoblasts and erythroid hyperplasia in bone marrow.

Chapter 38.9

Hemoglobinopathies

HP Pati, Deepti Mutreja

Hemoglobinopathies are defined as a group of genetic disorders caused by production of a structurally abnormal hemoglobin (Hb) molecule, where the amino acid sequence is altered and an unusual (variant Hb) is produced, e.g., hemoglobin S (HbS), hemoglobin E (HbE), hemoglobin C (HbC), hemoglobin D (HbD), etc. The quantitative disorders are the *thalassemia group of disorders*. Normal Hb constitution according to age is shown in **Table 1**.

EPIDEMIOLOGY

Hemoglobin E is found predominantly in Southeast Asia, India, China and Sri Lanka. A potentially large population; approximately 5–50% in Northeastern states of India are carriers of HbE. HbD Punjab (also known as HbD Los Angeles) occurs mostly in Northwest India, Pakistan and Iran. The greatest prevalence of HbD Punjab is among *Sikhs* in Punjab in India where it is reported to be around 2%. HbC has been described in United States among blacks where the prevalence is 2–3%. It has also been observed in Italians, Africans and Turkish populations.

STRUCTURAL HEMOGLOBINOPATHIES

This group of Hb disorders is caused by structural defects resulting from an altered amino acid sequence in α - or β -chains due to a point mutation. The mutation could result in either no physiological abnormality, i.e., clinically asymptomatic individuals HbQ India, O Indonesia, O Arab; variants with a tendency to aggregate, e.g., HbS and HbC; variants with abnormal Hb synthesis, e.g., HbE, HbD Punjab, HbD Iran; variants with a tendency to precipitate and with hemolysis (unstable Hbs), e.g., Hb Köln; variants with altered oxygen affinity, e.g., Hb Johnstown; variants with decreased oxygen carrying capacity (HbM); variants with fast moving in alkaline electrophoresis, HbJ group. Electrophoresis pattern of normal Hb is shown in **Figure 1**.

Table 1 Major hemoglobins (Hbs) and their constitution in normal adults, infants and intrauterine period

Hemoglobin	Globin chain composition	Remarks
HbA	$\alpha_2\beta_2$	Physiologically important Hb in normal adults; 95–96%
HbF	$\alpha_2\gamma_2$	Major physiologic Hb in postembryonal fetuses. Less than 1% in normal adults
HbA ₂	$\alpha_2\delta_2$	Slightly elevated in most β -thalassemias, but may be decreased in iron deficiency, thus making it an ingenious marker for evaluating microcytic, hypochromic anemias. Normal values are up to 3.5% in adults
Gower 1	zeta2epsilon2 ($\zeta_2\epsilon_2$)	Very early normal embryonal
Gower 2	$\alpha_2\epsilon_2$	Hbs that disappear after 8 weeks of gestation. The only one of clinical importance is Hb Portland, which may be seen at birth in cases of the severe form of α -thalassemia
Portland	zeta2gamma2 ($\zeta_2\gamma_2$)	

Figure 1 Normal hemoglobin high-performance liquid chromatography (HPLC)

Hemoglobin C Disease

Hemoglobin C is produced when lysine is substituted for glutamic acid at the sixth position in the β -chain ($\beta^{6\text{glu}\rightarrow\text{lys}}$). Intraerythrocytic crystals of oxygenated HbC can be found and this crystal formation is enhanced when cells are dehydrated or in hypertonic solution. These erythrocytes become rigid and are trapped and destroyed in the spleen.

Hemoglobin C homozygosity, or HbC disease, progresses in a similar way to sickle cell disease, but is less severe. Variable hemolytic anemia is the most dominant form. Clinically mild to moderate splenomegaly is common. Laboratory evaluation shows Hb in the range of 10–11 g/dL. Blood film shows an abundance of target cells, occasional microspherocytes, and HbC crystals especially in splenectomized patients. Hb analysis shows more than 90% HbC with slight increase in HbF. On cellulose acetate electrophoresis at alkaline pH, HbC migrates with HbA₂, HbE and HbO Arab. HbC can be separated from these other HbS by citrate agar electrophoresis at acid pH. HbC trait is asymptomatic. The coinheritance of HbC with HbS and β -thalassemias results in a wide spectrum of hemoglobinopathies with varying degrees of severity.

Hemoglobin E Disease

Hemoglobin E is the second most prevalent hemoglobinopathy worldwide. HbE is a result of the substitution of lysine for glutamic acid in the β -chain at the 26th amino acid ($\beta^{26\text{glu}\rightarrow\text{lys}}$). The β^E -allele is mildly thalassemic due to the activation of a cryptic splice site, and when it is inherited together with β^0 -thalassemia, there is a marked deficiency of β -chain production.

Homozygous HbE is characterized by the presence of a mild asymptomatic microcytic hypochromic anemia. Target cells are prominent. Hb analysis reveals 90% or more HbE with the remainder HbF and HbA₂. On alkaline electrophoresis, HbE migrates with HbA₂, HbC and HbO Arab. On agar gel at acid pH, HbE migrates with HbA. HbE trait is asymptomatic with 35–45% HbE on Hb analysis.

Compound heterozygosity for HbE/ β -thalassemia causes a moderate to severe anemia similar to thalassemia. The diagnosis is confirmed by finding only HbE and HbF on Hb analysis (**Fig. 2**) and by demonstrating HbE trait in one parent and β -thalassemia trait in the other. In other cases of HbE/ β^+ -thalassemia, variable quantities of HbA are present and the condition is milder. Hb EE state is clinically associated with mild anemia like β -thalassemia trait.

Figure 2 Hemoglobin HPLC in HbE β -thalassemia showing prominent peaks of HbF and HbE (eluting with HbA₂)

Hemoglobin D Disease

Hemoglobin D is the third variant Hb identified. The substitution in HbD is a glutamic acid to glutamine at the 121st amino acid of the β -globin chain ($\beta^{121}\text{Glu}\rightarrow\text{Gln}$). HbD migrates with HbS on alkaline electrophoresis. HbD heterozygotes are asymptomatic, nonanemic, and have normal red cell indices. Homozygotes for HbD-Los Angeles are asymptomatic and are hematologically normal with normal red cell indices. Blood films may show target cells. Osmotic fragility may be decreased. Compound heterozygotes for HbD-Los Angeles and a β^0 -thalassaemia mutation have mild microcytic anemia and show minimal hemolysis. Coinheritance of HbD-Los Angeles with HbS results in a severe sickle cell disease phenotype not different from homozygous HbS.

UNSTABLE HEMOGLOBIN DISORDERS

The unstable Hb disorders are a rare group of inherited hemolytic anemias that result from structural changes in the Hb molecule, which cause its intracellular precipitation with the formation of Heinz bodies. Prototypes include Hb Köln and Hb Zurich.

Molecular Pathology and Pathogenesis

Mechanisms that contribute to the instability of these mutant Hbs include mutations that weaken or modify the hemoglobin interactions, that interfere with the secondary or tertiary structure of the subunits, or that interfere with subunit interactions. As the unstable Hbs precipitate in the red cells or their precursors, they produce intracellular inclusions (Heinz bodies) which, together with oxidant damage to their membranes, make the cells more rigid and hence cause their premature destruction in the microcirculation.

Clinical Features

Patients with unstable Hbs can present in a number of ways, viz., congenital nonspherocytic hemolytic anemia with splenomegaly and pigmented (bilirubin) gallstones; Heinz body hemolytic anemia with sensitivity to oxidant drugs, such as sulfonamides; mild or minimal anemia with reticulocytosis out of proportion to the level of circulating Hb; thalassemia-like peripheral blood picture with hypochromic red blood cells; and increased formation of methemoglobin.

Laboratory Diagnosis

The diagnosis of an unstable Hb variant is established by the detection of Heinz bodies in red cells, the demonstration of Hb instability in the red cell hemolysate, and the presence of pigmenturia.

Management

Management of patients with an unstable Hb variant is mainly supportive, including the use of folic acid supplementation, transfusion when required, and in occasional patients, splenectomy.

CONGENITAL METHEMOGLOBINEMIA

In these cases, the amino acid substitution is near the heme pocket, close to iron molecule. The mutant Hb loses its ability to keep iron in the ferrous state and the resultant ferric iron is unable to carry oxygen. Several α - and β -globin variants associated with methemoglobinemia have been discovered. These disorders, unlike the genetic methemoglobinemias due to enzyme defects, follow a dominant pattern of inheritance. The patients are diagnosed by a history of cyanosis since birth, and may have mild polycythemia. Diagnosis is based on measuring methemoglobin levels by spectrophotometry, and analysis of Hb and DNA. No specific management is needed.

HIGH OXYGEN AFFINITY HEMOGLOBIN VARIANTS

Some Hb variants cause increased oxygen affinity, which results in varying degrees of polycythemia, e.g., Hb Bethesda. High oxygen affinity Hb variants result from amino acid substitutions at the interface of α - and β -subunits resulting in a molecule that are involved in the configurational changes which underlie heme-heme interaction or in others involve the amino acids concerned with the binding of 2, 3-DPG to Hb. This results in tight binding of oxygen to Hb resulting in functional anemia, with tissue hypoxia, which in turn causes an increased output of erythropoietin and an elevated red cell mass. The condition should be suspected in any patient with a pure red cell polycythemia associated with a left-shifted oxygen dissociation curve. The diagnosis can be confirmed by Hb analysis using chromatography, mass spectrometry or DNA analysis. In asymptomatic persons, no treatment is necessary. The difficulty arises if there is associated vascular disease, particularly coronary or cerebral artery insufficiency. As these patients require a high Hb level for oxygen transport, venesection should be carried out with great caution. Phlebotomy is undertaken to prevent high viscosity syndromes and typically the aim is to keep the hematocrit below 55%.

LOW-OXYGEN AFFINITY HEMOGLOBIN VARIANTS

This condition should be thought of in any patient with unexplained congenital cyanosis. The amino acid substitution in this variant was at the interface between α - and β -globin chains, giving rise to variants with a relatively low-oxygen affinity, e.g., Hb Kansas. Diagnosis is made by right-shifted oxygen dissociated curve. Hb levels and red cell mass are normal. No specific management is required as cyanosis is well tolerated if there is no physical exertion.

INVESTIGATIONS

Peripheral Blood Smear

In HbC disease, blood smear shows fully hemoglobinized RBCs confusing with sickled cells. In Hb EE disease, there may be plenty of target cells and mild hypochromia. In HbE β -thalassemia double heterozygous state, many bizarrely shaped, fragmented,

microcytic red cells and immature erythroid cells are seen as in cases of thalassemia major. Polychromasia and punctate basophils are also seen.

Biochemical Parameters

Serum bilirubin may be raised, serum haptoglobin and hemopexin are reduced. Serum ferritin, serum iron and iron binding capacity should be evaluated to distinguish from iron deficiency as mild anemia is common in many structural hemoglobinopathy. Also, many hemoglobinopathies are completely asymptomatic and there may be associated β -thalassemia trait or iron deficiency anemia to explain the anemia in them. Recommended assessment in hemoglobinopathy is shown in **Table 2**.

Hemoglobin Analysis

Cation-exchange high-performance liquid chromatography (CE-HPLC) or reverse phase HPLC Quantitative measurement of HbA₂, HbA and HbF allows the initial diagnosis of β -thalassemia trait as well as other β -thalassemia syndromes.

Hemoglobin Electrophoresis

Cellulose acetate in alkaline pH (pH 8.6) This simple method provides separation of the normal Hbs, HbA, HbF, and HbA₂ as well as the common variants HbS and HbC. On a cellulose acetate strip, HbA migrates the most towards the anode followed by HbF, HbS, and HbC.

Citrate agar in acid pH HbF, HbA, HbS, and HbC have distinct mobility patterns on citrate agar, which are different from those on cellulose acetate. The successive application of cellulose acetate and citrate agar electrophoresis allows for the definitive identification of HbS, HbC, HbE, and HbO Arab.

Isoelectric focusing Isoelectric focusing (IEF) on agarose gel is a good method for neonatal screening for hemoglobinopathies as it is sensitive to detect small amounts (less than 2%) of HbH.

Molecular Diagnostic Methods

Molecular diagnosis can be achieved by sequencing of the polymerase chain reaction (PCR) amplified globin gene PCR-based techniques including Gap PCR and reverse dot-blot hybridization techniques. Microarray-based detection methods for the identification of β -globin mutations can be used.

Multiple Ligand Probe Assay (MLPA) Gene amplifications, deletions, mutations and methylations of α - and β -genes have been identified by the MLPA technique.

IN A NUTSHELL

1. The term *hemoglobinopathy* includes all genetic Hb disorders.
2. The main types of abnormal Hb are HbS, HbE, and HbD and HbC. Within these main types there are several subtypes, with differing disease patterns.
3. Hemoglobin E in association with β -thalassemia can present with very variable clinical presentation from mild anemia to severe transfusion-dependent anemia.
4. Hemoglobin C is not seen in Indian subcontinent.
5. Awareness of hemoglobinopathies by education and counseling of families at risk is important for avoiding the burden of these to the society.

Chapter 38.10 Thalassemia

VP Choudhry, JS Arora

Thalassemia is group of inherited disorders of globin chain which were initially reported in 1920. Since this disorder was widely prevalent in Mediterranean region and was thus known as Mediterranean anemia. The word thalassemia was derived from Greek root "the sea" and "blood". However, presently it is prevalent all over the world and is the most common genetic disorder as per World Health Organization. It is inherited in a Mendelian recessive fashion. These disorders have been characterized at molecular level which has greatly helped in the understanding of its clinical presentation, course of the disease, and control of the disorder. However, these disorders are major public health problems in this millennium.

EPIDEMIOLOGY

Thalassemias occur at higher frequency from Mediterranean region through the Middle East and Southeast Asia. Nearly 4% of World's population is carrier of α - and β -thalassemia. In Southeast Asia 40 million are carriers. First case of thalassemia was published by Dr. Mukherjee from Calcutta in 1938. The mean prevalence of thalassemia is nearly 3.5% (1–17%). Its incidence varies in different regions and ethnic groups. Its prevalence is higher in communities like *Sindhis*, *Punjabis*, *Khatris*, *Gujratis*, *Mahars*, *Lohanas* and in certain *Muslim* and *Christian* communities. In India over 50 million persons are carriers of thalassemia. It is estimated that over 100,000 β -thalassemia major children are born all over the World and off these nearly 12,000 babies with β -thalassemia major are born only in India. There are evidences that milder form of β -thalassemia and carriers of β -thalassemia are protective against *Plasmodium falciparum* malaria.

MOLECULAR PATHOLOGY

Thalassemias were one of the first disorders which were characterized at the molecular level. These are caused by defects in synthesis of globin chain as a result of mutation in the globin gene. β -globin gene cluster is located on chromosome 11p15.5 while α -globin gene cluster is on chromosome 16p13.3 for alpha (α) (Fig. 1). In humans there are eight genetic loci which code for 6 types of globin chains. The genes on both globin cluster are

arranged 5'→3' on coding strands. β -globin chains is 60 kb long on which are located five functional genes 5'- ϵ - γ - δ - β -3'. The β -locus control region (LCR- β) between 5' and the ϵ -globin gene. Normal adult hemoglobin (HbA) is comprised of nearly 90–95% of total and minor component HbA₂ accounts for 2–3%. During fetal life and first few months of life fetal hemoglobin (HbF) is the main hemoglobin and it is present only in traces (<1%) in normal adults. Two most common types of thalassemia (α and β) result from decreased synthesis of α - and β -chains. Uncommon forms in which α - and β -chains or ϵ 1, gamma chain synthesis is defective resulting in $\delta\beta$ or $\epsilon\gamma\delta\beta$ thalassemias.

α -Thalassemia

Each individual inherits two α genes from each parent and thus genotype is written as $\alpha\alpha/\alpha\alpha$. α -thalassemia results from deletion of α gene or from a mutation that inactivates one of the pair. The homozygous state is written as $---/---$ and the heterozygous state as $---/\alpha\alpha$. On the other hand in α^+ thalassemia in which only one of α gene is lost. Then the homozygous and heterozygous states are termed as $-\alpha/\alpha\alpha$ and $-\alpha/-\alpha$ respectively. Clinical classification of α -thalassemia along with clinical presentation is given in Table 1.

β -Thalassemia

In this region β -thalassemia is most common which results from mutation in β -globin gene located on chromosome 11p15.5 (Fig. 1). This gene is constituted by three exons with two intervening sequences, 5' and 3' untranslated region (UTR) which is regulated by 5' promoter. β -locus control region (β -LCR) is another regulatory element of *HbB* gene located on upstream of promoter gene. Over 500 mutations have been reported all over the world and among these 5–10 mutations account for most cases in different region. These mutations can affect at any level such as transcription, processing of primary messenger, ribonucleic acid transcript, translation or post translational stability, etc. Rarely, β -thalassemia may also result from partial or complete deletion of β -globin gene. Some mutations result in complete absence of β -chain production and then the disorder is termed as β^0 thalassemia. When mutations result in reduced production of β -chain, then the disorder is called β^+ thalassemia. Individuals with β^0 mutations produce nonfunctional β -globin protein while others with β^+ produce reduced quantity of β -globin protein. Heterozygotes for β -thalassemia have mild anemia and raised HbA₂ levels and such individuals are termed as thalassemia minor/thalassemia carrier or thalassemia trait. In India five to eight mutations account for nearly 95% of cases with β -thalassemia major in different regions. These mutations are IVS-1-5(G→C), IVS-1-1(G→T) codons 8/9 (+G), codons 41/42 (-CTTT), 619 bp deletion, codon 15(G→A)-88 b (C→T), frameshift mutation codons 8/9 (+G). Mutations in (β -LCR) regions are uncommon.

All thalassemias result in imbalanced globin chain production. In β -thalassemia there is excess of α -chains which gets precipitated in precursor red cells causing reduced red cell survival in the bone marrow as well as in blood. While in α -thalassemia it is excess of γ -chains (Hbs Bart's) are produced forming γ_4 molecules in fetal and early life and H (β_4) molecules during childhood. These molecules are unstable and do not release the O₂ to the tissues because of high affinity of these molecules to oxygen leading to reduced oxygen delivery to various tissues.

PATHOPHYSIOLOGY

Excess of alpha chains precipitate to form inclusions in erythroid precursor leading to destruction of erythrocyte precursor cells in bone marrow leading to ineffective erythropoiesis and reduced red cell survival (Flow chart 1). Hemolysis is also contributed secondary to oxidization of α chains inclusions which cause

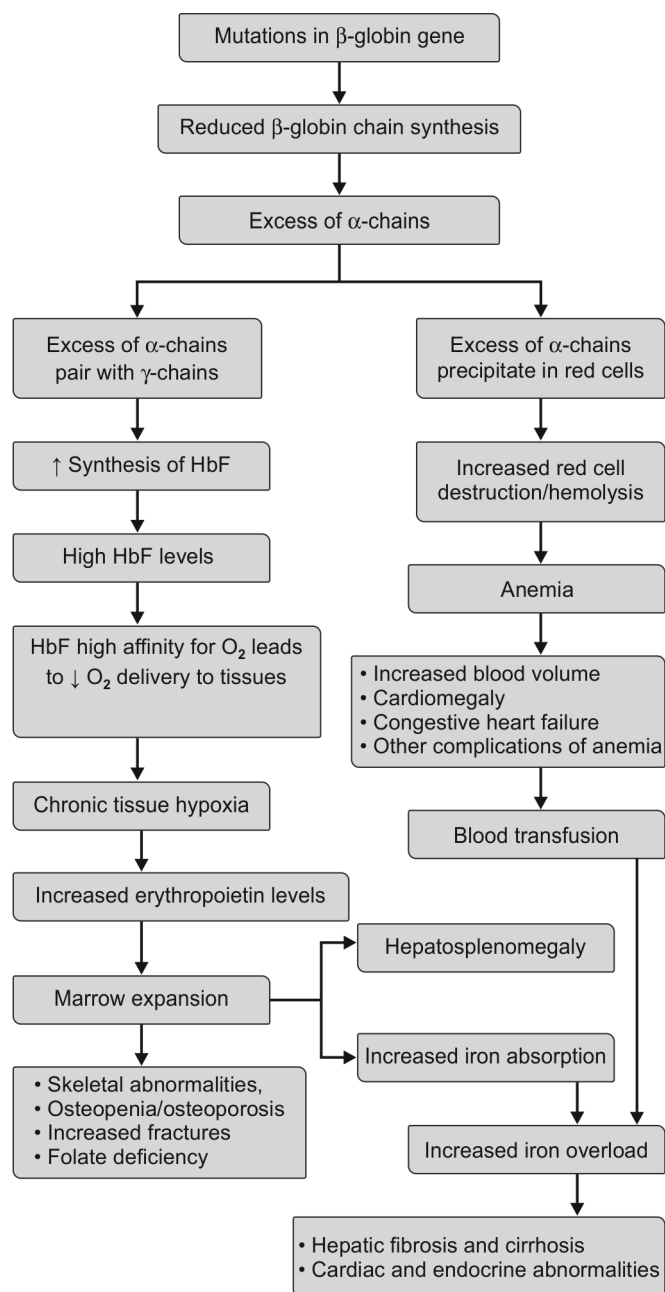

Figure 1 β - and α -globin gene cluster

Table 1 Classification of α thalassemia

Syndrome	Number of globin gene affected	Clinical picture	Hemoglobin pattern	Diagnosis
Silent carrier	One	Asymptomatic No anemia Normal red cells	1–2% Hb Bart (r_{μ})	Identification of mutations
α -thalassemia trait	Two	Mild anemia Microcytic hypochromic red cells	5–10% Hb Bart (r_{μ}) at birth low MCV and MCH	Identification of mutations
HbH disease	Three	Significant anemia hypochromic and microcytic picture hepatosplenomegaly	5–30% HbH (B_{μ})	Identification of mutations
Hydrops fetalis	Four	Severe anemia in fetal life. Hepatosplenomegaly, death in utero because of anemia	Mainly Hb Bart's, small amount of HbH	Identification of mutations

Flow chart 1 β -thalassemia pathophysiology

damage to red cell membrane. Molecular studies have revealed that excess of chains in β -thalassemia trigger the regulation of Fas and Fas ligand which play a major role in apoptosis of red blood cells and ineffective erythropoiesis with microcytic and hypochromic red cell morphology.

In response to anemia body secretes more of erythropoietin (EPO). Patients with high HbF levels have higher levels of EPO. High levels of EPO results in increase in erythropoiesis by 10–30 folds resulting in increase in metabolic activity, nutritional depletion of folic acid, growth stunting, increased cardiac load, congestive heart failure, etc. Splenomegaly primarily occurs secondary to increased entrapment of blood and to some extent due to extramedullary hematopoiesis. Large spleens may become hyperactive thus leading to exacerbation of anemia, increased blood requirements, thrombocytopenia and leukopenia. Such a state is termed as hypersplenism.

Iron overload in these children develops secondary to two main factors, viz. (a) increased iron absorption from gut secondary to excessive erythropoiesis and (b) transfusional iron which plays an important role. Normally iron is bound to plasma (transferrin) and storage proteins and there is hardly any level in form of toxic free radicals. In thalassemic patients transferrin and other iron binding proteins get saturated and free iron radicals cause widespread tissue damage through production of hydrogen peroxide (H_2O_2) and hydroxyl ions affecting liver, heart and endocrine organs. Iron in the liver is deposited in parenchymal and reticuloendothelial cells of liver leading to development of progressive liver fibrosis, cirrhosis and eventually carcinoma of liver.

Iron overload in the heart causes extensive myocardial fiber disruption and variable fibrosis which increases the uptake of toxic nontransferrin bound iron (NTBI) causing further cardiac damage. Free hydroxyl radicals cause damage to the lysosomal, membrane of myocytes further affecting cardiac functions adversely. Iron deposition in conducting system may lead to fatal arrhythmias.

Increase in erythropoietic activity results in marrow expansion resulting in body deformities, skeletal changes, and dental abnormalities. Other factors which contribute to bone pathology are secondary to endocrine disorders which include primary hypogonadism, growth hormone deficiency beside low vitamin D level, calcitonin levels and iron chelation therapy. These patients are prone to develop osteopenia, osteoporosis and bony fractures.

GENOTYPE AND PHENOTYPE CORRELATION

Thalassemia syndrome has a variable presentation from asymptomatic state to severe form requiring repeated blood transfusion within 6 month of age. Clinical presentation depends primarily upon the interaction among the following three genetic modifiers.

Primary Modifiers

Patients with β^0 homozygous mutations will hardly have β -chains and thus the disease will have severe form than baby having β^0 and β^+ mutations. In contrast child with β^+/β^+ with silent β thalassemia allele will have milder disease and present with mild to moderate anemia during late childhood. Some β -thalassemia allele will results in severe disease even in heterozygous state and have been termed as dominant β -thalassemia mutations. Nearly 30 alleles have been identified which are located in 3' third of exon 2 resulting in high levels of unstable β -globin protein which precipitate with β -globin chains. While some mutations are clustered in the promoter region are associated with high levels of HbF. The interaction of these factors affects the clinical presentation.

Secondary Modifiers

α -thalassemia α -thalassemia is also highly prevalent along with β -thalassemia in many regions of the world. Thus homozygous or compound heterozygous β -thalassemia patients who coinheritor α -thalassemia will have amelioration of clinical phenotype due to low levels of α -chains thus reducing the imbalance between α - and non- α -chains. Patients with single or double chain deletion will have milder clinical phenotype while patients with triple chain deletion will have clinical picture of thalassemia intermedia. In India, α 3.7 deletion is common among thalassemia intermedia cases.

α -Duplication/Quadruplication β -thalassemia carrier individuals who inherit excess of α -chains in form of triplicated or quadruplicated α -genes results in higher imbalance and thus these cases of thalassemia trait present as thalassemia intermedia. α -triplication has been observed in 5–20% of β -thalassemia intermedia in India.

Inherited disorders of hemoglobin These are group of autosomal recessive disorders of hemoglobin which are also common in some regions where thalassemia is common. Thus many people may inherit one of these along with thalassemia. Presence of these structural disorders has greater impact on the course of thalassemia. Among these hemoglobin E (HbE) and sickle cell disease (HbS) are common. These disorders are termed as compound heterozygosity.

HbE Beta globin variant G→A at codon 26 is known as HbE. HbE acts as a thalassemia variant associated with decreased beta globin production. The clinical phenotype of HbE beta-thalassemia is variable from very mild to severe transfusion dependent disease. In addition variation in phenotype occurs over the years with the decrease in transfusion requirement.

HbS It results from glutamic acid → valine amino acid substitution at 6th position of β -chain. Compound heterozygous state with β -thalassemia occurs frequently. Course of β -thalassemia in these cases is usually less severe and is variable depending upon the interaction of gene and whether it associated with β^0/β^+ inheritance.

Other hemoglobinopathies such as HbD Punjab and Hb-Q India are less common and have minimal impact on the natural course of thalassemia. On other hand HbD Iran is found among Iranian, Pakistanis, Jamaican Black and families in Northern Calabria, Italy. There is a mutation GAA → CAA at codon 22 of β chain responsible for HbD Iran. The prevalence of HbD Iran globin varies between 35% and 45%. It results in mild phenotype picture presenting as mild to moderate anemia with mild clinical pictures.

HbF levels It plays a major role as modifier of severity of β -thalassemia. Normally 5–8% of RBCs carry HbF and these cells are called F cells. Even small increase in HbF cells helps in ameliorating the severity of disease by reducing α versus non

α -globin imbalance. High levels of HbF occur in the following situations:

- β -thalassemia mutations in the promoter region are associated with high HbF levels.
- Increase in γ -chain synthesis results in prolonged red cell survival.
- Coinheritance of high of persistent fetal hemoglobin (*HPFH*) gene.
- Inheritance of Xmn 1-^s γ polymorphism was discovered initially which resulted in higher HbF levels in persons with homozygous β -thalassemia, E β or S β thalassemia. Association of this inheritance has resulted in delayed presentation with mild phenotype association.
- Single nucleotide polymorphisms (SNPs) in intron 2 of *BCL11A* gene on chromosome 2p16 is associated with raised HbF levels. Similarly, SNP presentation on three linkage disequilibrium block called HbSIL-MYB intergenic polymorphism (HMIP) block 1, 2 and 3 also results in high HbF levels.

Tertiary Modifiers

These modifiers neither affect the hemoglobin synthesis nor hemolysis but have adverse effect on the natural course of thalassemia. Patients with thalassemia have higher prevalence of jaundice and gall stones than general population as a result of excessive hemolysis. The risk of these complications gets enhanced in those with polymorphism in the promoter region of uridine diphosphate glucuronosyltransferase IA gene (*UGT1A*). Similarly, thalassemics having polymorphisms in vitamin D receptor gene and collagen type alpha genes are at much higher risk of developing osteopenia and osteoporosis.

Major Hemoglobin Disorders

Various hemoglobin disorders have been identified depending upon the mutations in α , β gene either alone or in combination with various inherited hemoglobin disorders (**Table 2**).

Table 2 Major hemoglobin disorders

<i>α-globin chain disorders</i>	<i>β-globin chain disorders</i>
HbH disease	• Thalassemia carrier
α -thalassemia (hydrops fetalis)	• Thalassemia intermedia (NTDT)
α -thalassemia	• Thalassemia major
	Compound thalassemia
	• HbS— β -thalassemia
	• HbE— β -thalassemia
	• HbD— β -thalassemia
	• Other rare thalassemia

CLINICAL PHENOTYPES OF β -THALASSEMIA

Clinical presentation is widely variable from asymptomatic state to severe anemia in the first few months of life. Based primarily upon the natural course of the disease, four types of phenotype presentations have been identified (**Table 3**).

Thalassemia Minor/Carrier/Trait

These individuals are usually asymptomatic or may have mild anemia. Anemia in some cases may worsen during stress like pregnancy, infection, etc. It is inherited as heterozygous β thalassemia. Hemoglobin levels may be normal or slightly reduced. Red cells have low mean corpuscular volume (MCV) less than 78 fL and mean corpuscular hemoglobin (MCH) less than 27 pg. Red blood cell counts are higher for the hemoglobin level. HbA₂ level is high more than 3.5% and is diagnostic. However, some β thalassemia mutations are so mild that even HbA₂ level in them

Table 3 Classification of β -thalassemia

Syndrome	β -globin gene affected	Clinical presentation	Hemoglobin pattern	Confirmatory diagnosis
Silent carrier	Heterozygous state	Asymptomatic persons without anemia	Normal with normal HPLC	Molecular studies
Thalassemia trait/carrier	Heterozygous state	Mild anemia \uparrow RBC count \downarrow MCV and MCH	HbA ₂ > 3.5%	Molecular studies
Thalassemia intermedia (NTDT)	Homozygous/heterozygous state	Moderate anemia not dependent on blood transfusion, hepatosplenomegaly Growth retardation, Bone abnormalities May require blood transfusion occasionally	Raised HbF or HbA ₂ level	Molecular studies
Thalassemia major	Homozygous state	Develops severe anemia below 2 years, hepatosplenomegaly, blood transfusions dependent	Markedly raised HbF level	Molecular studies

is normal. These mutations are termed as silent mutations such as -101C \rightarrow T, Cap+ 1A \rightarrow C, etc. Causes of normal RBC indices and HbA₂ levels individuals with β -thalassemia trait are given in **Table 4**. Thus it is essential to test for mutation in the spouse of a person who is thalassemia minor for purposes of genetic counseling. Thalassemia minor needs to be differentiated from iron deficiency anemia which is widely prevalent. The parameters to differentiate between these two are given in **Table 5**.

Thalassemia Intermedia

It constitutes heterogeneous group of patients having only mild anemia in absence of other causes of anemia to patients having growth retardation, jaundice (mild to moderate), hemolytic facies (**Fig. 2**), hepatosplenomegaly. These patients may develop iron overload secondary to increased iron absorption because of ineffective erythropoiesis. These patients often have thrombotic and other vascular complication besides complications secondary to iron overload. Course of the disease, complications and management in these cases is different than thalassemia major.

Thalassemia Major

Most babies with thalassemia major manifest in the first year of life and only few in the second year. They often present with varying degrees of pallor, failure to thrive and gain weight, irritability, excessive crying frequent, intercurrent infections, and hepatosplenomegaly (**Fig. 3**). Untreated or poorly treated children develop frontoparietal bossing, hot cross bun appearance of skull, malar prominence, depressed nose of bridge, malocclusion with protrusion of teeth, depressed nasal bridge (**Fig. 4**). X-ray of the skull shows widening of diploid spaces and hair on end appearance (**Fig. 5**). These children may develop osteopenia leading to osteoporosis and pathological fractures of long bones, leg ulcers, gall stones, etc.

Increased iron absorption in response to anemia or transfusional iron through blood often results in multiple endocrine dysfunctions such as pituitary, thyroid, parathyroid and pancreas resulting in various endocrine problems such as diabetes,

Table 5 Differences between thalassemia minor and iron-deficiency

	Thalassemia minor	Iron-deficiency anemia (IDA)
Anemia	Mild	Mild to moderate
Hemoglobin	Slightly low	Low dependency upon severity of IDA
RBC	Raised for Hb level	Decreases with Hb level
MCV	Low	Low
MCH	Low	Low
RDW	Normal	High
Serum iron and ferritin	Normal	Low
TIBC	Normal	High
HbA ₂ level	> 3.5%	< 3.5%

**Figure 2** Child having hemolytic face, protrusion of teeth**Table 4** Causes of normal RBC indices and HbA₂ in β -thalassemia trait

Phenotype	Genotype
Normal RBC indices	α - and β -thalassemia interaction
Normal HbA ₂ levels	Some cases of iron deficiency anemia Silent β -mutations Coinheritance of δ - and β -thalassemia α -globin chain triplication/quadruplication

hypothyroidism, growth retardation, delayed or absent puberty, osteoporosis, etc. Similarly cardiac iron overload along with anemia may result in cardiomegaly, congestive cardiac failure, poor left ventricular ejection fraction intractable arrhythmias, etc. Older children may develop hepatosplenomegaly because of extramedullary hematopoiesis especially in those who are poorly

Figure 3 Child showing the hemolytic face along with hepatosplenomegaly

Figure 4 Picture showing marked facial deformities (depression of nasal bridge, prominence of frontal and maxillary bones, protrusion of teeth and hemosiderosis)

Figure 5 Skull X-ray showing "hair on end" appearance

transfused. Some of these children may develop hypersplenism manifested by increased blood transfusion requirements, leukopenia and or thrombocytopenia. In addition these children may develop transfusion transmitted infections (hepatitis B or C, HIV, etc.) and alloimmunization following multiple transfusions.

MANAGEMENT

Over the years management of thalassemia has evolved from complete cure to supportive care offering near normal life (**Table 6**). Thalassemia monitoring and management are undertaken in day care centers.

Confirmation of Diagnosis

Complete blood counts reveal presence of anemia with peripheral film showing marked poikilocytosis, anisocytosis, microcytic and hypochromic picture with normoblasts target cells, fragmented red

Table 6 Principles of thalassemia management

• Confirmation of diagnosis
• Transfusion therapy to correct anemia
• Treatment of complication of transfusions and transfusion transmitted infection
• Iron overload and chelation therapy
• Splenectomy
• Management of endocrine problems
• Pharmacological therapies to increase gamma chain synthesis
• Curative therapy bone marrow/stem cell transplantation
• Gene therapy

cells (**Fig. 6**) and basophilic stippling (**Fig. 7**). Reticulocyte count ranges between 2% and 4%. MCV and MCH are reduced. Red cell distribution (RDW) is increased. Bone marrow is not essential for diagnosis but it shows erythroid hyperplasia with ineffective erythropoiesis.

Iron studies Serum iron and transferrin saturation are decreased in iron deficiency anemia (IDA), while it may be normal or increased in thalassemia. Total iron binding capacity is increased in IDA and is normal or reduced in thalassemias. Serum ferritin is high in thalassemia.

Hemoglobin electrophoresis Hemoglobin electrophoresis was earlier being done on paper or cellulose acetate membrane. However, with advent of fully automated cation exchange high performance liquid chromatography (HPLC) which is more accurate, reliable efficient methods and is widely used presently. Specific retention windows have been used for identification of various hemoglobin types. Hemoglobin F in untransfused patients varies between 50% and 100% in thalassemia major below 1 year (**Fig. 8**). HbA₂ varies between 2% and 7% depending upon the genotype. Children who have received blood transfusion in them HbF may be low and nondiagnostic. In such cases family studies involving CBC and HPLC will help in establishing the diagnosis.

Figure 6 Peripheral blood smear showing anisocytosis, poikilocytosis, microcytic hypochromic picture and nucleated normoblast

Figure 7 Peripheral smear showing microcytic hypochromic picture with basophilic stippling

F Concentration = 40.0*%

A₂ Concentration = 1.0*%

*Values outside of expected ranges

Analysis comments:

Figure 8 HPLC showing high fetal hemoglobin and normal HbA₂ level

However, in some cases molecular studies may be required to identify the mutation for correct diagnosis. Presently most centers prefer to have molecular studies which are essential for genetic counseling and control of thalassemia in these families.

Transfusion Therapy

The objective of transfusion therapy is given in **Table 7**. Over the years several regimens have been used (**Table 8**). Among these regimens, currently moderate transfusion therapy is being recommended. Initiation of blood transfusion therapy is recommended when Hb falls below 7 g/dL on two occasions done 2 weeks apart in the absence of any concurrent illness and anemia due to other causes. It is preferable to determine the complete genotype of red cells and to transfuse using group and type specific packed red cells which are compatible by direct antiglobulin test to reduce the risk of alloimmunization. It is preferable to transfuse fresh blood (4–5 days old). Currently many centers use prestorage leukodepletion blood for transfusion. In the absence of this facility bedside filters should be used. Generally, 15–20 mL packed red cells/kg should be transfused regularly at 15–25 days interval to maintain pretransfusion hemoglobin between 9.5 g/dL and 10 g/dL. In a normal child blood may be transfused 3–4 mL/kg/hour while in patients with cardiac decomposition it should be given 1–2 mL/kg/hour. All patients should receive hepatitis B immunization before transfusion and thereafter every 5 years. Parents and first degree relative blood should not be transfused in these cases.

Iron Overload

Normally iron is stored in minimal amount as ferritin and hemosiderin which is nontoxic. In thalassemic iron gets accumulated by multiple ways (**Fig. 9**). Initially transferrin gets saturated leading to increase in serum ferritin, free form as non-transferrin bound iron (NTBI) and enters the cell to form labile iron pool (LIP). LIP is an unstable form and releases toxic-free radicals which damage the microsomes, mitochondria, liposomes, various enzyme proteins, etc. The main source of iron overload is secondary to blood transfusion while iron absorption secondary to anemia from diet is minimal in well transfused children. Iron accumulates at different rates in different organs causing organ dysfunctions secondary to toxic form of iron such as NTBI and LIP. Approximate times for development of complications secondary to iron overload in children who are not well chelated are given in **Table 9**.

Table 7 Goals of transfusion therapy in thalassemia

- To obviate the ill effects of hypoxia
- To suppress endogenous erythropoiesis
- To promote normal growth and development and good quality of life
- To prevent complications of under transfusion (hemolytic facies)
- To prevent hepatosplenomegaly
- To ensure safe blood transfusion practices
- To provide transfusion services most suited to patient

Table 8 Types of transfusions regimen in thalassemia

Transfusion regimen	Pretransfusion Hb level (g/dL)
Palliative	8
Moderate	9.5–10.5
Hypertransfusion	10–12
Supertransfusion	> 12

Figure 9 Pathogenesis of iron overload in thalassemia

Table 9 Time for complications in poorly chelated thalassemic children

Increase in serum ferritin	15–20 transfusions
Hepatic fibrosis	3–5 years
Liver cirrhosis	10–15 years
Subclinical cardiac dysfunction	10–12 years
Heart disease	12–15 years
Heart failure	> 15 years
Various endocrine dysfunction	15–20 years

There are several methods of assessing the iron overload. Serum ferritin is simple and has advantage of serial monitoring and well correlates with various organ dysfunctions. Since serum ferritin acts as an acute phase reactant and its level vary greatly in presence of infection stress, etc. It also does not truly reflect various form of iron overload such as NTBI, LIP liver iron concentration (LIC), etc. Recently magnetic resonance imaging (MRI) methods such as spin echo (R_2), single breath hold gradient recalled echo (R_2^*), T_2^* have been used. Superconducting quantum interference device (SQUID) provides state art and is noninvasive method to assess the liver iron stores. It still remains as an experimental tool because of its high cost and availability of few machines in the World. Similarly, NTBI and LIP are being used as research tools. MRI T_2 is being widely used to assess iron overload for liver and cardiac tissue which is given in **Table 10**.

Chelation Therapy

Other important measure is to maintain serum ferritin around 1,000 ng/mL by chelation therapy. Properties of an ideal iron chelator are given in **Table 11**. Presently iron chelators are approved for chelation therapy as given below.

Desferrioxamine (DFO) It is hexadentate produced from *Streptomyces pilosus* and was introduced in 1962. One molecule binds with one iron molecule. It cannot be given orally and has short half-life (5 min). It is able to create negative iron balance when administered in doses of 30–50 mg/kg/day over 10–12 hours either intravenously or subcutaneously with the help of an infusion pump. Long-term chelation therapy in appropriate doses is able to reverse the complications of iron overload such as liver fibrosis, cardiac dysfunction such as arrhythmias, echocardiogram dysfunctions (LVEF), etc. Vitamin C helps to convert Fe^{+++} to Fe^{++} which is chelatable. It should not be mixed with blood; however, it can be given along with blood transfusion through Y-connection. It also chelates zinc, has audiovisual toxicity and delayed linear growth on prolonged use especially when used in higher doses. Side effects of DFO are given in **Table 12**.

Deferiprone deferiprone (DFP) was the first oral iron chelator developed in Hider's laboratory. It is bidentate and water soluble with

Table 10 T_2^* MRI interpretation for hepatic and cardiac iron overload

Liver iron Hepatic T_2^* (ms)	Iron overload	Cardiac iron Cardiac T_2^* (ms)
> 6.3	None	> 20
2.7–6.3	Mild	12–20
1.4–2.7	Moderate	8–12
< 1.4	Severe	< 8

Table 11 Properties of ideal iron chelator

• High affinity for ferric iron form and no/low affinity for other elements (copper, zinc, magnesium)
• High chelating efficiency
• Good tissue and cellular penetration
• To create negative iron balance
• No redistribution of iron
• Safe drug with least side effects
• Oral drug once or twice a day
• Slow rate of metabolism
• Affordable and easily available

Table 12 Side effects of desferrioxamine (DFO)

• Local reaction such as pain, redness, induration
• Retinal and optic nerve dysfunction
• Cataract
• High frequency hearing loss
• Cartilage dysplasia resulting in stunting of growth
• Acute pulmonary toxicity and renal complication in high doses
• <i>Yersinia enterocolitica</i> infection

half-life 1.5–5 hours. It is recommended in dose is between 75–100 mg/kg/day in 2–3 divided doses. It mobilizes iron from transferrin, ferritin and hemosiderin. It has better penetration within the cells. It does not chelate other elements and has no ill effects on eyes, ears and on growth and development. It chelates iron more effectively from heart than DFO. Few children develop gastrointestinal symptoms like nausea, vomiting and abdominal pain. Nearly 15–20% of children develop joint pain and some of them progress to arthropathy. This complication is more frequent in children with higher serum ferritin levels. Neutropenia occurs in less than 1% of cases and thus CBC should be done regularly. Drug should be stopped during febrile episodes and should be started once CBC is normal.

Shuttle hypothesis Deferiprone being smaller molecule enters tissue cells more easily and is able to bring DFP and iron complex into plasma where DFO with stronger affinity binds with iron molecules and excretes the DFO iron complex more effectively. DFO in different regimens has been used in dose of 30–50 mg/kg twice or thrice a week while DFP (50–75 mg/kg) has been used daily. Combination therapy (DFO and DFP) is recommended in patients with high serum ferritin or children with any cardiac, hepatic or endocrine complications due to iron overload to reduce serum ferritin rapidly without much toxicity.

Deferasirox Deferasirox (DFX/ICL670) is a tridentate molecule with high specificity for iron, and was approved in 2005. It has half-life of 12–18 hours and thus given once a day orally dissolved

in water or juice (orange/apple). It is started in dose of 20 mg/kg/day and dose can be increased to 40 mg/kg/day. It is a total body iron chelator and excretion of iron is dependent on dose and serum ferritin levels. Its side effects are minimal which include skin rashes, nausea, vomiting, abdominal pain, headache, fatigue, skin pigmentation. Transient rise in liver enzymes, blood urea and serum creatinine have been observed. Recently DFX has been used in combination with DFO and been shown to have synergetic effect. Phase II Hyperion study in smaller number of cases has shown that combination therapy is safe and more effective.

Newer iron chelators which are under trial include hydroxyethyl starch (HES). DFO having longer half-life and deferitin another tridentate chelator belonging to ferrothiocin class. Folic acid is cheap and safe should be given to all to prevent its deficiency.

Monitoring

All children require regular monitoring as recommended in **Table 13**. Primarily to prevent development of any complication and to detect the complication early and institute appropriate therapy.

Hypersplenism

It usually occurs secondary to inadequate transfusion, development of alloimmunization, chronic liver disease, etc. Indications of splenectomy are given in **Table 14**. It should not be undertaken in children below 5 years of age. All patients undergoing splenectomy should receive pneumococcal, *Haemophilus influenzae*, meningococcal vaccine 4 weeks prior to surgery. These children should also receive *Salmonella typhi* and other vaccines regularly. Lifelong oral penicillin prophylaxis is recommended. These children should be advised to start ciprofloxacin at start of febrile episode at home and

Table 13 Monitoring of children with thalassemia

Each visit
• Complete blood counts (CBC)
• Weight, height on growth charts, liver and spleen size
• Adverse reaction of blood transfusion, if any
Three monthly
• Urine analysis
• Liver and renal function
• Serum ferritin
Yearly
• Annual blood transfusion requirement
• Hepatic serology (HbsAg Anti HCV/HIV)
• T ₂ MRI for cardiac and iron overload
After 10 years (yearly)
• ECG, echocardiography
• Endocrine (e.g., for thyroid, hypoparathyroid, diabetes)
• Bone mineral density, 25 hydroxy vitamin D3 level
• Sexual development (LH, FSH, testosterone, Tanner staging)

Table 14 Indication of splenectomy in thalassemia

• Packed red cell requirement exceeds 200 mL/kg/year
• Annual packed cell transfusion 1.5 times of basal requirements
• Difficult to maintain pretransfusion Hb level of 10 g/dL
• Massive spleen size with or without abdominal discomfort or pain
• Presence of leukopenia or thrombocytopenia

Table 15 Risk factors and outcome of bone marrow transplantation

Risk factors	Class	Overall survival (%)	Thalassemia free survival (%)
Hepatomegaly > 2 cm	I. Absence of all risk factors	94	87
Liver fibrosis	II. Presence of one or two factors	84	81
Irregular chelation (high serum ferritin level)	III. Presence of all three factors	70	58

should report to doctor for appropriate treatment at the earliest possible. Thrombocytosis may occur following surgery and aspirin (75 mg/kg/day) should be administered as long as platelet counts are more than 800,000/mm³.

Fetal Hemoglobin Inducer

Several drugs such as 5-azacytidine, butyrate, decitabine, EPO and hydroxyurea either singly or in combination have been used to increase the fetal hemoglobin to decrease the imbalance between alpha globin versus nonalpha globin chains. Among these drugs hydroxyurea is most promising and has been found to improve the hemoglobin levels in following indications:

- $\delta\beta$ -thalassemia
- β -thalassemia intermedia homozygous for XmnI polymorphism
- Patients with hypercoagulability, pulmonary hypertension, leg ulcers
- Extramedullary hematopoiesis or pseudotumors
- Alloimmunized children requiring frequent blood transfusion.

This drug is well tolerated given in dose of 10 mg/kg/day and it should be gradually increased to maximally tolerated dose of 20 mg/kg/day. Folic acid supplementation is essential. Response usually occurs within 6 months of therapy.

Curative Therapy

Replacement of bone marrow stem cells with normal fully HLA matched hematopoietic stem cell will correct the underlying defect and thus offers complete cure. This has been possible over the last 3–4 decades using stem cells from bone marrow and process is called bone marrow transplant (BMT) hematopoietic stem cells from blood (HSC Transplant), cord blood (CB Transplant). Source of stem cells from sibling donor has much better results. The probability of sibling donor match availability is around 30%. Thus few centers have initiated unrelated BMT or HSCT program after finding an appropriate match through various bone marrow registries. Lucarelli and his colleagues have identified the risk factors (**Table 15**). Any child who is between 2–5 years, well chelated (serum ferritin around 1,000 ng/mL) and has fully matched sibling donor is best suited for transplant. With the improvement in conditioning regimens and management of graft versus host disease, the long-term results of BMT have improved significantly.

Thalassemia Screening and Control

Since thalassemia is inherited disorder it can be controlled by screening and control program. Few countries in the world have controlled the birth of thalassemia. It is possible by preventing the marriage between two carriers by screening and confirmation test. RBC indices (MCV < 78 fL/MCH < 27 pg with RBC count high for Hb levels), positive nestro test are suggestive of carrier state. These are simple and cheap mass screening test. Persons with positive screening test should be confirmed by Hb electrophoresis (HPLC) with HbA₂ > 3.5%. In the general population, the birth of thalassemia can be prevented by genetic counseling. Secondly, all women during their first antenatal check-up should be screened for thalassemia carrier and those who are positive on screening test need to undergo confirmatory test by HPLC. Husband of thalassemia carrier women need to undergo HPLC test to identify the couples at risk. Molecular studies are undertaken on couples at risk to identify the mutations. During 10–12 weeks of gestation

chorionic villus sample is taken to identify the affected fetus which is aborted to control the birth of thalassemia. The success of national program lies on mass awareness, commitment of medical profession and social organizations besides very strong political will.

IN A NUTSHELL

1. Nearly 4% of world's population is affected by thalassemia which is the most common hemoglobin disorder.
2. The molecular basis of alpha and beta thalassemia is well identified.
3. The clinical picture depends on thalassemia mutations along with the primary, secondary and tertiary modifiers.
4. Individuals with thalassemia minor are asymptomatic while children with thalassemia major present with severe anemia, and hepatosplenomegaly in the first year of life.
5. The principles of management include: (a) confirmation of diagnosis, (b) to maintain hemoglobin at 10 g/dL by repeated pack cell transfusions, (c) to maintain serum ferritin are around 1,000 ng/mL by chelation therapy.
6. All effort should be made to achieve the desired serum ferritin level by use of desferrioxamine, deferiprone and deferasirox either single or in combination.
7. Precautions should be taken to prevent the complications of disease and therapy.
8. Thalassemia can be prevented by screening and control methods.

Chapter 38.11

Sickle Cell Disease

Vibhawari S Dani, Dipty Jain

Sickle cell disease (SCD) is the most common hemoglobinopathy worldwide. It was first described by Herrick in 1910. Pathological basis of hemoglobin (Hb) molecule was defined by Hahn and Gillespie in 1927. The presence of sickle Hb was first described in India in 1952 in the tribal populations of Nilgiri hills in South India by Lehman. SCD is a monogenic disorder with considerable clinical diversity. SCD is a term used for a group of genetic disorder characterized by production of hemoglobin 'S' (HbS). Sickle cell hemoglobinopathy occurs due to mutation of β -globin gene situated on short arm of chromosome 11, where adenine is replaced by thymine in base of DNA coding for the amino acid in the 6th position in β -globin chain. This leads to an amino acid change in β -chain of Hb molecule, from glutamic acid to valine. The substitution of single amino acid is responsible for profound change in molecular stability and solubility of HbS. Minor variations in noncoding nucleotide sequence of genes are also seen. The polymorphic variations are called haplotypes. Four such haplotypes have been found. Arab-Indian haplotype is found in Eastern Saudi Arabia and Indian subcontinent, Bantu haplotype is prevalent in Central African Republic, Benin haplotype is prevalent in Central West Africa, Mediterranean countries, Northern and Southern American countries, Senegal haplotype is prevalent in Atlantic West Africa.

EPIDEMIOLOGY

Sickle cell disease is prevalent in populations that evolved in moderate and humid climates where malaria was endemic. Heterozygous sickle cell trait offers relative protection to malaria in comparison to normal population. This may be due to decreased invasion of parasite in the red cell due to cell wall rigidity, failure of parasite to grow within red cell, increased phagocytosis of infected red cells. SCD is particularly common among people having ancestral origin from sub-Saharan Africa, India, Saudi Arabia and Mediterranean countries. In broad term, the prevalence of the sickle cell trait, i.e., healthy carrier who has inherited the mutant gene from one person only, ranges between 10% and 40% across equatorial Africa, in West African countries such as Ghana and Nigeria the frequency of trait is 15–20%.

Prevalence of SCD in North-East India is 0 to 20%, Central India 22 to 44%, Western India 0 to 33% and South India 0 to 40% (Fig. 1). Nearly 20 million people are affected in India. The sickle cell gene is predominantly seen among tribal population in India, many of whom live in remote hilly regions. It is also prevalent among schedule castes and other backward classes who are economically disadvantaged. Children from India where the sickle gene is linked to the Arab-Indian haplotype are stated to have a milder disease than those with African haplotypes. However, a study from Central India has reported severity of homozygous SCD to be at par with African haplotypes.

SICKLE CELL SYNDROMES

The term SCD includes several distinct genotypes:

- Homozygous sickle cell disease (SS)— $\alpha_2\beta_2^{\text{val } 6}\alpha_2\beta_2^{\text{val } 6}$
- Heterozygous sickle cell disease (AS)— $\alpha_2\beta_2^{\text{val } 6}\alpha_2\beta_2^{\text{Glu } 6}$. This is a benign condition. There is no anemia or decreased red cell survival.

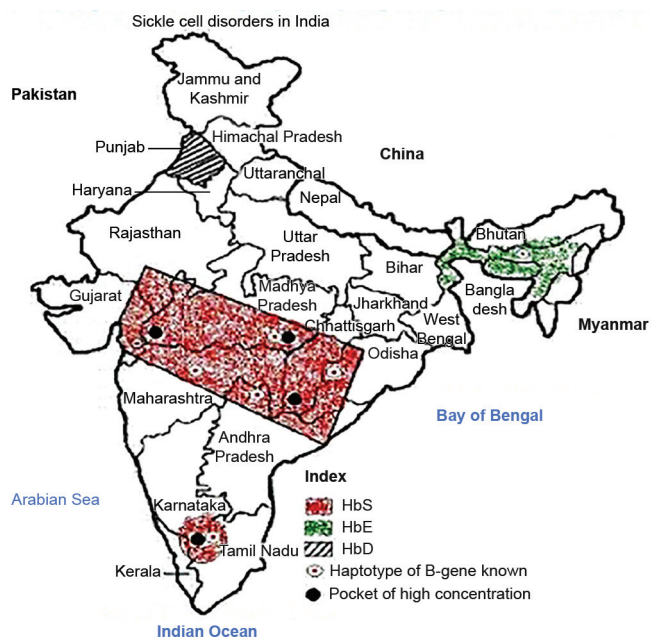

Figure 1 Prevalence of sickle cell gene in India

- Sickle- β -thalassemia—Clinical severity depends on output of thalassemic β gene.
- Less commonly seen forms are:
- SD Punjab disease— $\alpha_2\beta_2^{\text{val } 6}\alpha_2\beta_2^{\text{Glu } 121}$. It has severe clinical presentation.
- SO Arab disease— $\alpha_2\beta_2^{\text{val } 6}\alpha_2\beta_2^{\text{lys } 121}$. It has severe clinical presentation.
- SC disease $\alpha_2\beta_2^{\text{val } 6}\alpha_2\beta_2^{\text{lys } 6}$. It has milder clinical presentation than sickle cell disease.
- Sickle α -thalassemia.

PATHOPHYSIOLOGY

Hemoglobin is normally present in the soluble (Sol) form in the red blood corpuscle (RBC). The Sol form of Hb changes to Gel form, when 'HbS' is polymerized on deoxygenation. In gel form Hb is crystallized to small rigid boat shaped object known as tactoids. These tactoids polymerize forming insoluble fiber like structures, deforming RBC to sickle shape. The polymerization is facilitated by hypoxia, decreased pH, decreased 2,3-diphosphoglycerate (2,3-DPG) concentration and increased carbon monoxide concentration. On re-oxygenation the red cells initially resume normal configuration, but membrane damage is pronounced with repeated cycles of sickling and unsickling resulting in the fixation of membrane in sickle configuration leading to irreversible sickle cell formation and hemolysis. This hemolysis is responsible for anemia in SCD. Life span of sickle red cell is 8–21 days.

Mechanism of Membrane Damage

Red cell membrane associated 'HbS' leads to formation of spectrin-hemoglobin complex, which leads to erythrocyte rigidity. Auto oxidation of 'HbS' generates potent oxidants, e.g., superoxide, peroxide and hydroxyl radicals causing oxidative damage of red cell membrane. In SCD red blood cells have normal shape and normal viscosity when oxygenated, which allows them to slip into microvasculature, where these red cells become deoxygenated leading to distorted shape and become viscous, they cause blockage of microvascular circulation and formation of irreversible sickle cells. This is Trojan horse phenomenon.

Increased Red Blood Cell Adhesion to Endothelium

In SCD the red cells have increased adherence to endothelium. The red cells assume sickle shape after deoxygenation and damage the endothelial cells leading to subendothelial infiltration and narrowing of vessels. Leukocytes, platelets aggregate over the adherent red cell damaged endothelium causing blockade and ischemia of tissue. CD44 and integrin present on red cell membrane adhere to fibronectin and endothelial protein vascular cell adhesion molecule-1 (VCAM-1). Leukocytes adhere to intercellular adhesion molecule-1 (ICAM-1), and E-selectin present on endothelium.

Coagulopathy

It is known that patients with SCD present with activation of the blood coagulation and fibrinolytic systems, especially during vaso-occlusive crises and also during the steady state of the disease. The presence of mutation of the factor prothrombin gene (*G20210A*) variant, factor V gene (*G1691A*) and polymorphism of factor V Leiden, methylenetetrahydrofolate reductase (*MTHFR*) (*C677T*) may be risk factors for vascular complications in individuals with SCD.

Deregulation of Nitric Oxide Metabolism

Nitric oxide stimulates cGMP, and decreases smooth muscle calcium concentration. This causes muscle relaxation, vasodilatation and increase in regional blood flow. It also reduces adherence of endothelium and suppresses platelet aggregation.

Nitric oxide levels are depleted in SCD due increased reactive oxygen species, i.e., oxidants, denatured 'HbS', damage to red cell membrane, microvascular blockage causing tissue ischemia. There is increased free plasma Hb which consumes thousand times more nitric oxide than intracellular Hb.

CLINICAL MANIFESTATIONS

Clinical manifestations of SCD are extremely varied. Some patients are entirely asymptomatic whereas other patients are constantly troubled by painful episodes. The clinical picture in most patients falls between these two extremes.

Sickle Cell Crisis

The term sickle cell crisis was defined by Diggs as *any new syndrome that develops rapidly in patients with sickle disease due to inherited abnormality*. There are three categories of sickle crisis—vaso-occlusive crisis leading to painful episodes, sequestration crisis, and aplastic crisis.

Vaso-occlusive Sickle Cell Crisis

Vaso-occlusive crisis are acute painful episodes due to intravascular sickling and tissue infarction. Vaso-occlusive episode are major clinical manifestation of SCD and occur most commonly in bones, lungs, liver, spleen, brain, and penis.

Acute Painful Episode

This is the most common clinical feature of vaso-occlusive crisis. There is typically rapid onset severe deep throbbing pain, usually without any abnormal physical or laboratory finding but sometimes accompanied by local tenderness, erythema, warmth and swelling. The underlying pathologic cause is bone marrow ischemia, sometimes leading to frank infarction with acute inflammatory infiltrate. Lumbosacral spine, juxta-articular areas of joints like knee, shoulder, and elbow are most commonly involved. Precipitating factors for acute painful episodes are exercise, infection, dehydration, psychological stress, low fetal Hb ('HbF').

The treatment consists of medication for pain relief, rehydration and reassurance. Resolution is usually complete.

Hand and Foot Syndrome

In children younger than 5 years of age small bones of hands and feet are often affected. This painful *hand-foot syndrome* is typically the first clinical manifestation of SCD. Diagnosis is done by characteristic clinical appearance (**Fig. 2**). Involvement varies from individual bone to multiple small bones of hands and feet. Unilateral dactylitis should be differentiated from osteomyelitis because treatment differs significantly. Dactylitis requires pain medications such as acetaminophen with codeine, whereas osteomyelitis requires at least 6 weeks of antibiotics. Hand and foot syndrome disappears when bone marrow from small bones of hands and feet stop erythropoietic activity. The age at which a child experiences the *hand-foot syndrome* is strong predictor of overall severity by 10 years of age. These episodes resolve completely but attacks tend to recur.

Pain in Bones

Several ribs are affected with painful swelling. There is pleuritic pain on deep breathing. This may lead to secondary hypoventilation. Avascular necrosis of bone occur secondary to vaso-occlusion of nutrient artery. Femoral head, humerus, upper part of tibia can be affected but weight bearing makes femoral head necrosis more likely to cause severe disability. Most commonly occurs in adolescents and young adults. Persistent pain in hip joint is often associated with limp and painful limitation of movements (**Figs 3 and 4**).

Painful Abdominal Crisis

This occurs due to localized areas of bowel dysfunction. Its exact cause is unknown, although mesenteric vessels occlusion and vertebral diseases with nerve root compression have been suggested. There is severe abdominal pain associated with vomiting, abdominal distention, diminished bowel sounds. X-ray in standing position shows dilated bowel loops and fluid levels. The conservative management includes bowel rest and maintenance of hydration, pain relief. It usually resolves in 2–4 days, however it may recur.

Acute Central Nervous System Event

Among children with SCD, approximately 10–20% will have either overt or silent stroke respectively before 18 years of age. Incidence is estimated to be 0.7% per year during first 20 years of life, with highest rate in children 5–10 years of age. This complication

Figure 2 Dactylitis in sickle cell disease

Figure 3 Avascular necrosis of humerus

Figure 4 Avascular necrosis of head of femur

may occur in isolation but also appears in setting of pneumonia, aplastic crisis, viral illness, painful crisis, priapism or dehydration. The most common underlying lesion is internal carotid stenosis or obstruction but proximal medial carotid artery and anterior carotid artery are also involved. In the cerebral blood vessels, chronic damage to endothelium occur due to sickled red cells resulting in proliferation of fibroblast and smooth muscle, aggregation of leukocytes and platelets over damaged endothelium leading to stenosis. Thus, acute sickling may be the last precipitating event causing acute infarction in chronically damaged, already injured, and stenosed blood vessels. Hemiplegia, speech defect, seizures, and gait dysfunction occur.

Best initial diagnostic test is CT scan. But it is limited by not being able to pick up lesion in first 4–6 hours where MRI can be the investigation of choice. Oxygen is administered to maintain SPO_2 above 96%. Blood transfusion within 1 hour of presentation, with goal of increasing Hb to maximum of 11 g/dL is effective. If baseline Hb is more than 11 g/dL, then standard approach is exchange transfusion to reduce 'HbS' by at least less than 50% if not 30%. The maintenance blood transfusion program for secondary prevention of stroke should be considered to keep Hb level at 11 g/dL.

Primary prevention of stroke Transcranial Doppler assessment of blood velocity of internal carotid artery and proximal portion of middle carotid artery is done. Maintenance transfusion therapy to maintain 'HbS' less than 30% can be considered in those children with time averaged blood velocity of more than 200 m/s. This results in 85% reduction in the rate of overt strokes.

Intracranial Hemorrhage

It is also major category of sickle cell related events. Many of these episodes are subarachnoid hemorrhage from small bleeding aneurysm that probably arise from internal damage.

Priapism

Priapism is persistent painful penile erection. Highest incidence is in children between 2 years and 4 years. Recurrent priapism manifests with episode lasting for few minutes to several hours. It most commonly occurs around 4 am during sleep or soon after waking. It usually subsides spontaneously. If pain, engorgement persists for 24–48 hours, blood transfusion is indicated. Impotency may be a sequel. Prevention is done by oral stilbestrol 5 mg daily, gradually tapered and omitted over a period of 2 months.

Acute Chest Syndrome

These are episodes of acute lung injury with radiographic evidence of infiltrate and are usually accompanied by pleuritic chest pain, fever, cough, tachypnea and hypoxia. This is leading cause of morbidity and mortality in children and occurs more commonly in children under two years. In most cases the etiology is not clearly defined enough to allow prevention. Infection, infarction, acute pulmonary sequestration, etc. are contributory components.

Management Broad spectrum antibiotic coverage is advised. Oxygen therapy is important in hypoxic patient. PO_2 of less than 75 mm Hg indicate poor prognosis. Transfusion is critical for patient with persistent hypoxia. Exchange transfusion is indicated if hematocrit is high. Preliminary evidence inhaled nitric oxide may be of benefit in severe hypoxia.

Anemia

Anemia is due to chronic hemolysis and is very commonly associated with nutritional deficiency including folate and iron deficiency. The other causes of severe anemia are acute splenic sequestration, aplastic anemia, anemia due to infection and chronic hypersplenism.

Acute Splenic Sequestration Crisis

The event is characterized by sudden trapping of large amount of red cell mass in spleen or less commonly in liver and sudden, rapid, massive, enlargement of spleen. Patients become weak, dyspneic with rapidly enlarging spleen, anemia and shock. The hematocrit becomes half the patient's usual value within few hours. There is associated brisk reticulocytosis to 20–30%, with increased nucleated RBCs and moderate to severe thrombocytopenia. Occurrence is most common between 3 months and 5 years of age but rarely may occur in adults with persisting splenic tissue. Splenic dysfunction occurs due to obstruction of sinusoidal blood flow, leading to diversion of blood through intrasplenic shunts, bypassing phagocytic reticuloendothelial element of the spleen. Sequestration may recur within 4 months of initial episode. Blood transfusion is required in emergency but care must be taken as Hb level can exceed calculated amount as pooled blood may be thrown in circulation. To eliminate recurrence, elective splenectomy after second episode is recommended. Pneumococcal vaccine and prophylactic penicillin for 3 years is recommended following splenectomy.

Aplastic Crisis

This event associated with temporary cessation of bone marrow activity affecting predominantly the red cell precursors, due to suppression by intercurrent viral or bacterial infection. Parvovirus B19 is most commonly associated organism. The child presents with, severe anemia, having Hb 2–4 g/dL, without compensatory reticulocytosis. Reticulocytes are 0% during crisis, however there is daily marked increase consistent with recovery phase. Any child of SCD with reticulocytopenia should be considered as having parvovirus B19 infection until proven otherwise. Occurs in epidemics, mostly affects children below 15 years of age. Treatment requires packed red blood cell transfusion. Daily monitoring of reticulocyte count should be done.

Acute infection with parvovirus B19 may be associated with fever, pain, splenic sequestration, acute chest syndrome (ACA), glomerulonephritis, and stroke.

Chronic Hypersplenism

There is red cell sequestration in spleen, associated with marked splenomegaly. It is most common between ages of 5 years and 15 years and presents with marked anemia, gross splenomegaly and growth retardation. Gradual lowering of Hb below steady state level occurs usually over a period of few months. Hb level is maintained by blood transfusions. Splenectomy may be required if resolution does not occur in 6 months.

Jaundice

Mild or moderate jaundice is due to chronic hemolysis leading to high bilirubin load. Severe jaundice could be due to cholestasis, viral hepatitis or sickle hepatopathy. Cholestasis is due to high bilirubin load caused by hemolysis. Risk of viral hepatitis is increased because of frequent transfusions. G6PD deficiency, if present may be an added component leading to deep jaundice. Cholecystitis presents with pain in right upper quadrant, vomiting, fever and positive Murphy's sign. Ultrasound shows thick edematous gallbladder. Gallstones may be associated. Gallstones are formed due to high bilirubin excretion secondary to accelerated hemolysis. They may be multiple. Gallstones, if symptomatic, should be removed by endoscopic retrograde cholangiopancreatography (ERCP) or cholecystectomy. Hepatic sequestration, seen uncommonly, presents with liver enlargement, tenderness, very high bilirubin levels and abnormal liver enzyme concentration. Acute intrahepatic cholestasis, an uncommon complication may cause deep jaundice.

Infection

Infection is the most common cause of morbidity and mortality in children with SCD. The major risk factor for increased vulnerability to infection is splenic dysfunction, which leads to appearance of RBCs with *Howell-Jolly bodies* and irregular surface characteristics *pits*. When percentage of pitted RBCs exceeds 3.5%, the spleen is generally nonfunctional. Other risk factors are defective alternative pathway for complement-mediated lysis due to deficient levels of serum opsonin and abnormal production of antibodies. In young children, risk of pneumococcal sepsis is approximately 400 times that of normal children and *H. influenzae* sepsis appears to be 2–4 times common. Organisms most commonly involved are *Streptococcus pneumoniae*, and *H. influenzae*. Osteomyelitis is most often caused by *Salmonella*. High grade fever (> 39°C or 102.4°F) is potentially serious in children with homozygous 'SS' disease and possible septicemia must be investigated. *Streptococcus pneumoniae* is widely recognized but *H. influenzae*, *Staphylococcus*, *Klebsiella*, *Salmonella* are also important contributory factors. These children should be managed with intravenous third-generation cephalosporins. Prophylaxis with oral penicillin, erythromycin up to 5 years of age and pneumococcal vaccination is advised.

Chronic Organ Damage

Cardiovascular system Abnormal cardiac findings in most patients with sickle cell anemia are primarily due to chronic anemia and compensatory increased cardiac output. Cardiomegaly is found in most of the patient. Pulmonary hypertension is the most severe cardiovascular complication.

Renal system Sickle cell nephropathy includes papillary necrosis, nephrotic syndrome, renal infarction, hyposthenuria, pyelonephritis and renal medullary carcinoma. The presentation of these entities could be hematuria (microscopic or gross), proteinuria, renal insufficiency and urine concentrating defects.

Hepatobiliary system Hepatobiliary complications include cholelithiasis, hepatic infarction and transfusion related hepatitis.

Leg ulcers They are typically chronic ulcers around malleoli or shin of tibia. They have well demarcated border and surrounding skin is often hyperpigmented and indurated. Management includes cleaning the wound, with mild antiseptic wet dressing. Antibiotics have no role. Oral zinc sulfate improves healing. It is not a very common presentation in India.

Eyes Tortuosity and loculation of conjunctival vessels are seen. Sickle cell retinopathy includes proliferative and nonproliferative retinopathy which can lead to vitreous hemorrhage and retinal detachment.

Growth Somatic and sexual growth is delayed in SCD. Age of menarche is delayed by 2.5 years. Zinc deficiency has been suggested as a cause for poor growth. It has been observed that zinc supplementation augments sexual growth but does not affect somatic growth.

Enuresis It is common in SCD. It is probably secondary to hyposthenuria, associated with small bladder capacity up to 8–10 years of age. Eventually it always resolves.

GENETIC MODIFIERS

Remarkable heterogeneity in clinical severity is observed in homozygous sickle mutation. Genomic mapping has shown various aberrations associated with sickle mutation, responsible for variability in clinical picture. Genes that modulate hemolysis, vasoregulation, cell adhesion, oxidative stress and inflammation play role in clinical manifestation of severity of SCD. Genetic manifestations are associated with clinical complications; however expression of such association is variable. There can be variations in genes known to be associated with certain clinical condition, e.g., stroke, avascular necrosis of bone, priapism, elevated levels of 'HbF', leg ulcers, renal failure that coexist with sickle cell mutation.

Structural changes in β -globin gene like nondeletion mutation ($^G\gamma$ -C158→T) that increases 'HbF' level is associated with Indian Arab and Senegal β -globin haplotype. Locus for production of red cell with 'HbF' is on short arm of chromosome Xp22-23. It accounts for variations in 'HbF' levels in SCD. Other loci on chromosome 8, 6q22.3 are involved in base line maintenance of 'HbF'. Loci on chromosome 1, 12, 13 determine 'HbF' response to hydroxyurea therapy. Genetic mutations may be in the form of deletions in the globin gene region.

Hemoglobin F

Hemoglobin 'F' level in SCD may vary from 0.5% to 30%. 'HbF' reduces polymerization of 'HbS' molecule, thereby reduces severity of clinical picture. 'HbF' is heterogeneously distributed in red cells. Number of red cells with 'HbF' and amount of 'HbF' in red cells also varies in individuals. This results in variable preferential survival of 'F' cells over 'non-F' cells.

Alpha Thalassemia

It is due to structural variation, deletion and altered number of α -thalassemia genes. Primary effect of alpha thalassemia is to reduce the cellular content of 'HbS'. There is microcytosis. Reduction in mean cell hemoglobin concentration (MCHC) prolongs the time required for 'HbS' polymerization. The red cells are more deformable, less rigid and have greater ratio of membrane surface area to volume. Life expectancy is increased in association of alpha thalassemia with SCD. However, there is no protection from stroke, and increased incidence of avascular necrosis of femur is observed.

DIAGNOSIS

Community Screening

Community screening for SCD can be done by sodium metabisulfite slide test and solubility test. These are screening test and cannot differentiate between sickle cell trait and disease. These tests should not be used in first year of life as high level of 'HbF' is present. Confirmation is done by Hb electrophoresis, isoelectric focusing, high-performance liquid chromatography (HPLC), globin DNA analysis, etc. Diagnostic test for SCD should not be done within 3 months after receiving blood transfusion.

Prenatal Diagnosis

Chorionic villus biopsy or amniocentesis are procedures done at 8–12 weeks and 12–18 weeks respectively for prenatal diagnosis of SCD. After 18 weeks cordocentesis can be done but with a higher risk as compared to other two procedures. Polymerase chain reaction (PCR) technique is applied for amplification of DNA. (a) ARMs, i.e., amplified refractory mutations and b) CRDB, i.e., covalent reverse dot blot hybridization techniques are used.

Neonatal Screening

All newborns from high-risk population should be screened for SCD. SCD fulfills all criteria for neonatal screening since with early detection and comprehensive health-care; life expectancy of children having SCD can be increased with significant reduction in morbidity. Blood is obtained from umbilical cord or heel prick. Dried samples on filter paper may be sent to central laboratory for HPLC analysis. If newborn screening shows 'F' and 'S' hemoglobin with baseline hemoglobin range between 6 g/dL and 12 g/dL, the diagnosis is likely to be homozygous SCD or sickle β -thalassemia. In newborn, if screening shows hemoglobin analysis of 'F', 'A', 'S' hemoglobin the diagnosis is likely to be heterozygous SCD or sickle cell trait. Reconfirmation of diagnosis is advisable at 6 months by HPLC preferably along with molecular studies.

Investigations

Children of SCD should be under regular follow-up. Periodic investigations should be done. Complete blood count (CBC), reticulocyte count should be done every 3 months, liver and renal function studies should be done initially as baseline and later yearly, ophthalmic check-up once a year, carotid Doppler once a year, ultrasound for gallstones once a year should be done.

MANAGEMENT

Patients with SCD should be followed on routine basis. Patient and his family should be educated about the nature, course, treatment and its complications of the disease.

Prevention of Crisis

Exposure to hypoxia, dehydration, extreme cold, extreme heat, change in altitude, infections are precipitating factors for crisis. They should be avoided. Dehydration and loss of electrolytes may

lead to red cell dehydration precipitating sickling process. In our tropical country plenty of fluids should be taken regularly. Parent's education for recognizing specific complication at the earliest, should be done. Immunization should be done with pneumococcal conjugate vaccine at age of 6, 10 and, 14 weeks, booster at 18 months should be followed by polysaccharide (23 valent) pneumococcal vaccine after 2 years; Influenza (Hib) vaccine should be given at 6, 10, 14 weeks and booster at 18 months; Typhoid vaccine; Hepatitis B vaccines, at birth, 6 weeks, 6 months, booster every 5 years.

Prophylactic penicillin should be given to all children younger than 5 years (125 mg BD until the age of 3 years and, 250 mg BD after 3 years). Hemoglobin levels should be maintained at 10–12 g/dL. Folate supplementation should be given, as there is rapid turnover of bone marrow. Dose is 2.5 mg/day below age of 5 years and 5 mg/day above age of 5 years.

Pain Management

Painful events are usually treated with adequate hydration and analgesics. Early intervention of acute painful episodes should be done with oral analgesics at pain start point to cut-off the pain cycle. Fluid requirement is usually increased by 50% of the usual requirement during crisis. For mild pain—codeine, aspirin, ibuprofen, acetaminophen, naproxen, can be used. For severe pain—meperidine, ketorolac, tolmetin, oxycodone, etc., are useful. Vasodilators like pentoxifylline, nifedipine, and buflomedil increase microvascular circulation.

Hydroxyurea

Hydroxyurea is myelosuppressive agent, which is the only effective drug proved to reduce painful episodes and ameliorate the severity of SCD. It acts by increasing 'HbF' level, improving rheological properties by decreasing adhesiveness and absolute number of neutrophils and reticulocytes. It also decreases hemolysis by improving hydration of red cells, hampering sickling mechanism. It is started for the following indications: (A) child more than 5 years of age with admissions for painful episodes more than three in a year; (B) History of more than three blood transfusions in a year; (C) Single episode of acute chest syndrome; (D) Stroke; and (E) Avascular necrosis of bone.

Dose Starting dose is 15–20 mg/kg with an incremental dose increase every 8 weeks of 2.5–5 mg/kg if no toxicity occurs, up to a maximum of 35 mg/kg. Strict monitoring for hematological toxicity by CBCs, reticulocyte count should be done every 2 weeks. In Indian setup it is found that fixed low dose of 10–15 mg/kg without escalating is as effective as the recommended schedule.

Blood Transfusion

Patients with SCD tolerate chronic anemia well and may require transfusion in sequestration crisis, CNS infarction, aplastic crisis, preoperative, and hypoxia with acute chest syndrome. A standard simple transfusion in necessary in sequestration crisis and aplastic crisis, while in all other situation exchange transfusion is preferable. All compensated anemia do not require blood transfusion. Chronic transfusion program is used in children with recurrent stroke, to reduce number of 'HbS' containing cells. Autologous bone marrow transplant has been found successful in very severe SCD.

Bone Marrow Transplant

Bone marrow transplant with HLA compatible hematopoietic stem cells is done with good results.

Gene Therapy

It is still in experimental stage. Random insertion of normal β gene, or correction of the defective gene by genetic engineering in hematopoietic cell is still on horizon.

Behavior Change Communication for Prevention

Sickle cell disease is an autosomal recessive disorder. To prevent birth of homozygous SCD, multipronged community awareness approach is needed. Mass screening of marriageable youth for SCD and premarital counseling should be done. A carrier, i.e., sickle cell trait should not marry heterozygous or homozygous SCD.

IN A NUTSHELL

1. Sickle cell disease has autosomal recessive transmission. It has high prevalence in some areas with high-risk communities. It has high morbidity due to infection, pain, anemia, jaundice.
2. Cheaper simple screening tests like solubility test and sodium metabisulfite test are available, but for confirmation of diagnosis Hb electrophoresis is required.
3. Newborn screening program can reduce morbidity. Prenatal diagnosis facilities are available. Community awareness needs to be created.
4. High levels of hemoglobin 'F'; co-inherited alpha thalassemia have milder clinical course.
5. Common causes of death are pneumococcal septicemia, acute splenic sequestration and acute chest syndrome. Pneumococcal vaccine and penicillin prophylaxis can reduce mortality.
6. Nutritional correction of deficiency of iron and folate is important in management of anemia.
7. Analgesics at pain start point are important in cutting off pain cycle and improving quality of life. Hydroxyurea reduces painful crisis, acute chest syndrome. Bone marrow transplant has promising result. Premarital counseling can prevent SCD.
8. Chronic blood transfusion program reduces recurrent stroke.

Chapter 38.12

RBC Membrane Defects

Nitin Shah, Khushnuma Mullanfroze

Hemolytic anemias due to abnormalities of the RBC membrane are an important group of hematological disorders. These include hereditary spherocytosis (HS), hereditary elliptocytosis (HE), hereditary pyropoikilocytosis (HPP), hereditary ovalocytosis [South Asian ovalocytosis (SAO)] and hereditary stomatocytosis (HSt) syndromes. These disorders are characterized by wide clinical and laboratory heterogeneity.

EPIDEMIOLOGY

Only the severe forms of patients of HS, HE, HPP, SAO, HSt come to the notice of physician or a hematologist (since most are asymptomatic) and hence the exact prevalence is not known. Nevertheless these conditions are seen with an increased frequency in Southeast Asia, Africa, and the Mediterranean. It is more common in malaria-endemic regions and presence of these conditions might confer some resistance against falciparum malaria.

Hereditary spherocytosis has an estimated prevalence ranging from 1:2,000 to 1:5,000. Approximately 75% of cases display an autosomal dominant pattern of inheritance, the remaining comprise of recessive forms and de novo mutations. During each pregnancy there are 50% chances that the child from either sex will be affected and 50% chances of being normal. Other way speaking one must always examine parents of a suspected child with HS.

Hereditary elliptocytosis, HPP, SAO, HSt mostly follow an autosomal dominant pattern of inheritance. The prevalence of HE in West Africa, for example, approaches 2%. HPP is known to occur more commonly in the African descent. The prevalence of SAO may be as high as 25% in several Southeast Asian ethnic groups.

These groups are primarily found in the Philippines, southern Thailand, Malaysia, Papua New Guinea, Indonesia, Borneo, Brunei, Cambodia, and in native Australians and certain native South Africans.

PATHOPHYSIOLOGY

The normal RBC membrane can be divided into two parts for the sake of understanding. The outermost part is a lipid bilayer in which complex proteins like palladin, glycophorin, etc. are embedded. The other part of the RBC membrane is composed of a helical cytoskeleton of α - and β -spectrin which is like a meshwork. Ankyrin attaches the lipid bilayer, band 3 (anion exchanger) and band 4.2 (palladin) to α - and β -spectrin helix while band 4.1 attaches glycophorin and the bilayer to the helix of α - and β -spectrin (**Fig. 1**). This structure provides RBC a biconcave shape and gives it the ability to traverse small and large blood vessels without undue damage. A qualitative or quantitative defect in any of these structural proteins, leads to weakening between the phospholipid bilayer and other proteins, making the RBC membrane rigid.

The RBC hydration is largely governed by the content of water and cations. To regulate the influx and efflux of Na^+ , K^+ , Ca^{2+} , and water across the membrane, a number of ion exchangers are present at the RBC membrane. A defect in any of these transporters will lead to a change in the RBC volume [mean corpuscular volume (MCV)] as well as its function. The common RBC membrane defects and their etiopathogenesis are described briefly:

Hereditary Spherocytosis

Ankyrin deficiency is the most common cause of HS. It could be inherited in an autosomal dominant or recessive manner. β -spectrin deficiency is also a common cause of autosomal dominant HS. α -spectrin deficiency causes autosomal recessive HS. Mutations affecting the production of the band 3 or 4.2 can also result in HS. The loss of these structural proteins leads to weak *vertical interactions* and/or decreased lipid anchoring. Membrane microvesicle formation occurs which causes loss of

Figure 1 The lipid bilayer is seen embedded with complex proteins and the helical cytoskeleton of α - and β -spectrin is attached to the bilayer by ankyrin, palladin band 4.1

Abbreviations: GPC, glycophorin C; RhAG-Rhesus antigen

surface to volume ratio. On continual loss of membrane, the RBC loses its biconcave shape and becomes a sphere. Spherocytes have increased permeability to sodium which is compensated by an increased work by a cation pump which leads to active transport of sodium out of the cell. This active transport is driven by glycolysis that generates the adenosine triphosphate needed by the cation pump. These rigid spherocytes, then undergo further membrane loss and ultimately hemolysis while traversing through the spleen resulting in a shortened RBC life span. Thus hemolysis is extravascular and spleen is the major site for hemolysis. This explains benefits of splenectomy in patients with most of the RBC membrane disorders.

Hereditary Elliptocytosis and Hereditary Pyropoikilocytosis

Hereditary elliptocytosis has an autosomal dominant inheritance. At the molecular level, abnormalities of α - and β -spectrin and defective spectrin heterodimer self-association lead to HE. These defects lead to alteration in *horizontal interactions* and result in gross membrane fragmentation. Less commonly, mutations in protein 4.1 and glycophorin C can produce elliptocytosis. Recently, HPP has been included as a subtype of homozygous HE, resulting from spectrin deficiency. The abnormal spectrin denatures at 45–46°C compared to the usual 49–50°C and hence the name. There is increased fragmentation of RBC membrane leading to presence of bizarrely shaped RBCs on smear.

South Asian Ovalocytosis

South Asian ovalocytosis generally occurs in the neonatal period. It is associated with an abnormal protein 3 which functions as an anion exchanger on the RBC membrane.

Hereditary Stomatocytosis

There are two variants of HSt, hydrocytic (overhydrated) and xerocytic (dehydrated). In the hydrocytic variant, which is more severe but less common, there is increase Na^+ influx into the cell. This leads to RBC imbibing more water intracellularly causing it to swell. Xerocytic HSt is more common and causes lesser anemia. In this condition there is a net loss of K^+ from the cell, resulting in eventual cellular dehydration.

CLINICAL FEATURES

There is a wide clinical heterogeneity in disorders of RBC membrane defects ranging from asymptomatic patients who are incidentally identified on peripheral smear examination done for unrelated conditions to severe hyperbilirubinemia requiring exchange transfusion in the neonatal period. Largely, these defects present with symptoms and signs related to hemolysis like anemia, jaundice (indirect hyperbilirubinemia) and pigmentary gallstones. Splenomegaly is generally a common finding on clinical examination. Those with severe anemia may develop hemolytic facies and increased diploic spaces in skull bones as evident on X-ray of skull bones. While most neonates with HS are asymptomatic, some may develop severe hyperbilirubinemia needing exchange transfusion. This is due to the presence of fetal hemoglobin (HbF). HbF binds poorly to 2,3-diphosphoglycerate (2,3-DPG). Consequently increased levels of 2,3-DPG destabilize spectrin-actin-protein 4.1 interactions in the red cell membranes, leading to hemolysis. Some of these babies will go on to develop anemia in first few months of life and typical spherocytes on peripheral smear examination.

Development of pigment gallstones is one of the most common complications of HS and it is related to the hepatic ability to metabolize the unconjugated bilirubin. A homozygous mutation

in the *UGT1A* gene in a case of HS increases the risk of developing gallstones at a younger age.

Like all hemolytic diseases, children with membrane defects (most commonly with HS) can also be affected by a number of potential *crisis*. The types of crisis that can occur are as follows:

- **Aplastic crisis** Generally caused by parvovirus B19, this can lead to sudden and severe anemia with reticulocytopenia and resultant cardiac failure. It can also lead to mild neutropenia and thrombocytopenia. A bone marrow examination at this time classically shows the presence of giant pronormoblast. It is a self-limited condition and generally only requires supportive care. In case the symptoms do not improve, one can give intravenous immunoglobulin (IVIG).
- **Megaloblastic crisis** Patients of hemolytic anemia have a higher daily requirement of folate. In situations of inadequate dietary intake, lack of supplementation or during recovery from the aplastic crisis, a relative folate deficiency may ensue, resulting in megaloblastic crisis. This can be easily prevented by administering folic acid 0.5–1 mg/day to all those with hemolytic anemias, irrespective of the cause.
- **Hemolytic crisis** During the episode of any viral syndrome, in a child less than 6 years with hemolytic anemia, a sudden increase in splenomegaly along with jaundice, anemia and reticulocytosis may be observed. These features are generally mild and do not require any active intervention.

Gout, chronic leg ulcers, spinocerebellar degeneration are some of the rare long-term complications seen in untreated patients.

DIFFERENTIAL DIAGNOSIS

A diagnosis of HS is very obvious in the face of recurrent anemia which may have needed transfusions but is not typically transfusion dependent, recurrent indirect hyperbilirubinemia, reticulocytosis, splenomegaly and a positive family history of similar anemia, indirect jaundice, blood transfusion, chronic leg ulcers or need for splenectomy in parents and siblings along with typical peripheral smear findings of microspherocytes and other evidence of hemolysis like macrocytes, polychromasia, basophilic stippling. During the neonatal period, ABO incompatibility is a close differential diagnosis of HS. ABO incompatibility, generally presents with anemia, spherocytes on smear with hyperbilirubinemia and splenomegaly. But a good clinical history, absence of a palpable spleen on examination of the parents, presence of ABO incompatibility setting and a positive Direct Coombs test will point towards ABO incompatibility.

Autoimmune hemolytic anemia (AIHA), may also present with anemia, jaundice, splenomegaly and spherocytes on peripheral smear. Nevertheless, a history of recent change in color of urine, acute onset of anemia and positive Coombs test, differentiates AIHA from HS.

APPROACH TO DIAGNOSIS

Like most hemolytic anemias, the classic laboratory features of RBC membrane defects comprise of mild to moderate anemia, reticulocytosis, indirect hyperbilirubinemia, a mild decrease in serum haptoglobin and increased lactate dehydrogenase (LDH) levels. Peripheral smear will show changes of hemolysis like macrocytosis, anisocytosis, basophilic stippling and polychromasia. Few specific features of the common types of membrane defects are as follows.

Hereditary spherocytosis The hemoglobin (Hb) will be normal to low with a high corrected reticulocyte count (3–15%). Mean corpuscular hemoglobin concentration (MCHC) greater than 36 g/dL is highly suggestive of HS. The peripheral smear will show the presence of microspherocytes, which are identified as small, darkly staining cells with absence of the normal central pallor (**Fig. 2**).

Hereditary elliptocytosis and hereditary pyropoikilocytosis In HE, peripheral smear will classically show presence of elliptocytes (15–50%). These cells are normochromic and normocytic. Spherocytes, ovalocytes, stomatocytes and fragmented cells may also be seen. In HPP, RBCs are of bizarre shapes and may show fragmentation and budding. This may reflect as a low MCV, owing to the presence of cell fragments (**Figs 3 and 4**).

Hereditary stomatocytosis More than 3–5% of stomatocytes [cells that have a mouth-shaped (stoma) area of central pallor] are classically seen in HSt. (**Fig. 5**). In the hydrocytic variant, a high MCV and decreased MCHC are observed. Peripheral smear shows the presence of stomatocytes. In the xerocytic variant, high MCV but with elevated MCHC is often diagnostic. On peripheral smear, target cells and echinocytes are seen, as well as dense erythrocytes that have Hb puddled at the periphery. Stomatocytes are usually not seen, and most RBCs have normal morphology.

Special Tests

Osmotic fragility test This is currently the most useful and sensitive laboratory test for diagnosing HS. Osmotic fragility (OF) measures the resistance of RBCs to hemolysis during osmotic stress. It is performed by exposing RBC to hypotonic solutions of varying tonicity (from 0.9% to 0.1%). The test is read colorimetrically at the end of 30 min. Incubating RBC at 37°C for 24 hours, improves the sensitivity of the test. Normally hemolysis begins with 0.5% solution and complete hemolysis is seen with 0.2–0.3% solution. In HS, the hemolysis starts at 0.7% and complete hemolysis is seen at 0.4–0.5%. In HE also, OF is increased but not as much as in HS. The OF in a case of HS or HE may be falsely normal if there is superadded iron, folate or vitamin B₁₂ deficiency, β -thalassemia or Hb SC disease.

Acidified glycerol lysis test and pink test These are modifications of the OF test and are based on the same principle. Since this test is faster and more sensitive, it is now used as a rapid screening test to diagnose HS.

Hypertonic cryohemolysis test The principle of this test is based on the fact that HS cells are sensitive to cooling at 0°C in hypertonic solutions. It is claimed that this test is 90–100% sensitive, 94% specific for HS and 86% specific for cases of AIHA. But this test is rarely used in clinical practice.

Autohemolysis test After 48 hours of incubation of normal RBC, without glucose, less than 5% autohemolysis. In HS and other membrane defects, autohemolysis increases to 15–45%. If glucose is added during the incubation, hemolysis in HS is reduced whereas in RBC glycolytic disorder, the autohemolysis is not reduced.

Figure 2 Peripheral smear of hereditary spherocytosis: densely hemoglobinized spherocytes are seen

Ektacytometry This method is used to assess the surface-to-volume ratio and RBC membrane strength. Although few studies have observed 100% specificity of this test, compared with 66% rate of detection by the OF test in cases of HS, it is available in very few research laboratories.

Figure 3 Peripheral smear of hereditary elliptocytosis: pencil shaped elliptocytes are seen

Figure 4 Peripheral smear of hereditary pyropoikilocytosis: multiple fragmented cells with bizarre shapes are seen

Figure 5 Peripheral smear of hereditary stomatocytosis: multiple cells with 'stoma' shaped central pallor are seen

Quantifying membrane proteins, RNA or DNA Generally these specialized tests are done for confirmation. Membrane proteins are usually assessed with sodium dodecyl sulfate polyacrylamide (SDS-PAGE) gel electrophoresis. SDS gel electrophoresis is used to identify spectrin, ankyrin, protein 4.2 and band 3 deficiencies.

Also, suspected proteins or genomic DNA can be sequenced by PCR technique. But in the clinical setting these are not frequently used.

MANAGEMENT

Packed Red Blood Cell Transfusion

Most patients with membranopathy do not have severe anemia and do not need regular transfusions unlike a child with thalassemia major. In fact unnecessary and haphazard transfusions will lead to iron overload. Many patients can tolerate Hb as low as 6–7 g%. Indications for transfusions include presence of pedal edema, exercise intolerance, impending or overt cardiac failure, and severe growth retardation. In presence of infections, fever, cardiac illness or respiratory illness one may transfuse at higher Hb levels of 7–8 g% to tide over the crisis temporarily. Those who are transfused should be followed up regularly with Hb levels, growth monitoring to ascertain need for transfusion and development of complications. Abdominal sonography should be done every 2–3 years from 5 years of age to assess the development of gallstones. Iron studies should be done annually to look for iron overload and chelation should be started when ferritin rises to more than 500–1,000 ng/mL.

Folate Administration

There is an erythroid hyperplasia in the bone marrow in cases of RBC membrane defects. In view of this increased cellular production in the marrow, a relative folate deficiency can ensue especially in cases of inadequate dietary intake, periods of growth spurts, etc. Hence, folate must be administered to all patients of membrane defects at a dose of 0.5–1 mg/day to prevent megaloblastic crisis (see above).

Splenectomy

Since all inherited RBC membrane defects exhibit extravascular hemolysis and the predominant site of hemolysis is the spleen, splenectomy is the logical treatment option in most cases where there is significant anemia, except for hereditary xerocytosis in which case it is an absolute contraindication. A rough cut-off for splenectomy in cases of membrane defects, is a persistent Hb level of lower than 7 g%, reticulocyte count of more than 10% and severe growth failure. One can also consider splenectomy when cholecystectomy is contemplated for symptomatic gallstones. In most cases, the Hb normalizes, reticulocyte count decreases (1–3%) and RBC life span improves to almost near normal. The clinical improvement is also striking. But the benefits of splenectomy must be carefully weighed against the risks of overwhelming postsplenectomy sepsis.

Complications of Splenectomy

Overwhelming Postsplenectomy Infection (OPSI)

The spleen has an important immunological function against encapsulated bacteria viz. *Haemophilus influenzae*, *Streptococcus pneumoniae*, *Neisseria meningitidis*. The splenic macrophages phagocytose the opsonized encapsulated bacteria and cause its removal from the body. In the absence of spleen these bacteria proliferate and can cause fulminant sepsis and a high mortality. A way to prevent this complication is to immunize children against these organisms at least 6–8 weeks prior to splenectomy. As the risk of sepsis with these encapsulated organisms is maximum in the first 3–5 years of life, if feasible, splenectomy must be delayed until 5–9 years of age and should almost never be performed in a

child less than 3 years of age, even if recurrent blood transfusions are required in the interim. Postsplenectomy penicillin prophylaxis is given to the patients with oral penicillin V in the dose of 200 mg twice a day for children less than 30 kg and 400 mg twice a day for those more than 30 kg weight and this is continued lifelong. They are also instructed to double the dose of oral penicillin when they develop fever and seek appropriate medical help as soon as possible. Combined approach with immunization, penicillin prophylaxis and timely management of febrile episodes has significantly brought down the incidence and mortality of postsplenectomy sepsis. Of note, splenectomised individuals are also susceptible to *Capnocytophaga canimorsus*, malaria and babesiosis.

Thrombocytosis

Spleen filters almost 10–15% of the blood volume per minute. It filters the platelets in particular, a mechanism called *culling*. Hence, postsplenectomy thrombocytosis is frequently observed. But this alone, needs no treatment.

Thrombosis and Thromboembolism

There is an increased prevalence of thrombosis postsplenectomy. The etiology of thrombosis is complex. Chronic postsplenectomy thrombocytosis with platelet aggregation, decreased nitric oxide (NO) affecting vascular tone (postsplenectomy there is increased free circulating Hb which binds to NO), stasis, etc. are few of the postulated mechanisms. Thromboembolic episodes are treated with heparin and warfarin as per standard guidelines.

OUTCOME

Anemia, acholuric jaundice, splenomegaly and gallstones constitute the clinical spectrum of most membranopathies in children. Once diagnosed on the basis of complete blood count (CBC), peripheral smear and confirmatory tests, these children must be followed up regularly for evaluation of growth, transfusion dependency and surveillance of complications.

IN A NUTSHELL

1. RBC membrane defects are an important cause of hemolytic anemia in children. Most are asymptomatic and have a wide clinical spectrum of presentation.
2. The most common mode of inheritance is autosomal dominant.
3. The hemolysis in RBC membrane defects is mostly extravascular and occurs in the spleen.
4. Anemia, indirect hyperbilirubinemia, splenomegaly and cholelithiasis are the most common findings.
5. Folic acid administration (2.5–5 mg/day) is mandatory for all patients.
6. Splenectomy causes marked clinical improvement in most membrane defects but is contraindicated in hereditary xerocytosis.

Chapter 38.13

Red Blood Cell Enzyme Defects

Manoranjan Mahapatra

Mature red blood cells (RBCs) are unable to carry out oxidative phosphorylation and protein synthesis due to the loss of the nucleus, mitochondria, and ribosomes. However, it is optimally adapted to perform its most important function, i.e., the binding, transport and delivery of oxygen to all tissues. Red cell enzymes allow erythrocytes to meet these tasks by supporting three essential metabolic pathways:

- *Antioxidant pathways* necessary for the protection of RBC proteins against oxidation, through the synthesis of glutathione (GSH), and of hemoglobin against iron oxidation through the maintenance of iron in its functional, reduced, ferrous state (cytochrome b5 reductase).
- *Anaerobic glycolysis*, which is the only source of energy (ATP production) for maintenance of cell structure and function.
- *Nucleotide metabolism* for the maintenance of the purine and pyrimidine nucleotides.

Erythrocytes possess a unique glycolytic bypass for the production of 2,3-bisphosphoglycerate (2,3-BPG) a crucial metabolite in the regulation of hemoglobin affinity for oxygen. RBC enzyme defects have been described in all these metabolic pathways and almost all are associated with chronic hemolytic anemia (CHA), with the exception of the enzymopathies of the pentose phosphate pathway and glutathione metabolism, which are associated with acute hemolytic crises only after exposure to oxidant substances. In general, the genetic mutations that cause RBC enzyme defects are associated with three different clinical phenotypes:

1. Hemolytic syndrome associated with either CHA, hereditary nonspherocytic hemolytic anemia (HNSHA) or acute hemolytic crises (**Box 1**)
2. Permanent cyanosis with methemoglobinemia and
3. Increased RBC mass or erythrocytosis.

Over the past few years the inherited disorders of erythrocyte metabolism have been the object of intensive research which has resulted in a better understanding of their molecular basis. However, curative therapy for RBC enzyme defects still remains challenge.

BOX 1 RBC enzyme deficiencies associated with hemolytic anemia

- Hexose monophosphate (HMP) pathway deficiency
 - Glucose-6-phosphate dehydrogenase (G6PD)
 - Others
 - Glutathione reductase
 - Glutathione synthetase
 - Gamma-glutamylcysteine synthetase
- Embden–Meyerhof (EM) pathway deficiency
 - Pyruvate kinase (PK)
 - Others (rare, only small case series reported)
 - Glucose phosphate isomerase
 - Hexokinase
 - Phosphofructokinase
 - Triose phosphate isomerase
 - Phosphoglycerate kinase
 - Aldolase
- Abnormalities of nucleotide metabolism
 - Pyrimidine 5' nucleotidase (P5'N-1) deficiency
 - Adenylate kinase deficiency.

GLUCOSE-6-PHOSPHATE DEHYDROGENASE (G6PD) DEFICIENCY**Biology**

Glucose-6-phosphate dehydrogenase is a house keeping enzyme essential for basic cellular functions, including protecting red cell proteins from oxidative damage. G6PD catalyzes the first step in the hexose monophosphate shunt which is necessary for producing nicotinamide-adenine dinucleotide phosphate (NADPH). The enzymatic activity of G6PD generates NADPH that is utilized for glutathione reduction. Reduced glutathione restores hemoglobin to the soluble form. Thus, maintaining a high ratio of reduced-to-oxidized glutathione represents the major defense against oxidative damage of hemoglobin. Reticulocytes have five times higher G6PD enzyme activity than the oldest erythrocyte subpopulation.

Epidemiology and Clinical Phenotypes

Glucose-6-phosphate dehydrogenase deficiency is the most common known enzymopathy and it is estimated to affect 400 million people worldwide. Drug-induced hemolytic anemia due to G6PD deficiency has a high frequency in some populations, for example, Mediterranean's such as Sardinians 30%; south-east Asians especially Indians, Chinese, Malays, Thais, Filipinos, Melanesians; and blacks.

There is evidence to suggest that the defect confers some protection against falciparum malaria; thus it may decrease the severity of malarial infections in young children and infants. However, the mechanism of protection is unknown. Early studies of females heterozygous for G6PD deficiency showed higher levels of malaria parasites in normal compared to G6PD deficient red cells. Although malaria invasion of the cells was similar, the growth of the parasites in the G6PD deficient cells was inhibited. Similarly, conflicting results have been reported about whether hemizygous G6PD deficient males have protection against malaria. The most likely mechanism of malarial protection may be increased phagocytosis of G6PD deficient erythrocytes containing the early ring-stage parasites. In the ring-stage parasite-infected cells, the level of reduced glutathione was lower in the G6PD deficient cells compared with normal red cells, leading to membrane damage of deficient cells containing parasites that may be preferentially targeted for destruction.

G6PD deficiency is X-linked and caused by different mutations in the G6PD gene, resulting in protein variants with different levels of enzyme activity that are associated with a wide range of biochemical and clinical phenotypes. G6PD variants can be divided into three categories based on the type of hemolysis. Most common are those variants associated with acute intermittent hemolytic anemia; some of these variants are endemic. In contrast, the variants associated with CHA are very rare and the severity of hemolysis is highly variable, ranging from mild to transfusion dependent. The third type of variant is associated with no obvious risk of hemolysis. In 1967, an expert committee of the WHO proposed standard biochemical procedures for characterizing variants, such as enzyme activity, heat stability and electrophoretic pattern. After this, the WHO introduced a classification of G6PD variants into five classes according to the severity of the clinical phenotype. Class I: severe enzyme deficiency with chronic nonspherocytic hemolytic anemia; Class II: severe enzyme deficiency (less than 10% of normal); Class III: moderate-to-mild enzyme deficiency (10–60% of normal); Class IV: mild or no enzyme deficiency (60–100% of normal); and Class V: increased enzyme activity more than twice normal.

There appeared to be two types of mutations among Africans: G6PD A, a normally active enzyme with rapid electrophoretic mobility, and G6PD A⁻, an enzyme with the same mobility as G6PD A, but with diminished activity. Drug-induced hemolytic anemia in Greeks and Italians is usually due to the presence of G6PD Mediterranean. The deficiency of this enzyme is more severe

than that of the A⁺ type found in Africans, and this is reflected in susceptibility to a wider range of drugs. Affected patients may also develop neonatal jaundice and acute hemolysis on exposure to fava beans, both of which are rarely seen in Africans.

Clinical Features

Acute Hemolysis

The clinical features are those of an acute hemolytic anemia. In a subject with an acute intermittent hemolytic G6PD deficient variant, there is no clinical or laboratory evidence of hemolysis unless the individual is exposed to oxidants (drugs), infections or fava beans. The most common offending agents are drugs (**Box 2**). The severity of the hemolytic episode induced by a particular drug is, in general, related to its dose. This results in a self-limiting hemolysis, commencing in 2–3 days, and lasting for approximately 7 days, and followed by a return of the hemoglobin value to normal after 20–30 days despite continued drug administration. The self-limiting nature of the hemolysis is because RBC drug sensitivity is a function of cell age; older cells are destroyed, while younger cells are resistant. In some nonblack patients, the hemolysis is not self-limiting; in such patients withdrawal of the drug is of great importance.

Favism

Ingesting fava beans has been known since antiquity to induce hemolytic anemia in some individuals. It is characterized by acute hemolytic anemia of sudden onset, often with hemoglobinuria and mild jaundice, which occurs in persons sensitive to the fava bean, *Vicia fava*. More common in children, cases of hemolysis in breastfed infants of mothers who have ingested fava beans have been described. The degree of hemolysis varies in severity, but the anemia is usually severe; attacks last for 2–6 days, followed by spontaneous recovery, but death has been reported. Although favism occurs typically in Mediterranean people carrying the severe Mediterranean type of G6PD deficiency, it may also occur in certain non-Mediterranean persons with G6PD deficiency, including Chinese and Jews. All patients with favism are G6PD deficient, but many G6PD deficient individuals can eat fava beans with impunity. Thus, the deficiency is a necessary but not sufficient cause of hemolysis.

BOX 2 Common drugs that cause hemolysis in patients with G6PD deficiency

- *Analgesics*
 - Acetanilide
- *Antibiotics*
 - Nitrofurantoin
 - Nitrofurans
- *Antimalarial*
 - Primaquine
- *Sulfonamides*
 - Sulfacetamide
 - Sulfamethoxazole
 - Sulfanilamide
 - Sulfapyridine
 - Sulfasalazine
- *Others*
 - Methylene blue
 - Naphthalene
 - Phenylhydrazine
 - Toluidine blue
 - Phenazopyridine
 - Isobutyl nitrate.

Nonspherocytic Congenital Hemolytic Anemia

Another manifestation of G6PD deficiency was found to be hereditary nonspherocytic hemolytic anemia. They differ in severity and in hematological features, but as a group have in common the fact that spherocytes are not present on the blood film, the osmotic fragility of fresh blood is not usually increased, and splenectomy usually gives little or only moderate benefit. Most cases are due to an enzyme deficiency, although occasional cases are due to unstable hemoglobins.

Neonatal Jaundice

Glucose-6-phosphate dehydrogenase deficiency has an association with neonatal jaundice and, rarely, kernicterus in Mediterranean and Chinese infants. The jaundice is sometimes accentuated by exposure to vitamin K derivatives or other inciting drugs. Affected infants are usually mildly anemic. Quite understandably, it is commonly believed that this is a consequence of hemolysis, but in reality the hemoglobin level and reticulocyte count of the infants are generally normal, and using modern techniques it is been shown that there is only a modest and inconsistent shortening of red cell life span, which may contribute to a limited extent to the jaundice. The principal cause of neonatal icterus in G6PD-deficient infants is the inability of the liver to adequately conjugate bilirubin.

Investigations

The possibility of drug-induced hemolysis due to G6PD deficiency or favism should be considered in any patient with an unexplained acute hemolytic anemia in which the antiglobulin (Coombs) test is negative. When the diagnosis is suspected on clinical grounds, a screening test should be performed and, if possible, an enzyme assay.

Screening Tests

For diagnosis of G6PD deficiency, several screening tests are available. The principle of the test to demonstrate the presence or absence of G6PD by testing the ability of the RBCs to generate NADPH from NADP, a reaction that directly depends on the availability of G6PD.

Brilliant cresyl blue dye test NADPH reduces brilliant cresyl blue (BCB) to a colorless compound.

Methemoglobin reduction test Nitrite is used to oxidize hemoglobin to methemoglobin. Methylene blue stimulates the hexose monophosphate pathway, which if intact, supplies NADPH, which in turn reduces brown methemoglobin to red oxyhemoglobin.

Fluorescent spot test Nicotinamide-adenine dinucleotide phosphate fluoresces when activated by long-wave ultraviolet light. The screening tests satisfactorily detect hemizygous males and homozygous females.

Enzyme Assay

The enzymatic activity of G6PD can be assessed by quantitative spectrophotometric analysis. However, false-negative results are possible in milder forms of G6PD deficiency, especially if enzymatic analysis is performed shortly after resolution of acute hemolytic episodes when young erythrocytes, which have much higher enzymatic activity, predominate. The assay should be repeated 2–4 months after the hemolytic episode in patients in whom the diagnosis of G6PD deficiency is definitely suspected, despite a normal G6PD activity on assay during or shortly after hemolysis. Females heterozygous for G6PD deficiency are particularly difficult to diagnose by enzymatic assays, but now that the nucleotide substitutions of many G6PD deficient isoenzymes

have been established, molecular diagnostic methods can be used for the diagnosis of females who are heterozygous for common variants.

Therapy

Drugs that are known to precipitate hemolysis in G6PD deficient subjects should be avoided. In subjects with G6PDA⁻ deficiency, hemolysis is typically short lasting in spite of continuous use of the offending agent. This is not always the case in the more severe Mediterranean variant of G6PD deficiency, and the precipitating agent should always be withdrawn. When anemia is severe and symptomatic, blood transfusion may be necessary. Folate supplementation should be provided in those patients with chronic hemolysis.

PYRUVATE KINASE DEFICIENCY

Molecular Biology

The molecular biology of pyruvate kinase (PK) is complex. PK catalyzes the irreversible transfer of a phosphoryl group from phosphoenolpyruvate (PEP) to ADP, thus yielding pyruvate and ATP; it is a regulatory key enzyme of the glycolytic pathway. Four different PK isoenzymes (PK-M1, PK-M2, PK-L, and PK-R) are generated by the use of alternative promoters of two distinct genes (*PKLR* and *PKM*) that have variable expression in different tissues. The R isoform is unique to erythrocytes and gradually replaces the M2 isoform found in early erythroid and myeloid progenitors.

Clinical Presentation

Pyruvate kinase deficiency is the most common enzymopathy associated with CHA, and about 300 patients have been reported so far. The clinical severity of this disorder varies widely, ranging from a mildly compensated anemia to severe anemia of childhood. Affected individuals are either homozygous for the same mutation or compound heterozygotes for two different PK defects. PK deficiency is distributed worldwide, but it has been reported that the gene is more common among people of northern European extraction and perhaps Chinese and certain other ethnic and racial groups. Patients with severe hemolysis may be chronically jaundiced and may develop the clinical complications of chronic hemolytic states, including gallstones, transient aplastic anemia crises (often due to parvovirus infection), folate deficiency, and, infrequently, skin ulcers. In general, the clinical and hematological features tend to remain fairly constant in the individual patient, but there may be variation in severity in the same family; intercurrent infection, pregnancy, or surgery may cause a temporary increase in anemia.

Diagnosis

The diagnosis should be considered in any case of nonspherocytic congenital hemolytic anemia, especially when the clinical features suggest autosomal recessive inheritance. There are no specific clinical findings or morphological abnormalities in PK deficiency and no routinely available laboratory measurements aid in diagnosis. A fluorescent screening test for the diagnosis of PK deficiency is available. Specialized laboratories can perform quantitative PK enzyme analysis. Due to the large number of the mutations and their low prevalence, it is difficult to replace these tests with molecular diagnostic methods. There is often poor correlation between the enzyme level and the severity of the hemolytic anemia. Prenatal enzymatic testing is not optimal, because a large amount of fetal blood is required, and the test has a high rate of false-negative results.

Treatment

Treatment is supportive and includes folic acid supplementation in patients with mild and moderate PK deficiency. RBC transfusions may be necessary if the hemoglobin level decreases significantly, during infections, or during stress such as pregnancy or surgery. Splenectomy is indicated only for patients with severe anemia. Large doses of salicylates should be avoided in patients with severe anemia, because salicylates inhibit oxidative phosphorylation, thereby causing further ATP depletion.

GLUCOSE PHOSPHATE ISOMERASE DEFICIENCY

Glucose phosphate isomerase deficiency is the second most common erythroenzymopathy of glycolytic enzymes after PK deficiency, and approximately 50 different cases have been described to date. It is an autosomal recessive genetic disorder associated with mild to severe CHA in homozygotes or compound heterozygotes. In a very few cases, GPI deficiency is associated with neurological impairment and granulocyte dysfunction.

PYRIMIDINE 5'-NUCLEOTIDASE (P5'N-1) DEFICIENCY

Pyrimidine 5'-nucleotidase deficiency is an autosomal recessive disorder characterized by CHA with marked reticulocytosis and increased concentrations of pyrimidine nucleotides within mature erythrocytes, a characteristic RBC morphological abnormality is a heavy basophilic stippling, and its observation is very helpful for P5'N diagnosis. P5'N-1 deficiency can also be acquired as a result of lead poisoning or oxidative stress. Lead is a powerful inhibitor of P5'N and determination of lead levels should be included whenever the constellation of hemolytic anemia, P5'N deficiency, and basophilic stippling is found. Lead-induced acquired P5'N deficiency is treatable, unlike the congenital deficiency for which no therapy is available.

RBC ENZYMOPATHIES ASSOCIATED WITH METHEMOGLOBINEMIA

Methemoglobin is the derivative of hemoglobin in which the iron of the heme group is oxidized from the ferrous (Fe²⁺) to the ferric (Fe³⁺) state. The ferric hemes of methemoglobin are unable to bind oxygen and, in addition, the oxygen affinity of the accompanying ferrous hemes in the hemoglobin tetramer is increased. As a result, the oxygen dissociation curve is left shifted and oxygen delivery is impaired. Methemoglobinemia is usually a result of either enhanced methemoglobin production or decreased methemoglobin reduction. The primary reaction that reduces methemoglobin back to hemoglobin is catalyzed by the reduced form of nicotinamide-adenine dinucleotide (NADH)-cytochrome b5 reductase (b5R).

Methemoglobinemia due to b5R deficiency can be classified into two main groups with drastically different clinical manifestations. In one group, patients not unwell and the only clinical manifestation is cyanosis (hereditary b5R deficiency type I), which can be treated with the administration of methylene blue. In the other group, in addition to cyanosis there is a much more severe clinical syndrome characterized by microcephaly, opisthotonus, retarded growth and progressive neurological impairment leading to generalized hypertonía, mental retardation and death before puberty (hereditary b5R deficiency type II).

RBC ENZYMOPATHIES ASSOCIATED WITH ERYTHROCYTOSIS

Congenital erythrocytosis can result from an extremely rare RBC enzymopathy due to bisphosphoglycerate mutase (BPGM) deficiency. Only two affected families have been described so far. In both cases patients had a complete deficiency of erythrocyte BPGM, increased ATP levels, ruddy cyanosis, high hemoglobin concentration and no evidence of hemolysis.

IN A NUTSHELL

1. RBC enzyme defects are associated with three different clinical phenotypes: (i) Hemolytic syndrome associated with either chronic hemolytic anemia (CHA) or acute hemolytic crises; (ii) permanent cyanosis with methemoglobinemia and (iii) increased RBC mass or erythrocytosis.
2. Glucose-6-phosphate dehydrogenase (G6PD) deficiency is the most common enzymopathy associated with hemolytic anemia. However, patients with a longstanding CHA, one should suspect either PK deficiency or another glycolytic enzymopathy, or unstable hemoglobin.
3. In G6PD deficient individual, hemolysis usually occurs when the subject is exposed to oxidants, infections or fava beans. The most common offending agents are drugs.
4. For diagnosis of G6PD deficiency, several screening tests are available. Commonly used screening tests are brilliant cresyl blue (BCB) dye test, methemoglobin reduction test and fluorescent spot test. The enzymatic activity of G6PD can be assessed by quantitative spectrophotometric analysis.
5. Pyruvate kinase and glucose phosphate isomerase (GPI) are two other common RBC enzymes whose deficiencies result in CHA.

Chapter 38.14

Immune Hemolytic Anemia

Nita Radhakrishnan, Anupam Sachdeva

Autoimmune hemolytic anemia (AIHA) is characterized by production of antibodies directed against red blood cells (RBCs) and destruction by the mononuclear phagocytic system or complement system. Alloimmune hemolytic anemia on the other hand, occurs following exposure to red cells as in prior blood transfusion, pregnancy and transplantation. Advances in the pathogenesis and diagnostic modalities have led to refinement in the treatment of this disorder. AIHA is the most common cause of extracorporeal hemolysis in pediatric age group. AIHA observed in children is usually self-limiting and often precipitated by a viral infection. However, in adults the disease is usually secondary to autoimmune diseases, malignancy or infection, and often runs a prolonged course. Identifying the underlying disorder is very important considering the serious nature of it. Treatment aimed at specific targets in the immune system has emerged over the last decade for AIHA.

ETIOPATHOGENESIS AND APPROACH TO DIAGNOSIS

Autoimmune hemolytic anemia may also be classified into primary or secondary based on the etiology of the autoantibody. In primary AIHA there is no finding other than hemolytic anemia. Primary AIHA is further classified on the basis of the temperature at which the pathogenic antibody reacts with RBCs into warm, cold and mixed types. In secondary, an underlying cause of RBC autoantibodies can be identified (**Table 1**). Accurate diagnosis is essential for assessing the clinical features and for deciding and titrating management. The basic cause of autoantibody production is the failure of the immune system to recognize *self*. This occurs due to the failure of T-cell regulation of B-cells or due to subtle alterations in the antigenic structure of the patient's red cells. Inflammatory disorders, drugs, lymphoproliferative conditions, infections and genetic factors also contribute to initiating autoantibodies. In more than 80% of the patients, the destruction of the red cells is extravascular due to interaction of red cells coated with antibody or complement or both, interacting with

Table 1 Classification of autoimmune hemolytic anemia (AIHA)

III. Mixed type AIHA
Primary/Idiopathic
Secondary: seen in rheumatic disorders
IV. Drug-induced AIHA

mononuclear phagocytes. In the rest intravascular destruction occurs due to the interaction of red cells with lymphoid cells or granulocytes. Fixation of complement on the RBC surface leads to clearance by the reticuloendothelial system or amplification of complement cascade and formation of pores on the cell surface membrane. Serological specificity of the antibody is also clinically significant. Pan reactive autoantibody suggests that the antibody reacts to a surface antigen that is common to all human RBCs. Rh protein is the main antigenic determinant in warm reactive antibodies. IgM antibodies react against the polysaccharides on the RBC surface like I/i antigen rather than surface antigens.

Warm Autoimmune Hemolytic Anemia

Warm reactive antibodies are commonly seen in children especially in the age group 2–12 years and accounts of more than 60% of the cases. Although it is idiopathic in around half of the cases, secondary causes include infections, drug induced and autoimmune causes. Immunoglobulin G (IgG) is the class of autoantibody observed and it has maximal reactivity at 37°C. Warm AIHA may also be observed with IgA and IgM. RBCs bound to the autoantibodies, are removed in the spleen after binding to the Fc receptors within the spleen.

Cold Reactive Autoimmune Hemolytic Anemia

Cold reactive autoantibodies cause two distinct classes of AIHA; paroxysmal cold hemoglobinuria (PCH) and cold agglutinin syndrome (CAS).

Paroxysmal Cold Hemoglobinuria

Paroxysmal cold hemoglobinuria is otherwise called Donath-Landsteiner syndrome because the antibody in question is a polyclonal IgG antibody, which is a biphasic hemolysin. It activates complement at cold temperature by bringing the P antigen on the RBC. Intravascular hemolysis occurs in body temperature subsequently. PCH is commonly observed in children usually after a bout of viral respiratory illness. Previously, syphilis was identified as an etiology, but this is becoming less and less common. Infections such as mycoplasma, Epstein-Barr virus (EBV), varicella, hepatitis, mumps, cytomegalovirus (CMV), parvovirus and rubella may be ruled out.

Cold Agglutinin Syndrome

In children, CAS is much less common than warm AIHA or PCH. It occurs usually in the middle aged and elderly with a peak incidence at around 70 years of age. In CAS, hemolysis is caused primarily by C3 proteins, which lead to autoantibody-dependent lysis. Red cell phagocytosis also occurs in the liver. In CAS patients exhibit variable tendency to hemolysis and hence need for transfusions differ. The degree of hemolysis is dependent on active autoantibody concentration rather than abundant membrane bound C3 protein concentration. In CAS, the IgM antibodies bind to RBCs under cold conditions and cause their agglutination. They also initiate binding of complement to the RBC surface. The complement initiates hemolysis, which is mainly intravascular in nature. Infections and lymphoproliferative conditions are the usual secondary causes for CAS in adults. In children and young adults infectious etiology such as mycoplasma infection or infectious mononucleosis should be ruled out.

Mixed Type Autoimmune Hemolytic Anemia

Mixed type AIHA is characterized by both warm and cold antibodies that react with different RBC antigens. They account for a minor percentage of the total AIHA cases and is seen usually secondary to drugs and rheumatological conditions.

Secondary Autoimmune Hemolytic Anemia

In conditions where the reason for autoantibodies against red cells in another underlying disease, and hemolytic anemia is just one of the manifestations of this systemic illness, secondary AIHA may be considered. It is seen in patients with systemic lupus erythematosus (SLE) and other autoimmune inflammatory conditions. It also occurs in children with immunodeficiency such as common variable immunodeficiency (CVID), specific infections, certain drugs, etc. Evans syndrome is a clinical entity, which is associated with autoimmune pancytopenia although commonly red cells and platelets are most affected. Also, in children with persistent symptoms, autoimmune lymphoproliferative syndrome (ALPS) may be considered.

Drug-induced Autoimmune Hemolytic Anemia

Drug-induced AIHA is relatively rare and may go undiagnosed for a long time. Drug-induced AIHA is classified as drug dependent and drug independent AIHA, drug dependent AIHA occurs mainly due to two mechanisms: (1) Drugs such as penicillins, cephalosporins, etc., act as haptens and bind to the RBC. This drug-RBC complex is targeted by the autoantibody that results in lysis. (2) Drug autoantibody immune complexes are mediated by a complement dependent hemolysis.

Drug-dependent antibodies induce a response only when the drug is present. The antibody attaches to the drug, the drug's metabolites or the drug-RBC complex. The RBC lysis occurs via Fc receptor mediated mechanisms similar to warm AIHA. Hapten and drug adsorption mechanisms have been implicated with penicillin, cephalosporin, tetracycline, etc., whereas immune or ternary complex mechanism has been observed with cephalosporins, amphotericin B, rifampicin, probenecid, and diclofenac. Drug-independent antibodies are capable of causing an immune response even in the absence of the offending drug. Drugs such as methyldopa, cladribine and fludarabine stimulate autoantibody production, which results in RBC lysis. For treatment, discontinuation of the offending drug and supportive transfusions is usually enough. Most drugs are cleared rapidly from the body whereas the membrane bound antibodies may persist. Drugs implicated in AIHA and its pathogenic mechanisms have been detailed in **Table 2**.

CLINICAL MANIFESTATIONS

Anemia and jaundice are usual initial manifestations. Symptoms of anemia include tiredness, fatigue, dizziness and effort intolerance. The onset of symptoms is usually slow and insidious. However, especially in children the onset may be abrupt and often life-threatening. In children with PCH the presenting symptoms are abdominal pain, fever and dark colored urine that indicate

intravascular hemolysis. Exacerbation of pallor and hemolysis with hemoglobinuria is observed in cold environment with cold reactive antibody. On clinical examinations, patients with rapid onset of the disease may exhibit tachycardia and features of cardiac failure. However, unlike patients with acute onset of hemolysis such as in G6PD deficiency or malaria, anemia is usually well compensated. Splenomegaly is seen in 20% of the patients. In patients with CAS, acrocyanosis and vaso-occlusive phenomenon affecting ears, nose and fingers may be observed. In secondary AIHA, the features of the underlying disease should be looked. Lymphadenopathy, splenomegaly and hepatomegaly suggest an underlying infection, malignancy or inflammatory disorder. Children with AIHA have unremarkable past medical history and family history. History pertaining to SLE and other autoimmune inflammatory conditions must be considered and appropriate investigation should be undertaken to exclude these disorders if required.

DIAGNOSIS

Hemoglobin is usually in the range of 4-7 g% and red cell indices may be apparently normal. Microspherocytes along with large reticulocytes may falsely normalize mean corpuscular volume (MCV). In patients with cold agglutinin disease and red cell agglutination, falsely elevated MCV may be noticed. MCHC may be elevated due to the presence of spherocytes. Low platelet count should warrant a search for bone marrow failure syndromes, bone marrow infiltration, microangiopathy or Evans syndrome. Neutropenia or pancytopenia also needs further work-up for bone marrow pathology or autoimmune causes. Peripheral smear is vital in evaluating children with suspected immune hemolysis. In patients with warm AIHA, small spherocytes are observed that represent splenic remodeling of antibody coated RBCs. Presence of complement on the surface of the RBC may also induce spherocyte formation. In cold reactive AIHA, spherocytes are less frequently observed. RBC agglutination can be observed in room temperature in cases of CAS. Blood film made at 37°C shows reversal of this agglutination due to dissociation of the antibody from the red cells. Polychromasia (reticulocytosis), teardrop cells, anisopoikilocytosis and erythrophagocytosis are other features observed in peripheral smear in up to 10% of children with AIHA. Reticulocytopenia may be observed. Autoantibody acting against erythroid precursors in the bone marrow, immune mediated clearance by the macrophages in the bone marrow and coexistent parvovirus B19 infections are explanations for the unusual finding of reticulocytopenia.

Bone marrow aspiration and biopsy are generally not required for diagnosis of AIHA. However, it may be done in patients with suspicion of bone marrow failure or malignancies. If done in AIHA, bone marrow reveals erythroid hyperplasia and mild dyserythropoiesis.

Urine examination is helpful in patients who present with high colored urine. Presence of hemoglobin in the urine in the absence of red cells indicates intravascular hemolysis. In patients with chronic hemolysis, hemosiderin may be observed in the urine. Biochemical investigations reveal unconjugated hyperbilirubinemia, elevated lactate dehydrogenase and aspartate aminotransferase and low serum haptoglobin.

The most important laboratory diagnosis in patients with AIHA is the demonstration of the RBC autoantibodies and their characteristics. *Direct agglutinin test* or *Coombs test* demonstrates membrane bound immunoglobulins or fragments of complement on patient's RBCs (**Figs 1 and 2**). Polyspecific direct antiglobulin test (DAT) is done initially using antihuman gamma globulin reagent. A thorough understanding of the procedure of DAT is vital in interpreting the results and deciding further treatment. Anticoagulated RBCs from the patient are washed several times

Table 2 Pathogenesis of drug-induced autoimmune hemolytic anemia (AIHA)

1. <i>Hapten and drug adsorption mechanisms</i> : Penicillins, cephalosporins, tetracycline, oxaliplatin, tolbutamide
2. <i>Immune/tertiary complex mechanisms</i> : Metformin, quinine, quinidine, cephalosporins, amphotericin b, rifampicin, thiopental, probenecid, diclofenac and doxepin
3. <i>Autoantibody mechanism</i> : Cephalosporins, tolmetin, α-methyldopa, L-dopa, mefenamic acid, cladribine, fludarabine, lenalidomide, procainamide, diclofenac
4. <i>Nonimmunologic protein adsorption</i> : Cephalosporins, carboplatin, cisplatin
5. <i>Unknown methods of AIHA causation</i> : Phenacetin, insecticides, chlorpromazine, acetaminophen, ibuprofen, thiazides, omeprazole, carboplatin, nalidixic acid, erythromycin, streptomycin

Figure 1 Direct Coombs test/direct antiglobulin test

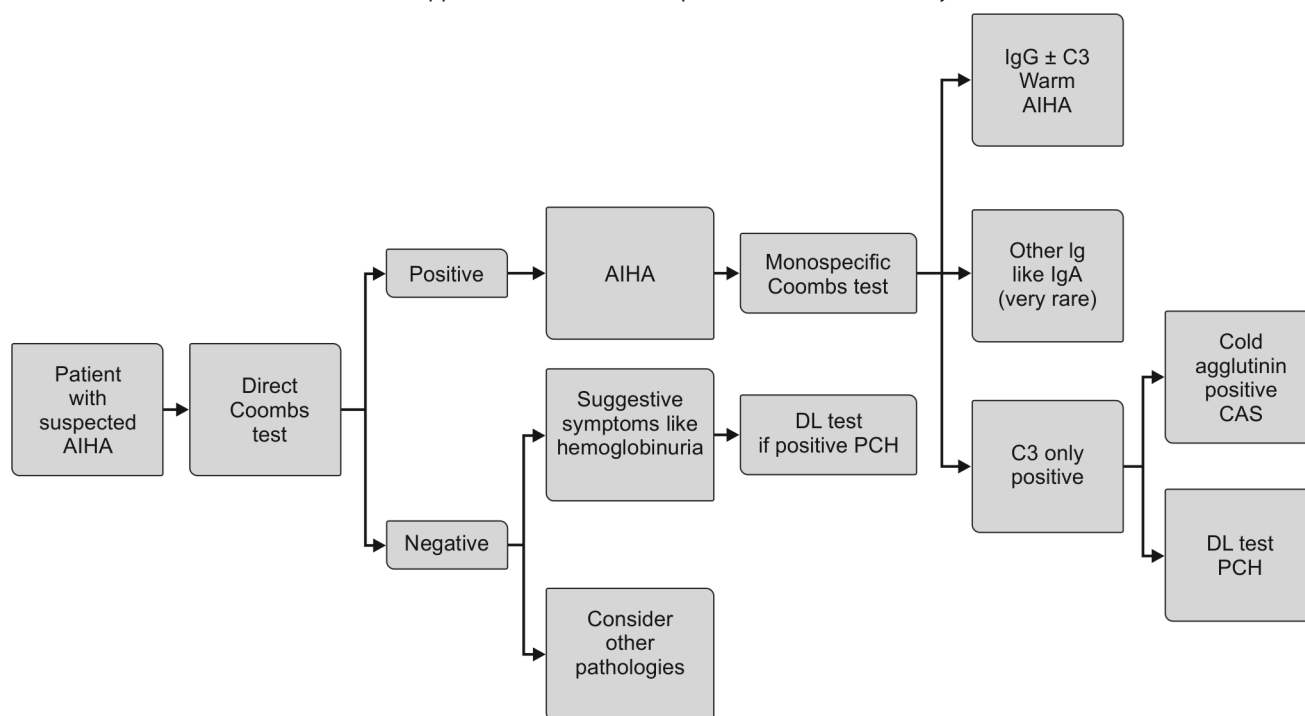

Figure 2 Indirect Coombs test/indirect antiglobulin test

to remove the plasma proteins and then incubated with Coombs reagent at 37°C. Coombs reagent contains polyclonal antiserum that is derived from rabbits that is directed against human IgG and human complement. This broad spectrum Coombs reagent helps to bridge the gap between autoantibodies on the surface of red cells. Indirect antiglobulin test detects antibodies in the serum of the patient. The detailed procedure of the test is depicted in **Figures 1 and 2**. In patients who are polyspecific DAT positive, monospecific DAT should be done to further elucidate the immunoglobulin or fraction of complement. IgG subclass determination helps more in prognostication. The vast majority of IgG antibodies are IgG1 subclass (> 70%) followed by IgG3.

Positive DAT with polyspecific Coombs reagent needs further discrimination between IgG and complement on RBC surface. The presence of IgG on the RBC with or without complement is

suggestive of warm reactive AIHA. The presence of complement alone needs to be further delineated into CAS or PCH. Serum of the patient needs to be analyzed for the presence of IgM autoantibody or IgG Donath-Landsteiner antibody. Performing the test at 37°C, 4°C, 10°C and room temperature further helps in characterizing the thermal reactivity of the antibody. DAT is scored on a scale of 1 to 4 based on the amount of agglutination. Approach to a child with suspected AIHA is detailed in **Flow chart 1**.

IgG positive DAT is typical of warm AIHA. Over 95% of warm AIHA have a positive DAT and this is consistent with the high prevalence of IgG. Among patients with warm AIHA, up to 60% have IgG antibodies alone on the RBC surface, 20–60% have IgG and C3, and 7–14% have only C3 on the RBC surface. Complement is not fixed tightly to the RBCs and thus helps to confirm warm AIHA.

Flow chart 1 Approach to a child with suspected autoimmune hemolytic anemia

Abbreviations: AIHA, autoimmune hemolytic anemia; PCH, paroxysmal cold hemoglobinuria; CAS, cold agglutinin syndrome; DL test, Donath-Landsteiner test

Direct antiglobulin test is more homogeneous in patients with CAS. Most patients have positive DAT due to the C3 on the RBC surface. Presence of IgM in the serum of the patients is suggestive of cold AIHA. This is usually accompanied by agglutination of RBCs in room temperature, which is reversed on warming. DAT demonstrates anti-C3 in patients with cold agglutinin disease. Cold autoantibodies react more at 0–4°C than at higher temperatures. The thermal amplitude and titer of the antibody is important as it predicts the degree of hemolysis. Larger thermal amplitude with activity noted at 37°C is always clinically significant. Most cold autoantibodies show specificity against the I/i antigen on the RBC surface.

Paroxysmal cold hemoglobinuria (PCH) is caused by a biphasic hemolysin that fixes complement to RBC at lower temperature but ultimately dissociates at higher temperature. Thus the DAT is positive for anti-C3, but negative for IgG at room temperature. In cases where DAT is positive due to C3 and is negative due to IgG, then further demonstration of the thermal reactivity is needed to differentiate between PCH and cold agglutinin disease. Donath-Landsteiner test (DL test) is done to demonstrate the biphasic hemolysis observed in PCH. The IgG autoantibody in this case, binds to RBCs and fixes complement at 4°C, but on warming to 37°C the complement cascade gets amplified and this leads to hemolysis. Two samples of the patient are kept at 37°C and centrifuged and serum is separated. This is then incubated with normal RBCs and a source of complement in a melting ice bath and at 37°C. Both these reactions are then again warmed to 37°C. In the sample that had cold incubation with complement, RBC lysis occurs due to binding of the antibody to RBCs and fixing of complement. In the sample that continued to be at 37°C, there is no lysis due to absent complement fixation. The actual incidence of PCH in childhood AIHA is a matter of debate. Up to 30–60% of children with AIHA have been reported in various studies as having PCH. Often PCH is not diagnosed because DL test is not ordered routinely, many

patients have negative DAT, DL test may become negative after few days and may be falsely negative if not done correctly.

Demonstration of autoantibodies that are active both at 37°C and 0–10°C are characteristic of mixed AIHA. Another observation is the presence of RBC agglutination on a peripheral smear along with positive DAT due to both IgG and C3. The red cells typically demonstrate pan reactive warm IgG antibody and the cold autoantibody against I/i antigen. In cases with drug-induced AIHA, serological diagnosis with DAT is similar to that by observed in warm AIHA. The diagnosis can be confirmed only on improvement observed on withdrawing the drug.

Drawbacks of DAT include the nonavailability of proper personnel for conducting the test, cost and the fact that it is subject to observer variation. Also, up to 10% of DAT may be falsely negative. This may be due to less density of immunoglobulins on the surface of RBCs, immunoglobulins other than IgG such as IgA, monomeric IgM and also due to technical errors. Manual DAT requires 100–500 molecules of IgG per red cell and around 400–1,100 molecules of C3d per red cell. Smaller amounts may need to be identified in some cases at diagnosis and also for following up the progress. In such cases, more sensitive techniques like enzyme linked DAT, column agglutination technology, flow cytometry and gel cards are helpful. Flow cytometry is the most sensitive of these tests and can detect even up to 35 IgG molecules per red cell.

DIFFERENTIAL DIAGNOSIS

In patients who present with anemia and jaundice, hemolytic anemia should be suspected and other causes such as microangiopathy, membrane defects and G6PD deficiency should be ruled out. In patients with positive osmotic fragility test and spherocytosis, DAT is usually done to rule out AIHA. In cases where reticulocyte count is less than expected, transient erythroblastopenia of childhood, aplastic anemia, bone marrow infiltration, etc., may be considered.

NATURAL HISTORY AND PROGNOSIS

In majority of children, the disease runs a short course and the prognosis is good. In general, cold reactive AIHA in children have a better outcome than warm AIHA. PCH runs a short course where aggressive supportive care is required. Warm AIHA may have a longer course with intermittent remissions and relapses. CAS in elderly has an indolent onset and runs a chronic course for years. Mortality in children with primary AIHA is less than 10% and more than 70% of patients have a self-limited disease. Mortality has been reported in children with chronic refractory disease probably with underlying ALPS or Evans syndrome. Factors that predict better prognosis in children include age between 2 years and 12 years, abrupt onset of symptoms, otherwise normal blood counts and lower number of reticulocytes than expected for the degree of anemia. Younger children or teenagers and those with indolent onset of symptoms tend to fare worse. Thus AIHA especially warm reactive, tends to resemble childhood immune thrombocytopenic purpura (ITP) in terms of pathogenesis, approach to treatment and prognosis. In a recent observational study from France, out of 265 children with AIHA, at a median follow-up of 3 years, it was observed that 4% children died, 285 were dependent on treatment and 39% were in complete remission. Isolated C3d positive AIHA was observed to have good prognosis IgG/IgG+C3d was associated with a lower rate of remission or survival.

TREATMENT

There are neither accepted guidelines nor definitions for response and refractoriness in AIHA. Supportive care in patients would include monitoring of vitals in children who present with cardiorespiratory compromise; transfusion of best cross-matched units as fast as possible and observation for features of intravascular hemolysis and renal shutdown. Folic acid supplementation is recommended in all, especially in warm AIHA.

Transfusing AIHA patients is often very challenging because of difficulties in ABO grouping and cross matching. Specialized tests such as allo or auto adsorption may often be required. At times it may be impossible to find a fully matched unit to transfuse. In such cases, *least incompatible* or *best matched* units may be transfused under supervision. Donor RBCs are destroyed at the same rate, as autologous RBCs. Antigen negative RBCs should be preferred in such cases. The likelihood of finding a cross matched unit is determined by the serological specificity of the antibody. In case of pan reactive antibody a proper cross-matched unit is often never found. Also, RBC units negative for I antigen and P antigen are difficult to obtain in cases of CAS and PCH respectively.

Patients with warm AIHA require immunosuppression to suppress the autoantibodies and reduce the immune hemolysis. Corticosteroids are the first line agents used. They inhibit the Fc receptor mediated clearance of sensitized erythrocytes and thus are effective within 24–48 hours of administration. They also inhibit autoantibody production, but this effect usually takes weeks. Oral prednisolone at 2 mg/kg/day or intravenous methyl prednisolone 1–2 mg/kg used 6–8 hourly may be used depending on the clinical condition. Up to 70% of children with warm AIHA respond initially to steroids and among them around 20% achieve a complete response. In these patients, steroids are tapered slowly over 2–3 months. However, steroid dependence is common and in almost one-third of the cases tapering of steroids is difficult. In patients who do not respond, or in whom tapering is not possible or in relapse, second line therapy is required. These include anti-CD20 monoclonal antibody rituximab, splenectomy or other immunosuppressive agents such as danazol, azathioprine,

cyclophosphamide, etc. Overall response after rituximab is up to 80%.

Intravenous immunoglobulin (IVIG) although an attractive option, demonstrates response only in a third of the warm reactive AIHA. Low pretreatment hemoglobin and hepatomegaly have been found to predict response to IVIG in few studies. Due to issues of cost, safety and less efficacy IVIG is not considered as a standard treatment for patients with AIHA. In patients who have recurrence after splenectomy or those who are not candidates for splenectomy, rituximab remains a reasonable alternative. Two-thirds of patients respond to splenectomy and remain transfusion free.

Cold agglutinin disease is more insidious and few patients require treatment. Keeping patients warm, wearing full sleeved clothing, covering the fingers and ears, giving blood and intravenous fluids using a blood warmer helps in reducing the extent of red cell agglutination and lysis. Using socks, earmuffs, mittens and moving to warmer climate help prevent development of acute hemolytic crisis. As most of the antibody is IgM and it remains intravascular, plasmapheresis is a treatment option in critical patients. IgM antibody being larger in size remains intravascular is amenable to removal by plasmapheresis. Also, IgM antibodies are less fixed to RBCs than IgG and are easily removed by pheresis. However, the extracorporeal circuit should be warmed in order to prevent exacerbation of agglutination. Steroids and splenectomy are less effective. Hemolysis is usually intravascular, if at all extravascular is usually the liver. Rituximab may be used in acutely ill symptomatic patients. Rituximab shows a response in up to 50% of patients treated and the median duration of remission is 11 months. Combination of rituximab and fludarabine although more toxic, has also been reported to show response in up to 75% patients. Cyclophosphamide, chlorambucil, interferon, etc., are agents that have been found beneficial in CAS. Eculizumab, traditionally used in patients with paroxysmal nocturnal hemoglobinuria has been studied in patients with CAS and shown to reduce hemolysis by blocking the C5 complement.

Treatment of PCH is only supportive as most cases are self-limited. In drug induced AIHA, removal of the offending drug is often the only treatment required. Steroids are not required and other treatment modalities discussed earlier are also of questionable benefit. Occasionally it may take months of removal of the drug in order to get a complete resolution.

Management of chronic refractory AIHA is often very difficult, there are no accepted algorithms or practice guidelines. Treatment is often individualized based on the hematological response and side effect profile. Rituximab is a relatively safe option for chronic patients. Rituximab eliminates circulating B-cells, thus eliminating the autoreactive B-lymphocytes.

IN A NUTSHELL

1. Autoimmune hemolytic anemia (AIHA) is an uncommon disorder in children with varying severity.
2. The diagnosis is based upon immune-hematological investigations including characterization of autoantibodies.
3. Grouping and cross matching pack cell transfusion is difficult. Most compatible leukodepleted blood should be transfused under close supervision.
4. Steroids are first line of therapy.
5. Rituximab is relatively safe and it eliminates circulating autoreactive B-lymphocytes.
6. Immunosuppressive drugs may be used in children who fail to respond to steroids.
7. Children with AIHA required long-term follow-up.

Chapter 38.15

Physiology of Hemostasis

Renu Saxena, Neha Singh

Hemostasis refers more widely to the process whereby blood coagulation is initiated and terminated in a tightly regulated fashion, together with the removal of the clot as part of vascular remodeling. Hemostasis preserves vascular integrity by balancing the physiologic processes that maintain blood in a fluid state under normal circumstances and prevent excessive bleeding after vascular injury. It depends on an intact vascular endothelium and a complex series of regulatory pathways that maintain platelets in a quiescent state and keeps the coagulation system in check.

Vascular damage begins with the initiation of clotting with the goal of producing a localized fibrin-platelet plug to prevent blood loss: this action is followed by processes that lead to clot containment, wound healing, clot dissolution, tissue regeneration and remodeling. In healthy persons, all these reactions occur simultaneously and in a balanced fashion, such that bleeding is contained, yet blood vessels simultaneously remain patent to deliver adequate organ blood flow. When any of these hemostatic processes is disrupted, because of inherited defects or acquired abnormalities, disordered hemostasis may result in bleeding or thrombosis.

Blood flow in the arterial and venous system is disparate and imposes different needs on the coagulation system. In the pressurized arteries, relatively minor vascular damage can result in massive blood loss, the procoagulant response in arteries must rapidly arrest bleeding. Platelets are critical to this arterial response. They initially limit blood loss and then provide an active surface for soluble clotting factors to both localize and accelerate fibrin clot formation. By contrast, in the venous circulation, the slower flow rates produce slower bleeding, a feature that makes platelets less critical. Instead controlling the balance of the venous system is most dependent on the rate of thrombin generation.

The four major components of the hemostatic system are the vascular endothelium, platelets and the coagulation and the fibrinolytic systems (**Fig. 1**). The general sequence of events in hemostasis at a site of vascular injury are:

- Endothelial injury exposes highly thrombogenic subendothelial extracellular matrix (ECM), facilitating platelet adherence and activation. Activation of platelets results in shape change, as well as the release of secretory granules. Within minutes the secreted products recruit more platelets for aggregation to form a hemostatic plug; this process is referred to as *primary hemostasis*.
- Tissue factor (TF) is also exposed at the site of injury. It is a membrane-bound procoagulant glycoprotein synthesized by endothelial cells (ECs). It acts in association with factor VII as the major *in vivo* initiator of the coagulation cascade, eventually resulting in thrombin generation. Thrombin cleaves circulating fibrinogen into insoluble fibrin, creating a fibrin meshwork, and also induces additional platelet recruitment and activation. This sequence, *secondary hemostasis*, consolidates the initial platelet plug.
- Polymerized fibrin and platelet aggregates form a solid, permanent plug to prevent any further hemorrhage. At this stage, counter-regulatory mechanisms [e.g., tissue plasminogen activator (t-PA)] are set into motion to limit the hemostatic plug to the site of injury (*tertiary hemostasis*).

Figure 1 Four important components of the hemostatic system

VASCULAR ENDOTHELIUM

The endothelium forms a continuous monolayer at the interface between blood and tissue, contributing significantly to sensing and transducing of signals and maintenance of a nonthrombogenic surface permitting flow of blood. It is a dynamic organ that actively regulates hemostasis by inhibiting platelet aggregation, suppressing the activation and propagation of coagulation, enhancing fibrinolysis and modulating vascular tone and permeability. Conversely, when injured or under inflammatory conditions, the endothelium may become procoagulant. Defective vascular function can lead to bleeding if the endothelium becomes more permeable to blood cells, if vasoconstriction does not occur, or if premature degradation of hemostatic plugs opens seals in the vasculature. The anticoagulant functions of endothelium are (**Fig. 2A**):

Platelet Inhibition

Endothelial cells (EC) synthesize prostacyclin and nitric oxide which serve as potent vasodilators and also inhibit platelet activation and subsequent aggregation by stimulating adenylate cyclase and increasing the intracellular levels of cyclic adenosine monophosphate (cAMP). In addition, ECs also express CD39, which is a membrane associated ADPase. It attenuates platelet activation by inhibiting adenosine diphosphate (ADP), which is a platelet agonist.

Anticoagulant Action

Endothelial cells use three important mechanisms to inhibit thrombin generation and limit coagulation. Heparin sulfate proteoglycans secreted into the luminal surface of ECs, are capable of binding and activating antithrombin III, thus accelerating the inactivation of thrombin, factor Xa and factor IXa. Thrombomodulin on the surface of ECs binds thrombin. Once bound, the thrombin-thrombomodulin complex gains the ability to activate protein C to its active form-activated protein C (APC). APC, along with its cofactor protein S, phospholipid surface and calcium ions, acts to down-regulate thrombin generation by proteolyzing factor Va and factor

Figure 2A Depicts the anticoagulant properties of the vascular endothelium

Abbreviations: PGI₂, prostacyclin; NO, nitrous oxide; cAMP, cyclic adenosine monophosphate; TFPI, tissue factor pathway inhibitor; t-PA, tissue plasminogen activator

VIIIa. ECs synthesize tissue factor pathway inhibitor (TFPI), which is a serine protease inhibitor, that modulates TF initiated coagulation by directly inhibiting the TF-factor VIIa-factor Xa complex.

Fibrinolytic Activity

The vascular endothelium promotes fibrinolysis by synthesizing and releasing tissue-type and urokinase-type plasminogen activator (t-PA and u-PA), which initiate fibrinolysis by converting plasminogen (PLG) into plasmin.

Perturbation of the vascular lining by inflammatory mediators such as interleukin-1, tissue necrosis factor, converts the endothelium from a nonthrombogenic to a procoagulant surface by down-regulating the anticoagulant mechanisms and shifting the equilibrium towards procoagulant properties (**Fig. 2B**).

Platelet Activation

When endothelium is physically damaged or becomes activated, the balance of coagulant properties is shifted to procoagulant state. This function is mediated by endothelium and the underlying subendothelial matrix that is exposed by vascular injury. Activated endothelium expresses adhesive ligands on their surface including selectins, beta 1 and beta 2 integrins and von Willebrand factor (vWF) multimers. On the endothelial surface, vWF multimers localize and promote platelet adhesion whereas integrins mediate adhesion and subsequent transendothelial migration of leukocytes into the tissues. Exposed subendothelial matrix also bind vWF multimers and contain other adhesive procoagulant proteins, i.e., thrombospondin, fibronectin and collagen, which serve as ligands to capture platelets. Collagen, in particular is a platelet ligand and as well as platelet agonist. It causes platelets to undergo dense granule release and to express conformationally active ligands such as glycoprotein IIb/IIIa.

Procoagulant Effects

In response to cytokines or bacterial endotoxin, ECs synthesize *TF*, the major activator of the extrinsic clotting cascade, which is constitutively expressed by subendothelial muscle cells and fibroblasts. In addition, activated ECs augment the catalytic function of activated coagulation factors IXa and Xa.

Antifibrinolytic Effects

It also produces type I plasminogen-activator-inhibitor (PAI-I). Which is the major regulator of t-PA and u-PA. It blocks the ability

Figure 2B Depicts the procoagulant functions of the vascular endothelium in response to injury

Abbreviations: TAFI, thrombin-activatable fibrinolytic inhibitor; PAI-1, plasminogen-activator-inhibitor-1; vWF, von Willebrand factor; TF, tissue factor

of t-PA to turn on plasmin, the primary enzyme of fibrinolysis. Also, the thrombin-activatable fibrinolytic inhibitor (TAFI) is cleaved to its active form by the thrombin-thrombomodulin complex on endothelial surface which further catalyzes the removal of lysine residues from the fibrin clot, making it less recognizable as a substrate for plasmin. Fibrinolysis localizes to the endothelial surface because these cells express annexin II, which acts as a coreceptor for PLG and t-PA and promotes their interaction.

PLATELETS

Platelets are discoid anucleate particles arising from megakaryocytes in the bone marrow that play a critical role in hemostasis and thrombosis. Platelets ordinarily circulate in the bloodstream in a quiescent state but undergo *explosive* activation following damage to the vessel wall, leading to rapid formation of a platelet aggregate or vascular plug and occlusion of the site of damage. Damage to the intimal lining of the vessel exposes the underlying subendothelial matrix. Platelets home to such sites of vascular disruption and adhere to the exposed matrix proteins. Adherent platelets undergo activation and release substances that recruit additional platelets to the site of injury as well as promote thrombin generation and fibrin clot formation.

Platelet Adhesion

Platelets adhere to exposed collagen and vWF and form a monolayer that supports fibrin formation. It depends upon constitutively expressed receptors on the platelet surface, $\alpha 2\beta 1$ and glycoprotein VI, which bind collagen and GPIIb/IIIa, which bind vWF. vWF is synthesized by ECs and megakaryocytes and assembles into multimers.

When released from Weibel-Palade bodies of the ECs or α -granules of platelets, most of the vWF enters the circulation but the vWF released from the abluminal surface of the ECs accumulates in the subendothelial matrix, where it binds collagen via its A3 domain. This surface-immobilized vWF can simultaneously bind platelets via its A3 domain. The larger vWF multimers provide additional binding sites for collagen and enhance platelet adhesion because platelets have higher vWF receptors than collagen receptors.

Platelet Activation and Secretion

Adhesion to collagen and vWF initiates signals leading to platelet activation, mainly cyclooxygenase dependent synthesis and

release of thromboxane A₂, and the release of ADP from storage granules, which recruit platelets to the site of injury. To activate platelets, both thromboxane A₂ and ADP must bind to their own G-protein-coupled receptors (TP and P2Y₁₂), respectively. This results in an increase in the intracellular calcium concentration within the platelets, thus inducing a shape change. Shape change is mediated by phosphorylation of myosin light chains, either as a consequence of elevation in intracellular Ca²⁺ ions, which activate myosin light chain kinase, or through inhibition of myosin light chain phosphatase, which is regulated downstream of Rho kinase.

Activated platelets promote coagulation by expressing phosphatidylserine on their surface, which is an anionic phospholipid that supports assembly of coagulation factor complexes, thereby triggering thrombin generation and subsequent fibrin formation. They also cause stabilization of clot by releasing factor V, factor XI, fibrinogen and factor XIII.

Activated platelets also release vWF, fibronectin and thrombospondin which may augment platelet adhesion at sites of injury as well as platelet-derived growth factor (PDGF) and transforming growth factor-beta (TGF-β), which promote wound healing.

Platelet Aggregation

Platelet aggregation links platelets to form clumps. GPIIb/IIIa mediates these platelet to platelet linkages. On nonactivated platelets, GPIIb/IIIa exhibits minimal affinity for its ligands. Upon platelet activation, GPIIb/IIIa undergoes a conformational change, which reflects transmission of inside-out signals from its cytoplasmic domain to its extracellular domain, enhancing its affinity for ligands such as fibrinogen and vWF. Arginine-glycine-aspartic acid (RGD) sequences on fibrinogen and vWF as well as platelet binding lysine-glycine-aspartic acid (KGD) sequence on fibrinogen mediate their interaction with GPIIb/IIIa, divalent fibrinogen and multivalent vWF molecules serve as bridges to and bind adjacent platelets together. After being bound to GPIIb/IIIa, fibrinogen and vWF induce signals that augment platelet activation and result in activation of additional GPIIb/IIIa receptors, creating a positive feedback loop.

COAGULATION CASCADE

Coagulation results in the generation of thrombin, which converts soluble fibrinogen into an insoluble fibrin clot. Coagulation occurs through the action of discrete enzyme complexes, which are composed of a vitamin K-dependent enzyme and a nonenzyme cofactor, and assemble on anionic phospholipid membranes in a calcium-dependent manner. The important enzyme complexes involved in thrombin generation include extrinsic tenase, intrinsic tenase and prothrombinase complex comprising of TF-VIIa-IX-X, VIII-IXa-X, and V-Xa-II respectively.

Factors II, VII, IX, and X (as well as proteins C, S, and Z) are the zymogen forms of vitamin K-dependent serine proteases. Vitamin K is a necessary cofactor for a post-translational modification that adds a carboxyl group to the 10–12 glutamic acid residues in the amino terminal portion of each of these proteins. The vitamin K-dependent proteins utilize these clusters of γ-carboxyl glutamic acid (Gla) residues to adhere to phospholipid surfaces and assemble multimolecular coagulation complexes. Without this important post-translational modification, the assembly of cell-based coagulation complexes is impaired, leading to ineffective fibrin formation. Calcium and phospholipid (a platelet membrane constituent) are required for the tenase and prothrombinase complexes to function. Calcium mediates the binding of the complexes via the terminal gamma-carboxy residues on FXa and FIXa to the phospholipid surfaces expressed by platelets, as well as procoagulant microparticles or microvesicles shed from them. Calcium is also required at other points in the coagulation cascade.

Table 1 shows the list of all the coagulation proteins involved in formation of a fibrin clot.

Blood coagulation is traditionally classified into *extrinsic* and *intrinsic* pathways that converge on the activation of factor X (**Fig. 3**). The extrinsic pathway was so designated because it required the addition of an exogenous trigger (originally provided by tissue extracts); the intrinsic pathway only required exposing factor XII (Hageman factor) to thrombogenic surfaces (even glass would suffice). However, such a division is largely an artifact of in vitro testing; there are, in fact, several interconnections between the two pathways. Moreover, the extrinsic pathway is the most physiologically relevant pathway for coagulation occurring when vascular damage has occurred; it is activated by *TF* (also known as *thromboplastin* or factor III), a membrane-bound lipoprotein expressed at sites of injury. *TF* initiated coagulation has two phases—an initiation phase and propagation phase.

Initiation Phase

It begins as the exposed *TF* binds to activated VIIa, in a 1:1 ratio, picomolar amounts of which is in the circulation at all times to form extrinsic tenase complex (*TF*-VIIa). This complex catalyzes the conversion of very small amounts of *FX* to *FXa*, which in turn generates nanomolar amounts of thrombin. Extrinsic tenase activates factor X and IX to their activated forms through cleavage of an activation peptide. This seemingly trivial amount of thrombin during the initiation phase sparks the inception of the propagation phase, successful completion of which results in extensive thrombin generation and fibrin deposition. Once the pathway commences, the *TF*/factor VIIa activation of factor X is rapidly shut down by an inhibitor produced by ECs, *TFPI*.

Table 1 List of coagulation proteins involved in the formation of a fibrin clot

Coagulation proteins	Function
Fibrinogen (Factor I)	Adhesive protein that forms the fibrin clot
Prothrombin (Factor II)	Main enzyme of coagulation in activated form
Tissue factor (Factor III)	Initiator of extrinsic pathway
Calcium ions (Factor IV)	Metal cation necessary for coagulation reactions
Factor V (labile factor)	Cofactor for activation of prothrombin to thrombin
Factor VII (proconvertin)	Initiates extrinsic pathway with tissue factor
Factor VIII (antihemophilic factor)	Cofactor for intrinsic activation of factor X
Factor IX (Christmas factor)	Enzyme for intrinsic activation of factor X
Factor X (Stuart-Prower factor)	Enzyme for final common pathway activation of prothrombin
Factor XI (plasma thromboplastin antecedent)	Intrinsic activator of factor IX
Factor XII (Hageman factor)	Starts aPTT-based intrinsic pathway
Factor XIII (fibrin stabilizing factor)	Transamidase that cross links fibrin clot
High molecular weight kininogen	Cofactor
Prekallikrein (Fletcher factor)	Acts at the beginning of aPTT-based intrinsic pathway

Abbreviation: aPTT, activated partial thromboplastin time.

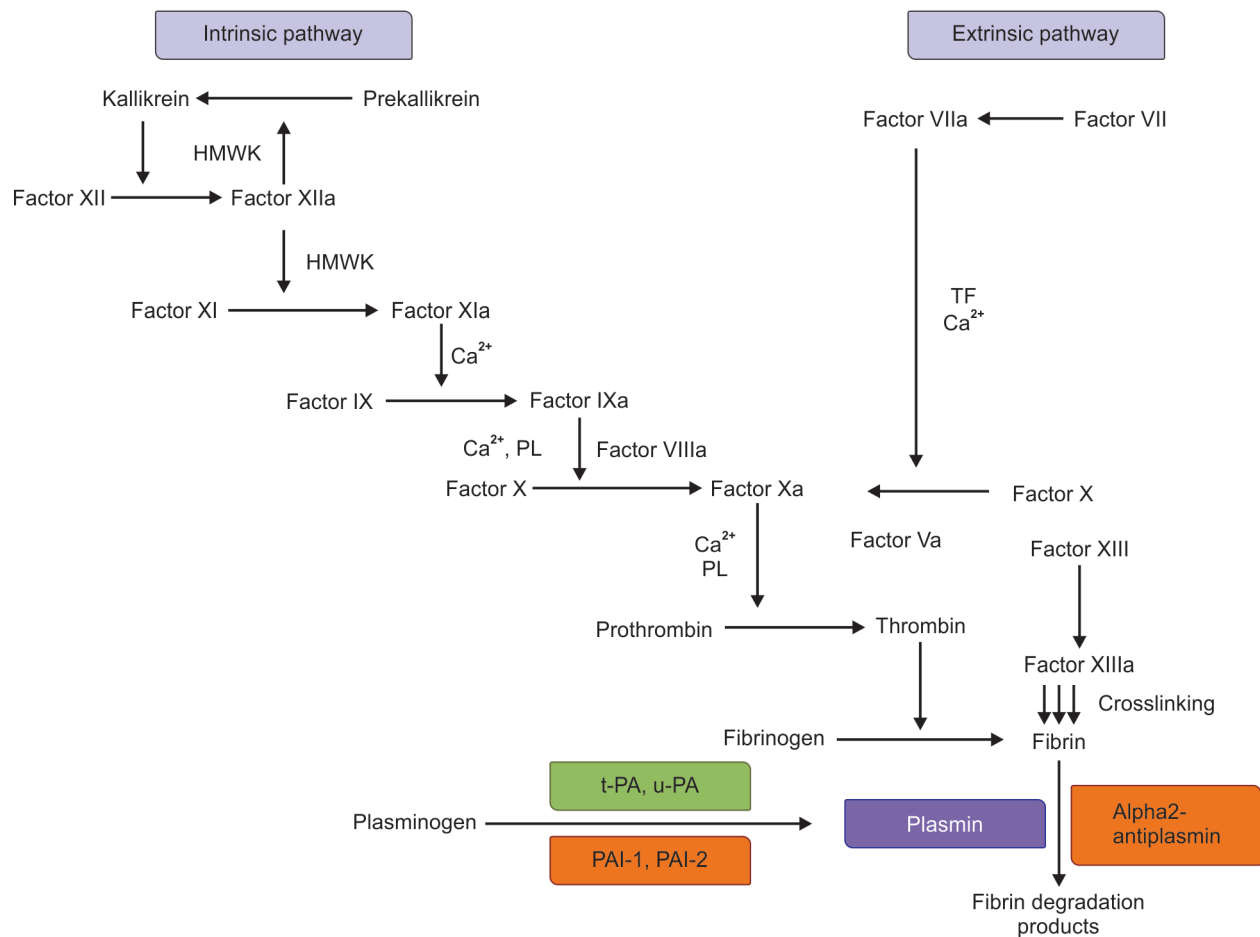

Figure 3 Coagulation and fibrinolytic pathways

Inhibitory proteins are indicated in orange

Abbreviations: HMWK, high molecular weight kininogens; Ca²⁺, calcium; PL, phospholipids; TF, tissue factor; t-PA, tissue plasminogen activator; u-PA, urokinase plasminogen activator; PAI-1, plasminogen activator inhibitor 1; PAI-2, plasminogen activator inhibitor 2.

Propagation Phase

Thrombin generated during the initiation phase is a potent platelet activator supplying the developing clot with a activated platelet surface membrane and abundant platelet-released factor V which is promptly activated to Va by thrombin. Factor VIII, conveniently shifted to the bleeding site by its carrier vWF, is also activated by thrombin. Factor VIII then complexes with picomolar amounts of FIXa generated by TF-VIIa complex during the initiation phase to create FVIIIa-FIXa complex (intrinsic tenase complex). Formation of this complex on the platelet surface heralds the switch of the primary path of Xa generation from extrinsic tenase (TF-VIIa) to intrinsic tenase (VIIIa-IXa). This has significant kinetic advantage, with intrinsic pathway exhibiting 50 fold higher efficiency than the extrinsic pathway.

The activation of factor X-Xa starts the final, common pathway for thrombin activation. Factor Xa combines with the cofactor, factor Va, together with calcium on phospholipid surfaces to form the prothrombinase complex. This complex then effects the conversion of prothrombin to thrombin by cleavage of an activation peptide, prothrombin F 1.2. Activation of factors V and VIII by thrombin results in a further burst of coagulation activity through increased activity of the tenase and prothrombinase complexes.

Fibrinogen is the ultimate substrate protein of the coagulation cascade and forms the principal structural protein of the fibrin clot. Fibrinogen, produced in the liver, is a dimer composed of three pairs of protein chains, A α , B β , and γ , that are disulfide

linked at their N-terminal ends. Thrombin cleaves small peptides, termed fibrinopeptides A and B, from the A α and B β chains, respectively, to form a fibrin monomer. These monomers assemble into protofibrils in a half-staggered, side-to-side fashion that is stabilized by noncovalent interactions between fibrin molecules. The protofibrils laterally associate into thicker fibrin fibers and form the fibrin clot. This clot, however, is not stable and ultimately will come apart if not covalently cross-linked. Thrombin activates factor XIII to the transglutaminase enzyme factor XIIIa. Factor XIIIa, acting upon the glutamic acid and lysine side chains in the fibrin amino acid sequence, creates covalent bonds between fibrin monomer γ chains, creating a stable clot.

Once activated, the coagulation cascade must be restricted to the site of vascular injury to prevent runaway clotting of the entire vascular tree. Besides restricting factor activation to sites of exposed phospholipids, three important categories of endogenous anticoagulants also control clotting (**Table 2**).

- Antithrombins (e.g., antithrombin III) inhibit the activity of thrombin and other serine proteases, including factors IXa, Xa, XIa, and XIIa. Antithrombin III is activated by binding to heparin-like molecules on ECs.
- Proteins C and S are vitamin K-dependent proteins that act in a complex that proteolytically inactivates factors Va and VIIIa. Protein C activation by thrombomodulin was described earlier.
- TFPI is a protein produced by endothelium (and other cell types) that inactivates TF-factor VIIa complexes.

Table 2 List of blood coagulation regulatory molecules

Regulatory proteins in coagulation	Function
Protein C	Anticoagulant protease
Protein S	APC cofactor and coagulation inhibitor
Thrombomodulin	Receptor for protein C/thrombin
Endothelial protein C receptor	Receptor for protein C/APC
Protease activated receptor-I	G-protein coupled inhibitor
Antithrombin	Protease inhibitor
Tissue factor pathway inhibitor	Protease inhibitor
Heparin cofactor-II	Protease inhibitor
Protein Z	Protease inhibitor
Protein Z-dependent protease inhibitor	Protease inhibitor

Abbreviation: APC, activated protein C.

FIBRINOLYTIC SYSTEM

Activation of the coagulation cascade also sets into motion a fibrinolytic cascade that moderates the size of the ultimate clot. Fibrinolysis initiates when PLG activators convert PLG into plasmin, which then degrades fibrin into soluble fragments (**Fig. 3**). Blood contains two immunologically and functionally distinct PLG activators, t-PA and u-PA. Whereas t-PA mediates intravascular fibrin degradation, u-PA binds to a specific u-PA receptor (u-PAR) on the surface of cells, where it activates cell-bound PLG. Pericellular proteolysis during cell migration and tissue remodeling and repair are the main functions of u-PA. Regulation of fibrinolysis occurs at two levels:

PAI-1 and PAI-2 Inhibit the Plasminogen Activators

Endothelial cells synthesize PAI-1, which inhibits both u-PA and t-PA whereas monocytes and placenta synthesize PAI-2, which specifically inhibits u-PA. PAI-1 inhibits its target proteinases by formation of a 1:1 stoichiometric reversible complex, followed by covalent binding between the hydroxyl group of the active site serine residue of the proteinase and the carboxyl group of the P1 residue of the serpin. Highly positively charged regions in t-PA and in u-PA are involved in the rapid interaction. PAI production is increased by thrombin as well as certain cytokines, and probably plays a role in the intravascular thrombosis accompanying severe inflammation.

α 2-Antiplasmin Inhibits Plasmin

It forms a stable 1:1 complex with plasmin, in which the protease is completely inactivated. In addition to inactivating preformed

plasmin, α 2-AP retards fibrinolysis by reducing PLG activation and by *masking* the lysine binding sites through which PLG interacts with fibrin.

IN A NUTSHELL

1. The coagulation pathway is a complex interaction of many elements—the endothelium, coagulation factors, and platelets—with the ultimate goals of stemming the loss of blood at the site of an injury and laying the groundwork for injury repair and healing.
2. Bleeding will occur if there is failure to seal vascular leaks because of defective hemostatic plug formation or their premature breakdown.
3. In contrast, thrombosis may occur if prothrombotic stimuli are unregulated. Control of coagulation reactions is essential for normal hemostasis.
4. Pathologic thrombosis occurs when the protective clot is extended beyond its beneficial size, when a clot occurs inappropriately at sites of vascular disease, or when a clot embolizes to other sites in the circulatory bed.
5. For normal hemostasis, both procoagulant and anticoagulant factors must interact with the vascular components and cell surfaces, including the vessel wall and platelets.
6. Moreover, the action of the fibrinolytic system must be integrated with coagulation reactions for timely formation and dissolution of blood clots.

Chapter 38.16

Bleeding and Coagulation Disorders

Tulika Seth

A bleeding child is not an uncommon problem; this can occur in many ill or even apparently well looking children. Bleeding episodes cause fear and alarm to the child and family. The etiology of bleeding is varied and ranges from immune thrombocytopenia, medications which interfere with platelet function, inherited coagulation factor defects, to disseminated intravascular coagulation (DIC). Sometimes even bone marrow failure or an underlying malignancy may be the cause, and it is always of extreme urgency to identify the etiology and provide definitive treatment. Hence due to the vast etiological causes a good assessment and approach is needed to evaluate the child, so as to speedily reach a diagnosis and limit the number of tests.

Initial assessment of a bleeding patient involves evaluation of the vitals and hemodynamic status. Stabilization is a priority, as most tests can be performed even after fluid resuscitation or even blood transfusion, if necessary. Attempt to control the bleeding, if blood loss is significant and give fluid resuscitation. In presence of significant blood loss, packed red cell transfusions may be given. If a coagulation defect is suspected, promptly send samples for baseline coagulation tests and give fresh frozen plasma (FFP), to control the bleeding. If platelet dysfunction like Glanzmann thrombasthenia is suspected, give platelet transfusions after sending sample. If samples cannot be sent prior to FFP, it is important to stabilize child in a life threatening situation, the required tests can be performed later, in consultation with the hematologist.

EPIDEMIOLOGY AND ETIOLOGY

The causes of bleeding and coagulation disorders is extremely varied; it stretches from acquired nutritional deficiency like scurvy, to viral infections like dengue. From inherited disorders, like X-linked hemophilia A and B and rare factor autosomal recessive deficiency states like factor X and XIII deficiency, and platelet function disorders, to von Willebrand disease (vWD) an autosomal dominant condition. Bleeding can be associated with aplastic anemia, childhood malignancies and hepatic or renal dysfunction. DIC can be seen in children due to a wide variety of causes. The incidence of hemophilia A is about 1 in 5,000 boys, whereas the incidence of hemophilia B is less common about 1 in 30,000 boys. The incidence of many of the rarer factor deficiencies has little data from India, and many cases may go uninvestigated.

The true incidence of aplastic anemia and inherited bone marrow failure syndromes (IBMFS) is not known in India but is thought to be higher than that mentioned in western literature. Hence, it is important to have a high index of suspicion and follow the given algorithms so as to not miss a bleeding or coagulation disorder. Child abuse is often missed and unusual bruising and frenulum injury may point to nonaccidental trauma.

PATHOPHYSIOLOGY

The normal coagulation cascade (see chapter 38.15) requires all factors to be present in the normal range. Any defect can lead to disturbances in clotting (**Table 1**). Risk factors strongly associated with inherited hemophilia include family history (from the maternal side), male sex, and history of recurrent or severe

bleeding. Musculoskeletal bleeding is the hallmark of hemophilia. Low platelet count is seen in immune thrombocytopenic purpura (ITP), aplastic anemia, leukemia, etc. Adequate platelet number and function is also important to control bleeding.

CLINICAL FEATURES

Children with bleeding may have an inherited or acquired defect. A detailed bleeding history is an essential part of the work up, this includes the child's age at presentation, sex, clinical manifestation, past history and family history, response to prior trauma, minor surgery and medications. A detailed description of type of bleeding, sites, seriousness of bleeds and need for prior intervention for bleeding episodes is required to differentiate between platelet and coagulation disorders (**Table 2**). An excessive bleeding response to commonly encountered challenges suggests the possibility of an underlying bleeding disorder. Certain inherited genetic conditions (**Box 1**) are associated with bleeding; presence of phenotypic features may assist in suspecting such conditions, which can be confirmed by diagnostic tests (**Flow charts 1 and 2**). This helps in narrowing down the evaluation and identification of the possible defect in coagulation mechanism and prioritizing relevant diagnostic tests.

Mucocutaneous bleeds, such as petechiae, purpura, epistaxis and oral bleeding are characteristic of platelet and blood vessel disorders. Soft tissue, muscle or joint hematomas are suggestive of coagulation factor deficiency like hemophilia. Early childhood bleeding occurs most frequently in congenital disorders, while a later presentation is more likely to be associated with acquired disorders. A child who is clinically ill may have sepsis and DIC.

Acute massive mucocutaneous bleeding in a patient previously without symptoms should suggest ITP. Massive bruising and oozing from multiple sites in an otherwise asymptomatic patient might suggest accidental warfarin ingestion. Postoperative bleeding at a surgical site is usually related to a local surgical problem. Spontaneous or excessive post-traumatic bleed, if immediate, can indicate a localized pathologic process and if delayed after 2–3 days, without infection is usually due to a hemostatic deficiency, like hemophilia, even in mild hemophiliacs. Serious bleeding episodes including intracranial, massive gastrointestinal, bleeding in neck and retroperitoneal bleeds, need urgent investigation and warrant a complete coagulation workup. These sites of hemorrhage may not be diagnosed easily and can lead to shock and even death.

DIFFERENTIAL DIAGNOSES

The most common presentation of bleeding is epistaxis, but not every child with epistaxis needs a full coagulation disorder work up. Hence it is important to evaluate the child and see if this is a local problem or more sinister.

A typical episode of epistaxis in a child is usually minor bleeding, which resolves spontaneously or with pressure. It usually occurs on one side of nose only, rarely leads to anemia or hospitalization. No other sites of bleeding are present. Though, some cases may need repeated attention, if nose picking, repeated upper respiratory tract infections or if Little's area is affected. They show good response to cautery, local application of vasoconstrictor or nasal packing. If there is profuse bleeding or it persists despite nasal packing, the child is more likely to have a coagulopathy. Also, the child is more likely to have either coagulation or bleeding defect if other sites of bleeding and ecchymoses are present. Possible causes of coagulopathy include primary disorders of coagulation (e.g., hemophilia, vWD), liver disease, and medicines that impair clotting [e.g., aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), warfarin].

Table 1 Conditions associated with abnormal coagulation assays

Condition	Platelet count	Prothrombin Time	aPTT	Thrombin time	Other tests
Hemophilia A or B	Normal	Normal	Prolonged	Normal	Specific assay for factor VIII or IX
von Willebrand disease	Normal decreased in type 2 N	Normal	Prolonged or normal	Normal	Platelet function assay Factor VIII and vWF low and impaired ristocetin-induced platelet aggregation
Disseminated intravascular coagulopathy	Low	Prolonged	Prolonged	Grossly prolonged	D-dimer and FDP raised
Massive transfusion	Low	Prolonged	Prolonged	Normal	
Oral anticoagulants (Warfarin)	Normal	Grossly prolonged	Prolonged	Normal	
Liver disease	Low	Prolonged	Prolonged	Normal (rarely prolonged)	Liver function tests abnormal
Unfractionated Heparin	Normal (rarely low)	Normal	Prolonged	Prolonged	
Low molecular weight heparins	Normal	Normal	Normal	Normal	Specific anti-Xa assay, needs monitoring in neonates and in presence of renal dysfunction.

Table 2 Differentiation of mucosal versus deep bleeding by historical facts in patients with suspected coagulation or platelet disorders

Pertinent questions	Deep bleeds (coagulation factor disorders)	Mucosal bleeding (Platelet disorders and von Willebrand disease)
Hemarthrosis, muscle bleeds	Very common	Rare
Bruising on trunk and limbs	Large bruises	Small bruises, petechiae (rarely large if due to trauma)
Bleeding from cuts	Relatively slight	Profuse
Nosebleeds, oral bleeds, history of heavy menstrual bleeding	Uncommon	Common, frequently profuse and of long duration
Bleeding after surgery or dental extraction	After 1 or 2 days	Immediate
Gastrointestinal bleeding	Uncommon	Common
Hematuria	Common	Rare

BOX 1 Clinical syndromes associated with inherited bleeding disorders**Thrombocytopenia**

1. Wiskott-Aldrich syndrome—eczema, immunodeficiency and thrombocytopenia
2. Thrombocytopenia with absent radii, amegakaryocytic thrombocytopenia with radioulnar synostosis skeletal defects
3. DiGeorge/velocardiofacial syndrome—cleft palate, cardiac defects, facial anomalies, learning disabilities
4. Paris-Trousseau/Jacobsen syndrome—cardiac defects, craniofacial anomalies, mental retardation
5. X-linked thrombocytopenia and dyserythropoiesis with or without anemia/X-linked thrombocytopenia α -thalassemia—microcytosis of red blood cells, unbalanced hemoglobin chain synthesis resembling β -thalassemia minor

Pancytopenia

1. Fanconi anemia—short stature, bone marrow failure, renal and skeletal defects and increased risk of malignancy
2. Dyskeratosis congenital—tooth and nail dysplasia, skin rash, bone marrow failure, increased risk of malignancy

Platelet function defects

1. Hermansky-Pudlak syndrome—oculocutaneous albinism, mucosal bleeding
2. Chédiak-Higashi syndrome oculocutaneous albinism, infections, neutrophil peroxidase-positive inclusions
3. MYH9-related disorders cataracts, sensorineural hearing defect, nephritis
4. Leukocyte adhesion deficiency type III recurrent severe infections, delayed separation of the umbilical cord, neutrophilia

Other

1. Fabry disease—typical skin lesions (angiokeratomas), renal and heart disease, typical ocular signs, mucosal bleeding
2. Ehler-Danlos syndrome—skin hyperextensibility, joint laxity present with mucosal bleeding.

APPROACH**History**

A complete history should include age of onset, type of bleeding, sites of bleeding, fate of siblings and any recent illness, surgery or trauma. A past medical history, history suggestive of liver or kidney disease, or malabsorption, should be taken. A medication history should be obtained, with particular attention to anticoagulants,

antiplatelet drugs, NSAIDs, prolonged antibiotic use, and vitamin K and C deficiency. A family history of bleeding disorders may be helpful for assessing pathologic bleeding; probing questions may be needed to elicit a detailed family history.

Examination

Perform a thorough examination to see for petechiae, bruising, and if any cuts or clot are present and if they are still oozing. See

for presence of petechiae (non-blanching hemorrhagic spot < 2 mm diameter), purpura (2–10 mm diameter) or ecchymosis (> 10 mm diameter). Examine for signs of systemic disease—cushingoid features and striae; lymphadenopathy or hepatosplenomegaly; and icterus. Examine joints for prior hemarthrosis or connective tissue disorder. The physical examination should focus on identifying signs of bleeding (e.g., petechiae, mucosal bleeding, soft tissue bleeding, and ecchymoses) as well as signs of systemic disease.

Investigation

A complete history is followed by laboratory evaluation. If there is a suspicion of liver or renal disease, perform liver function and renal function tests. Initial laboratory evaluation for a suspected bleeding or coagulation disorder includes a complete blood count (CBC), prothrombin time (PT), activated partial thromboplastin time (aPTT), and a 1:1 mixing study (**Flow charts 1 and 2**). The 1:1 mixing study helps to identify deficiency or inhibitor of a factor. A bleeding time is useful but needs to be done properly to ensure its validity, platelet function studies should be done after excluding all antiplatelet medications.

SPECIFIC CONDITIONS OF SPECIAL IMPORTANCE

This section has separate chapters on hemophilia, disseminated intravascular coagulopathy (DIC) and ITP.

von Willebrand Disease

If the platelet count and the PT are normal and the aPTT is mildly elevated or normal, then vWD is a likely diagnosis, vWD must be suspected in any patient who has frequent epistaxis, easy bruising or prolonged bleeding from dental surgery. The child may even

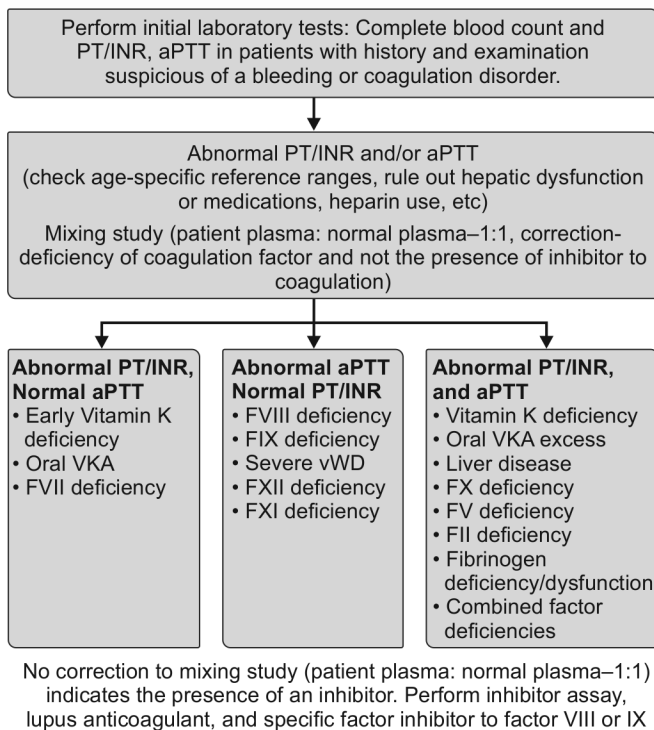

have iron deficiency anemia from chronic blood loss. vWD is the most common inherited bleeding disorder, with an estimated prevalence of 1 in 100. It is inherited as an autosomal dominant disorder, a family history is frequently elicited, however mild cases may go undiagnosed. Diagnosis is based on various tests, including von Willebrand factor (vWF) antigen, vWF activity (ristocetin cofactor or collagen-binding assay), factor VIII assay, and vWF multimers. vWF is a carrier protein for factor VIII in fibrin clot formation. There are three major types. Types 1 and 3 are quantitative deficiencies of vWF, and type 2 defects are qualitative. Laboratory evaluation includes a vWF antigen level, ristocetin cofactor activity (vWF activity level) and factor VIII activity level. All three values are low in type 1 disease and absent in type 3 disease. Type 2 subtype has normal vW antigen levels but low vW and factor VIII activity.

Thrombocytopenia

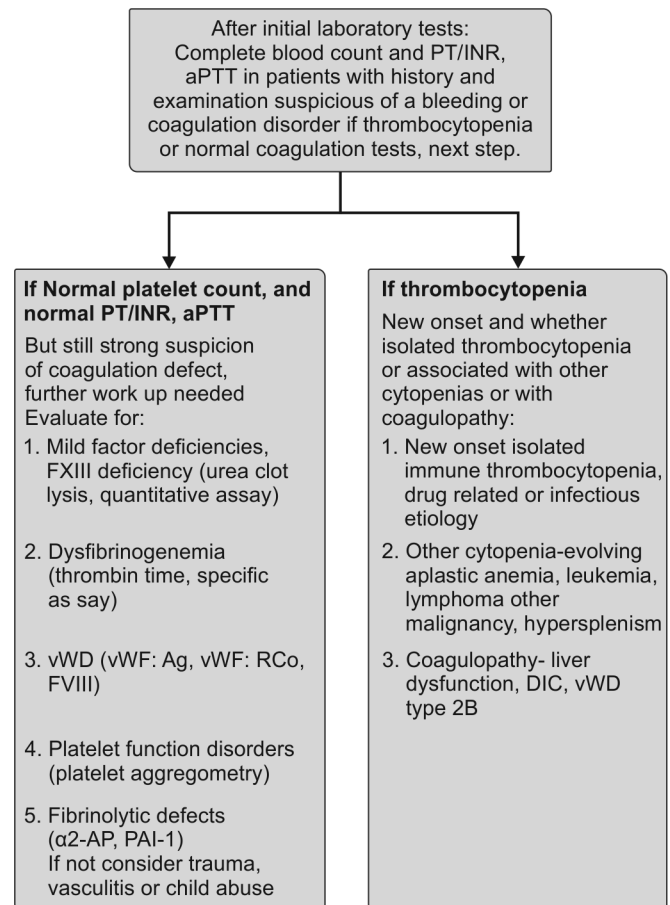

The cause of platelet count reduction in thrombocytopenia depends on the cause. The common causes involve reduced production, increased destruction or sequestration of platelets. Reduced production of platelets like in transient viral suppression of marrow, marrow failure due to acquired aplastic anemia or

Flow chart 2 Approach to a child with bleeding/coagulation disorder; with normal coagulation tests or thrombocytopenia

Flow chart 1 Approach to a child with abnormal coagulation profile

Abbreviations: PT, prothrombin time; INR, international normalized ratio; aPTT, activated partial thromboplastin time.

Abbreviations: PT, prothrombin time; INR, international normalized ratio; aPTT, activated partial thromboplastin time; vWD, von Willebrand disease; vWF, von Willebrand factor.

inherited bone marrow failure syndromes or post-chemotherapy. Increased destruction or loss of platelets occurs in ITP, DIC, sepsis, drug-induced destruction, or dilution in massive transfusion. Sequestration of platelets occurs in conditions of hypersplenism. A bone marrow test may be needed to identify the cause.

Platelet Dysfunction

Common symptoms of platelet function disorders are: frequent nose bleeds, easy bruising, bleeding from the gums. Usually the severe disorders are diagnosed early in life, however, some cases may be milder and present later. Even in the same family symptoms can be very different even among individuals in the same family. Inherited dysfunctions of platelets are recessive rare conditions, usually found in consanguineous families. These include Glanzmann thrombasthenia, Bernard-Soulier and other rare conditions (**Tables 3 and 4**). Here the platelets are normal in number but are abnormal functionally. They require specialized tests to confirm the diagnosis (**Table 5**).

Other Causes of Thrombocytopenia

In pediatric patients with cancer, aplastic anemia or severe sepsis, thrombocytopenia may result from underproduction or excessive consumption of platelets. Studies in adults with normal splenic function indicate that a dose of one single donor apheresis platelet unit/m² (5.5×10^{10} /m²) increases the peripheral platelet count by $10\text{--}12 \times 10^9$ L ($10,000\text{--}12,000/\text{mm}^3$). A rise of less than $5\text{--}6.5 \times 10^9$ L ($< 5,000\text{--}6,500/\text{mm}^3$) for each transfused unit per square meter (i.e., $< 50\%$ of expected) on two consecutive transfusions suggests active destruction resulting from alloimmunization, which can be confirmed with a low post-transfusion platelet count obtained 15–20 min after platelet transfusion and by the presence of antiplatelet

Table 3 Inherited defects with platelet dysfunction and abnormalities of platelet structure or number

<i>Inherited platelet dysfunction, with normal platelet count</i>	<i>Low platelet count and abnormalities in platelets</i>
1. Bernard-Soulier syndrome	1. May-Hegglin anomaly
2. Glanzmann Thrombasthenia	2. Alport syndrome
3. Alpha granule deficiency also called Gray platelet syndrome	3. Wiskott-Aldrich syndrome
4. Dense granule deficiency also called Delta storage pool deficiency	4. vWD type 2B
5. Scott syndrome	

Table 4 Medications and diseases that affect platelet function

<i>Medications- these effects are reversible</i>	<i>Medical conditions</i>
1. Aspirin and other drugs containing aspirin	1. Uremia
2. Nonsteroidal anti-inflammatory drugs like indomethacin, ibuprofen and naproxen	2. Postheart bypass surgery
3. Commonly used drugs can also affect platelet function, e.g., some antibiotics, antihistaminics, etc.	
4. Others clopidogrel, etc.	

Table 5 Evaluation of a child with suspected platelet function defect

<i>Test</i>	<i>Interpretation</i>
Bleeding time	Screening test, difficult in children. If performed needs stringent control. This measures the length of time it takes for a simple cut to stop bleeding
Platelet aggregation studies	Evaluates abnormalities in platelets clumping to different agonists (ADP, adrenaline, collagen, ristocetin, and arachidonic acid)
von Willebrand Factor studies	vWF:Ag, vWF:RCO, FVIII
Specialized tests	Flow cytometry for glycoprotein evaluation, platelet electron microscopy and molecular tests if available

antibodies. Antiplatelet antibodies cause platelet destruction more rapidly than other forms of consumption, and no substantial rise is noted at 15 min after a transfusion.

ACQUIRED DISORDERS OF HEMOSTASIS

Liver Failure and Vitamin K Deficiency

Liver failure causes bleeding through several mechanisms, it results in prolongation of the PT and partial thromboplastin time due to impaired hepatic synthesis or vitamin K deficiency (this decreases factor II, VII, IX and X) (**Box 2**). There is difficulty in correlation of prolongation of PT and aPTT tests, and functional status of the liver. Factor VII has a very short half-life and its deficiency severely influences the PT. Low levels of fibrinogen levels occur in hepatic failure, there may be also be abnormal fibrinogen (dysfibrinogenemia), increased fibrinolysis and thrombocytopenia, dysfunction of platelets is also known to occur.

BOX 2 Etiology of deficiency of vitamin K-dependent factors

- Hemorrhagic disease of the newborn
- Malabsorption of vitamin K (prolonged antibiotic use, short gut, tropical sprue, gluten-induced enteropathy), biliary obstruction
- Vitamin K antagonist therapy (e.g., coumarins, etc.)
- Liver disease
- Disseminated intravascular coagulation.

Uremia

Uremia affects platelet function as do other drugs (**see Table 5**) and causes bleeding by several mechanisms, it is thought that there is dysfunction of GPIIb/IIIa, a platelet membrane glycoprotein which plays a major role in platelet aggregation and adhesion. The other coagulation parameters are generally intact, though platelet count may be slightly reduced, and there is no prolongation of the PT or aPTT. The risk of bleeding is increased and platelet transfusions are needed for major surgery, regular dialysis prior to surgery may improve platelet function. Avoid heparin with the dialysis on the day of surgery.

Disseminated Intravascular Coagulopathy

Disseminated intravascular coagulopathy is an acquired disorder. The presentation range from only an isolated derangement of laboratory parameters to a condition of severe bleeding from multiple sites, associated with high mortality. DIC is triggered by a variety of conditions all of which result in activation of the clotting

BOX 3 What disease states to investigate for in a case of suspected bleeding/coagulation disorder, if baseline tests are normal (normal PT/INR, normal aPTT, normal platelet count)

- All platelet function disorders
- Collagen disorder: Ehler-Danlos, scurvy
- Mild von Willebrand disease
- Factor XIII deficiency
- Mild hemophilia A or B
- α -2-antiplasmin deficiency
- Plasminogen activation inhibitor-1 deficiency

cascade, this leads to deposition of fibrin in the microcirculation resulting in consumption of platelets and clotting factors. As DIC continues, fibrinogen, prothrombin, platelets and other clotting factors are consumed beyond the capacity of the body to compensate and bleeding ensues. Activated protein C has an anti-inflammatory effect and down regulates transcription factor (TF) expression, decreases calcium ion flux. It is consumed in DIC and its supplementation may have an important role in DIC due to sepsis. Antithrombin (AT) is a serine protease inhibitor that can neutralize thrombin and factor Xa, which is also consumed in DIC.

Rare Coagulation Disorders which Cause Clinically Significant Bleeding

Factor X Deficiency

It is an autosomal recessive inherited disorder characterized by severe bleeding episodes. This may also present as a rare acquired condition in patients of amyloidosis, multiple myeloma and other malignancies; *Mycoplasma pneumoniae* infection, and lupus anticoagulant as transient phenomenon and in patients with severe hepatic dysfunction. They present with hematomas, hemarthrosis, and menorrhagia.

Factor XIII Deficiency

It is also a rare (1/1,000,000) autosomal recessive inherited disorder. Even more rarely, an acquired factor XIII deficiency may be seen with Henoch-Schönlein purpura, erosive gastritis, and some leukemias. Patients with factor XIII deficiency will usually have a history of bleeding starting from early childhood, high incidence of intracranial hemorrhage. Hemarthroses are rare, and female patients may have recurrent abortions if they do not receive replacement therapy. The PT, PTT are normal, the diagnosis is made by clot solubility test with 5 M urea and 1% monochloroacetic acid, and confirmed by factor XIII assay.

Congenital Afibrinogenemia

It is a rare (1/1,000,000) autosomal recessive inherited bleeding disorder characterized by the absence of fibrinogen. These patients will have bleeding episodes from early childhood oral, gastrointestinal are common, but can bleed from any site.

CONCLUSION

Occasionally a mild coagulation defects may be missed in early childhood, if the presentation is severe then even if the initial coagulation studies are normal, the child may need further detailed work up as given in **Box 3**. A critically sick, bleeding patient in intensive care may have multifactorial causes for bleeding. Vitamin K deficiency, liver disease and DIC are common causes of bleeding in sick patients, and distinguishing between them is a difficult problem.

IN A NUTSHELL

1. All bleeding children do not have inherited disorders of bleeding or coagulation defects.
2. A detailed history of onset, nature and degree of bleeding is needed.
3. Initial screening tests are complete blood count with platelet count and prothrombin time (PT)/activated partial thromboplastin time (aPTT).
4. Suspect a bleeding or coagulation defect even if initial screening tests are normal, if excessive bleeding, or not controlled by routine measures.
5. Stabilization of child is important, give fluid resuscitation, assess blood volume loss and give blood transfusions if needed.
6. Follow algorithms if screening test are abnormal so that specific diagnostic tests can be performed with less cost and in a timely manner.
7. Consider acquired causes of bleeding in a sick child, in very ill children bleeding may be multifactorial.

Chapter 38.17

Hemophilia

Pravas Mishra

Hemophilia is congenital X-linked disorder of the coagulation system whereby deficiency of factor VIII (hemophilia A) or factor IX (hemophilia B) predisposes the affected male to a lifelong risk of bleeds. Descriptions of hemophilia are among the earliest known accounts of genetic disease. Jewish texts in 5th century and Arab physicians in the 12th century AD have described it. In its severe form, it primarily involves the joints but could also result in fatal bleeds involving organs such as the central nervous system or the gastrointestinal tract. Early and adequate support with factor replacement will prevent death from fatal bleeds. Factor replacement along with physiotherapy will ensure that debilitating joint deformities are avoided as also fatal bleeds. This is not an uncommon deficiency. However awareness levels among students and general practitioners continue to be very low resulting in inappropriate therapeutic interventions including potentially surgical interventions. This chapter will focus on the presentation, genetic aspects, prophylactic therapy and management of bleeds including factor support during surgery.

EPIDEMIOLOGY

The inheritance of hemophilia is X-linked, with an overall incidence of about 1:5,000 males for hemophilia A and 1:30,000 males for hemophilia B. Prevalence data of hemophilia A varies from 2.26 per 100,000 males in India to 20.6 per 100,000 males in the U.S. Corresponding figures for hemophilia B are 0.6 and 5.3 respectively. The Indian data reflects the poor awareness of the disease at the primary care level resulting in underreporting rather than a real prevalence. As per data from the Hemophilia Federation of India (HFI), there are 19,000 patients registered in the 70 HFI chapters all over India. There are 2,500 patients in the Delhi and surrounding regions. As per internationally published incidence and prevalence in various countries, including other Asian countries, as per estimates 1,90,000 patients should be in India.

ETIOLOGY

Hemophilia is a genetic disorder. The gene loci for factors VIII and factor IX exist on the long arm of the X chromosome (Xq28 and Xq27 respectively). Thus hemophilia is an X-linked disorder that is transmitted to 50% of children of a carrier mother, 50% of daughters will be carriers and 50% sons will be hemophiliac. It is transmitted as a carrier state to all female children of an affected male and to none of his male offspring, who get their normal X chromosome from the mother. Besides this mode of transmission, there is an approximately 30% chance of developing a new mutation resulting in a male hemophiliac or a female carrier with no family history of bleeding. This is more likely for factor VIII, which has a large and complex gene structure compared to factor IX. Indeed a positive family history is absent in nearly half of patients. There is no known environmental trigger for a spontaneous mutation. A family history is useful if present, in determining the presence of a suspected hemophiliac. The converse is not true, as in addition to chances of spontaneous mutation; the gene could have been transmitted through female carriers alone. A female hemophiliac is possible in the rare events as in cases of lyonization whereby the normal X chromosome is inactivated or in cases of Turner's syndrome. Homozygous transmission (affected father and carrier mother) has also been rarely described resulting in classical hemophilia

presentation in females. However a diagnosis of hemophilia must not form the primary differential in a female bleeder where von Willebrand factor (vWF) deficiency is a more likely cause of a prolonged activated partial thromboplastin time (APTT) with normal prothrombin time (PT).

PATHOPHYSIOLOGY

Factors VIII and IX are components of the *intrinsic system* of the coagulation cascade. The classical extrinsic and intrinsic systems are closely intertwined in the human body. The coagulation pathway is initiated after vessel wall injury whereby exposed tissue factor (TF) and activated factor VII (VIIa) combine to activate factor X and factor V. The activated factor X-factor V combination is called the *prothrombinase complex*. This leads to a small clot following thrombin generation, which is insufficient for maintaining homeostasis. This small quantity of thrombin activates factor VIII and factor IX, which together form the *tenase complex*, so named because it activates factor X. The tenase complex is a far more potent activator of the factor X compared to the TF-VIIa complex and generates greater amounts of the prothrombinase complex ultimately producing sufficient quantities of thrombin to form a stable and effective clot. Thus both these factors, VIII and IX, form important components of a positive feedback loop system and deficiencies of factor VIII (hemophilia A) and factor IX (hemophilia B) result in the classical bleeding manifestations of hemophilia. Patients with mild (factor level > 5% of normal) or moderate hemophilia (factor levels between 1% and 5%) generally bleed only after trauma. Experimental models have demonstrated that complete absence of coagulation factors such as factors VII, X, V, prothrombin and TF is incompatible with life whereas null alleles for factors VIII and IX result in the spontaneous bleeds characteristic of patients with severe hemophilia (factor levels < 1% of normal).

PATHOGENESIS OF JOINT DAMAGE

A young male with deformed swollen joints, with restricted range of movements, often unable to walk without support is the classical picture of severe hemophilia. The reason for predilection of joints to bleed is not entirely clear. The large joints are routinely exposed to mechanical stresses. In addition the joint capsule has been found to be deficient in thromboplastic activity. The synovium also synthesizes TF pathway inhibitor which has anti-Xa activity. This perhaps makes it more likely for joints to bleed more readily.

In the initial phases, hemorrhage occurs into the synovial cavity or into the diaphysis or epiphysis of bone. The muscles surrounding the affected area go into a painful spasm. Without further bleed, the blood gets broken down and is removed by the subsynovial venous plexus over 3–4 weeks. The joint regains its normal shape and functions normally following the initial bleeds. At this point the joint retains its full range of motion and the only evidence of an affected joint on clinical examination could be the presence of crepitus on movement of the affected joint. Repeated bleeds into the joint overcomes the capacity of the synovium to remove the accumulated blood and finally it gets permanently swollen. The swollen joint may be painful with restricted range of movement. This swelling is because of synovial hypertrophy. The synovium gets chronically inflamed because of the retained blood products which break down to release iron, which in turn stimulates inflammatory cytokines which further damage the cartilage and bone. These cytokines induced c-myc and mdm2 oncogenes which stimulate synovial proliferation. Successive bleeds result in a thickened, irregular synovium with folds and friable outcrops, which are extremely vascular. These folds get caught between the joint surfaces and cause further bleeds. Progressive damage to synovium and

cartilage is followed by development of subchondral cysts in the initial stages. Joint damage in hemophilia progresses through five stages (**Table 1**). In the final stages, loss of hyaline cartilage at the joint margins, subchondral hemorrhages, diffuse demineralization of affected bone occur, ultimately leading to ankylosed bone which may manifest as a fixed flexion deformity. Permanent joint damage starts to set in after 3–6 consecutive bleeds.

CLINICAL PRESENTATION

Hemophilia A is 4–6 times commoner than hemophilia B. This ratio has varied from 4.2:1 to 6.4:1 in Indian studies. The presentation of both hemophilia A and B are the same. The median age at diagnosis in western data is 8 months for severe and 12 months for moderate hemophilia A and B. Nearly half of patients in India had history of bleed by the age of 1 year. As seen from **Figures 1 to 4**, the frequency of symptoms reduces with increasing factor levels. Joint bleeds predominate in the severe hemophilia group. Skin bleeds and other superficial bleeds following trauma predominate as presenting complaints in children below 2 years, whereas joint bleeds without any history of trauma are the primary problem as the child grows. The earliest superficial skin bleeds in the form of spontaneous ecchymosis patches and easy bruising appear by age of 1 month and peaks by 1 year of age. Thereafter dental issues lead to mucosal bleeds in the form of spontaneous gum or dental bleed. Joint swellings start appearing by the age of 1 year. This is also the time traumatic bleeds predominate. After the age of 10 years, joint bleeds are the major cause of bleed. Absence of umbilical bleed at birth or bleed following circumcision does not rule out hemophilia. Post-circumcision bleed has been described in less than half of severe hemophiliacs.

Pattern of Musculoskeletal Bleeds

The knee is most commonly involved (40–50%), followed by the elbow (30–35%), ankle (20–30%), shoulder and hip (5–15%) and wrist in nearly 20% of patients. In the absence of swelling and inability to describe their problem, small children present with irritability and guarding of the affected joint. Intramuscular bleed has been reported in 30% of severe hemophiliacs, predominantly iliopsoas bleeds, followed by the thigh and calf muscles. Chronic hemophilic arthropathy in untreated individuals would present with muscle atrophy and weakness around the joint which predisposes to further bleeds. Joint appear swollen and often have fixed flexion and valgus deformities (**Fig. 5**). Bleed in the forearm could result in compartment syndrome if left untreated. It has been seen commonly after injections or attempts at phlebotomy in the antecubital fossa.

Pseudotumors

They are infrequent complications in western patients on account of prophylactic therapy. These are essentially collections of blood surrounded by a *capsule* of surrounding structures, either soft tissue or muscle or bone (**Fig. 6**). Pseudotumors in bony structures result from subperiosteal bleeding which separates the periosteum

Table 1 The five stages of joint damage in hemophilia

Stage 1	Intraarticular and periarticular swelling due to acute bleed
Stage 2	Loss of bone density around the joint and epiphyseal hypertrophy secondary to chronic synovial hypertrophy
Stage 3	Progression of epiphyseal hypertrophy with widening of intercondylar notch
Stage 4	Articular cartilage surfaces affected
Stage 5	Advanced cartilage erosion, loss of joint space, joint fusion and fibrosis

Figure 1 Bleeding manifestations of severe hemophilia

Figure 2 Bleeding manifestations of moderate hemophilia

Figure 3 Bleeding manifestations of mild hemophilia

Figure 4 Bleeding episodes leading to a diagnosis of hemophilia

from the underlying bone. Subsequent bleeds into the cyst result in an expansile lesion which erodes surrounding structures like a tumor. Some of these lesions develop sinus tracts which keep on oozing and get chronically infected. These masses usually develop in the lower limbs and pelvis but are known to occur in the small bones of the hands and feet in children.

Other Severe Bleeds

Intracranial bleed is life threatening and has been observed in less than 5% of cases. Uncomplicated vaginal deliveries pose a small risk for intracranial bleed (< 3.8%) and cesarian section does not completely eliminate the risk. However application of forceps or vacuum extraction and prolonged labor increases the risk of

Figure 5 Hemophilic joints

Figure 6 Hemophilic pseudotumor with secondary calcification

intracranial bleeds. Prior to effective factor replacement therapy, the mortality rate for this complication was as high as 70% (in the 1960s), reduced to 25–35% after introduction of factor concentrate therapy. In studies where detailed psychomotor analyses in the form of EEGs combined with psychiatric assessment were done, the incidence of neurological deficits was as high as 75%. However, only 3–10% of intracranial bleed survivors with such deficits had severe malfunctions. Gastrointestinal bleed occurs in nearly 10% of cases while 5% of children may present with urinary bleed.

INVESTIGATIONS

A prolonged APTT could mean any of the following deficiencies: factor VIII, factor IX, factor XI and factor XII. von Willebrand and factor deficiency could also result in a prolonged APTT owing to low levels of factor VIII. The first step would be to do a mixing study with normal plasma in a 50:50 mixture. In case of a factor deficiency, the prolonged APTT would be corrected but it would remain prolonged in case of an inhibitor such as lupus or other acquired inhibitor. If the mixing study demonstrates a correction of APTT, then specific factor assays would need to be performed

to determine the exact deficiency. These tests are bioassays, which determine the factor activity levels of the deficient factor (factor VIIIc or factor IXc) rather than actual factor antigen levels (VIII Ag or IX Ag). There is good correlation between factor antigen levels as determined by immunoradiometric methods and enzyme-linked immunoassay techniques.

As an example a bioassay for factor VIII requires three samples: the test sample, a standard reference sample (this contains 100% of all factors) and a substrate sample (a sample with known deficiency of factor VIII). APTT is performed on serial dilutions of the standard and test samples mixed with equal volumes of the substrate. The APTT values obtained are plotted on semi log paper and factor levels in the test sample determined from this log paper. As the substrate sample has normal levels of all factors other than factor VIII, APTT of the test sample would overlap with the standard sample if there were no deficiency of factor VIII. In such a case the test would have to be repeated using a factor IX deficient substrate. Bioassays for all factor deficiencies follow the same principle as described here for factor VIII.

In the event of factor VIII or IX deficiency the test results are reported in terms of factor activity percentage. Factor levels less than 1% are considered severe, 1–5% as moderate and levels greater than 5% but less than 30% are considered mild deficiencies. It is essential that the following precautions be taken for coagulation studies. The sample is preferably drawn from a clean venipuncture site avoiding indwelling heparinized catheters. The sample is collected into a citrate tube with 3.2% trisodium citrate concentration. The volume of blood as specified by markings on the tube has to be adhered to. This corresponds to a 9:1 dilution of blood to citrate. The sample tube, ideally collected near the laboratory, is to be transported at 15–22°C. Temperatures more than 22°C and less than 8°C could activate clotting factors. Samples to evaluate efficacy of factor therapy have to be drawn within 15 min of administration of factor. The platelet poor plasma is separated by centrifuge within 1 hour of drawing the sample. This can then be evaluated within 4 hours. If this is not possible, then a platelet poor plasma sample can be stored at –30°C for 4 weeks and –70°C for 6 months.

MANAGEMENT

General Care of a Hemophilic Child

The patient and his family must be educated about the disease and when to seek medical care. A detailed description of diagnosis and possible factor replacement products along with emergency contact numbers must be given to the patient. The mother must be counseled about prenatal diagnosis for future pregnancies. Intramuscular injections are contraindicated and injections should be given intravenously or subcutaneously. These children should receive all recommended immunization. The injection should only be given subcutaneously using a 26-gauge needle and pressure applied for 2–3 min. Infants should be allowed soft toys and must not be left unattended in raised seats or beds. Furniture in rooms should be minimum and should not be sharp edged. As the child grows and becomes mobile, he is at risk of injuries and joint bleeds. Ideally a severe hemophilic should be on factor prophylaxis. The aim of factor prophylaxis is to provide normal life as any other child. The child on prophylaxis should be encouraged to take part in routine physical exercises. He must avoid contact sports with significant risk of trauma such as football, cricket and high impact activities such as jumping on a trampoline. Sports such as badminton, swimming, cycling is considered safe. The child must wear protective gear such as helmets, knee and elbow pads while cycling. Martial arts (without physical contact) and dance are also considered safe but in general any activity, which involves possibility of high impact, sudden or jerky movements,

must be avoided. Blood clotting agents such as tranexamic acid are contraindicated in presence of urinary bleeds to avoid clot colic. The child must avoid nonsteroidal anti-inflammatory agents.

First Aid

In case of a joint or limb bleed, the patient is advised RICE (**R**est, **I**ce, **I**mmobilization, **C**ompression, and **E**levation) therapy (**Table 2**). RICE therapy has to be accompanied by factor replacement for successful management of the bleed.

Factor Replacement Therapy: Basic Considerations

Table 3 describes the recommended factor levels for acute bleeds including factor support during acute bleeds and surgical procedures. The hemostatic levels or the approximate blood levels of the deficient factor required to control bleeding episode has been empirically determined. It is 25–30 IU/dL for factor VIII and 15–30 IU/dL for factor IX. An example of factor correction is as follows: a 100% correction in a 30 kg child with severe hemophilia requires 3,000 units of factor (30×100). In case of hemophilia A, each unit of factor VIII raises the factor levels to 0.02 U/mL.

Table 2 RICE (Rest, Ice, Immobilization, Compress, Elevation) therapy

<i>Rest</i>	The joint should be rested till it heals. If knee or ankle is involved then walking must not be allowed
<i>Ice</i>	Use crushed ice wrapped in a damp towel for 10–15 min at a time. Ice baths are useful for ankle, wrist or hand involvement
<i>Immobilization</i>	A half cast or splint is used to limit movement
<i>Compress</i>	Wrap the foot or muscle starting well below the affected area and ending well above the affected area, using crisscross pattern
<i>Elevation</i>	Elevate the affected limb above the level of the heart using cushions

Therefore the required dose would be 1,500 units. However as the median half-life of factor VIII is 12 hours, another dose of 750 units is required after 12 hours to maintain 100% factor levels.

In case of hemophilia B, each unit of factor IX raises the levels to 0.01 U/mL and the median half-life of factor IX is 24 hours. A single dose of 3,000 units is required in this case, administered once every 24 hours, to maintain 100% factor levels. If factor concentrates were required on subsequent days as for a major bleed or surgery, one would need to make allowance for residual factor activity from the previous day's administration. Duration of therapy and factor level required to control various bleeds are given in **Table 3**. **Table 4** provides a guideline to administer factor concentrate so as to achieve the recommended factor levels in patients undergoing major surgery. It is necessary to monitor factor levels daily for the first 3–4 days followed by a reduced frequency of testing. This would ensure target levels are maintained. This also ensures that over dosage and wastage of factor is avoided.

Physiotherapy and Rehabilitation

Physiotherapy is a useful and necessary adjunct to prophylactic therapy, with the likelihood of reducing the dependence of factor requirement. Physiotherapy forms an important part of a comprehensive hemophilia treatment center, which would have orthopedicians, physiotherapists, and nurses in addition to hematologists. Effective physiotherapy increases the muscular strength. Physiotherapy should be initiated as quickly as feasible to avoid weakness in the other joints that would compensate for loss of activity in the affected joint. An exercise regimen would aim to restore range of movement, muscle strength and proprioception, at least to the degree that existed prior to the bleed. These regimens typically put the patient gradually through different levels of difficulty. An example of an exercise regimen for a hemophilic knee is given in **Table 5**. Level 1 exercise could start after the bleeding subsides. Even if no factor is available a patient could be encouraged to take up a level 1 exercise and gradually go to

Table 3 Suggested correction of factor deficiency in hemophilia as per indication

Type of bleed	Hemophilia A		Hemophilia B	
	Desired level (%)	Duration (days): adjusted as per response	Desired level (%)	Duration (days): adjusted as per response
Joint	10–20	1–2 days	10–20	1–2 days

Table 4 Guidelines to administer factors during major surgery

Day	Bolus dosing (IU/kg)		Interval frequency in hours	
	VIII	IX	VIII	IX
Preoperative	40–50	60–70	Preoperative	Preoperative
1–3	20–25	40–60	12	24
4+	15–20	20–40	12	24

the next level if there is no discomfort. At the same time one must take care of the following points:

- Patient comfort is of paramount importance and no patient must be asked to continue exercise in case of discomfort.
- One would need to tailor a target level of movement as per the patient's requirement.
- Each level of exercise has to be crossed gradually and the next level started only if there is no discomfort with the previous level.
- Isometric exercises where a patient contracts groups of muscles without joint movement are useful in case any form of discomfort arises from joint motion.

Prevention of Bleeding Episodes

Most moderate and mild hemophiliacs do not have spontaneous bleed and therefore do not require replacement therapy. However severe hemophiliacs have lifetime risk of fatal bleeds and joint bleeds. Replacement therapy is called *prophylaxis* when factor concentrate is given at regular intervals in the absence of bleed and it is called *episodic* or on demand when given only when a bleed occurs.

Prophylaxis is primary where factor replacement therapy is started after first large joint bleed (ankles, knees, hips, elbows, shoulders) before age of 2 years. There should not be any clinical or radiological evidence of joint damage. Prophylaxis is secondary when one waits for two major joint bleeds but no joint involvement, clinically or radiologically. Tertiary prophylaxis starts after the onset

of joint damage. The world federation of hemophilia further defines prophylaxis as continuous where prophylactic therapy is provided for at least 45 weeks/year and intermittent if less than 45 weeks. It is not necessary to maintain trough levels of factor more than 1% for efficacy. Prophylaxis for hemophilia A is traditionally given thrice a week and twice in case of hemophilia B. The various dosing regimens in use are enumerated in **Table 6**. The Malmo protocol is associated with least bleeds but results in high factor requirements; on average about 6,000 IU/kg/year/person. The Utrecht protocol uses 2,100 IU/kg/person/year at the cost of 1.3 bleeds every year and somewhat more joint damage as compared to Swedish patients on the Malmo protocol. A Chinese study attempted very low doses of factor VIII at 20 IU/kg/dose/week. However the patients in this study suffered 12–15 joint bleeds every year the Canadian protocol recommends factor replacement to patients on once weekly dosing.

Treatment of Minor Bleeding Episodes

Vasopressin (DDAVP) is an alternative to plasma or factor concentrate administration in case of minor bleeds or minor surgical procedures in mild hemophiliacs. Vasopressin acts on vascular endothelial cells to release high molecular weight multimers of vWF (and thereby factor VIII which is bound to vWF) to 2–5 times normal levels. Thus it is most useful in patients with factor levels more than 5%. The vWF so released increases platelet adhesion and function at sites of tissue injury. Repeated use of DDAVP results in diminishing effect (tachyphylaxis). DDAVP is administered intravenously at a dose of 0.3 mcg/kg up to a maximum of 24 mcg/kg/day. It is also available as a nasal spray. The DDAVP nasal spray for hemophilia supplies 150 mcg/metered dose. Other useful adjuncts are epsilon aminocaproic acid (EACA) administered orally or intravenously every 4–6 hours to total dose not exceeding 24 g/day or tranexamic acid (25 mg/kg orally every 6–8 hours). These could be used for minor bleeds but are of limited benefit in prevention or treatment of major bleeds. Both EACA and tranexamic acid are contraindicated for use in hematuria as blood clots could cause ureteric obstruction.

Table 5 Rehabilitation regimen for hemophilic knee

Levels of exercise	Range of motion	Strength	Proprioception
1	Sitting with legs out straight, bend hip and knee, slide heel towards body. Then straighten knee by sliding heel away from body. Repeat several times	Lie on back with roll under knee. Extend the knee and lift heel. Hold and relax. Repeat several times	Stand on affected leg. Maintain balance as long as possible
2	Sit on a chair. Bend knee as much as comfortable then extend knee	Sit on chair. Extend knee and lift foot off ground. Keep up as long as possible	Do level 1 with eyes closed as long as possible
3	Lie on stomach and bend knee to touch heel to buttock, then straighten out	Sit on chair. Cross ankles together and press them towards each other keeping them so as long as possible	Do level 1 on an uneven surface like pillow
4		Lie on back with roll under knee. Do level 1 with weights on ankle	Do level 3 with eyes closed
5		Stand on both feet and squat down as much as comfortable. Hold for few seconds then straighten up	Jump off a step (10–15 cm) and keep balance on standing. To be attempted only if knee or ankle are not swollen
6		Stand with back to wall. Slide down the wall till comfortable and then slide back up after few seconds	
7		Step up with affected leg onto a step	
8		Stand on a step and step down using the better leg	
9		Stand up from kneeling posture using affected foot	

The patient should go to the next level only if there is no pain on the previous level.

Table 6 Prophylaxis regimens for hemophilia

Protocol	Dosing schedule	Time to start
Malmo (Sweden)	25–40 IU/kg thrice weekly for factor VIII, twice weekly for factor IX	Age < 2 years before any joint bleed
Utrecht	15–25 IU/kg thrice weekly for factor VIII, twice weekly for factor IX	After 1–2 joint bleeds
Canadian	50 IU/kg/dose weekly; option to increase dose and frequency as per bleed	Before 2 years of age; before any joint bleed

Novel Therapies

Gene therapy for hemophilia could potentially free the patients from need for regular intravenous injections for replacement therapy. A recent study demonstrated some success in maintaining factor IX expression in humans using adeno-associated virus (AAV) vector. This approach is under clinical trials but is limited by the fact that 40% males would have antibodies to AAV due to prior exposure. Factor VIII molecule is too large to be packaged into conventional AAV vector. Recombinant retroviruses were studied initially but there is risk of insertional mutagenesis. This is less with self-inactivating lentiviral vector which have been used to transduce hematopoietic stem cells without risk of mutagenesis. Lentiviruses are not yet approved for clinical trials.

Inhibitors

Patients with hemophilia sometimes develop inhibitors to the deficient factor. These are alloantibodies directed against the deficient factor, more often factor VIII and result from the administration of exogenous factor. Patients who develop inhibitors no longer respond to pharmacological doses of factor concentrate therapy. Bleeds in these patients would require large doses of factor concentrate if the inhibitor titer is low. In most cases where the inhibitor titer is high, the factor bypassing agents such as factor eight inhibitor bypassing agent (FEIBA) or recombinant factor VII are required to stop the bleed. The overall incidence of inhibitors worldwide is 30% of all severe Hemophiliacs and that of persistent clinically significant inhibitors (> 10 BU/mL) is 10–20%.

Genetic predisposition plays a large role in inhibitor formation. Patients with large deletions (inversions of intron 22, intron 1, large deletions, nonsense mutations and missense mutations) are more likely to develop inhibitors. These are patients who have very little factor and thus would develop antibodies more readily on exposure to exogenous factor. Intron 22 inversion is seen in 35–42% patients with severe hemophilia. The proportion is roughly the same in Indian and western literature.

PREVENTION OF HEMOPHILIA

Birth of hemophilic child can be prevented by aborting the affected fetuses (if acceptable to the parents). One would continue to have

sporadic cases of hemophilia in families. However a positive family history provides an opportunity to prevent further hemophilic births by first identifying carriers and then affected fetuses. This is possible through prenatal counseling and testing of the mother for carrier status and the male fetus for hemophilia. Carrier status is important to plan future pregnancies and to decide continuation of a present pregnancy. Carriers could be obligate or possible (Table 7). Suspected carriers can be screened by coagulation and DNA based assays. A family history and a reduced ratio of factor VIIIc to vWF are associated with an increased probability of being a carrier. However this is not as reliable as DNA based tests. Direct DNA mutation analysis of the gene amplified by polymerase chain reaction is the most accurate method. Linkage analysis is another method using restricted fragment length polymorphism (RFLP) techniques where direct mutation analysis is not available. Linkage analysis looks for genes, which are known to co-segregate with the affected gene. These are present in affected family members and absent in the others. Thus indirect information about the carrier status can be obtained without knowing the actual mutation. Combination of single nucleotide polymorphisms such as xba1 and bcl1, variable number of tandem repeats (VNTR) in introns 13 and 22 (CA-13, CA-22) and direct mutation analysis of inversions in introns 22 and 1 provided informative data in 85% of cases with a family history and 52% of sporadic cases of hemophilia A. The intron 22 inversion is common and accounts for over 40% of severe hemophiliacs. This combination of markers could vary in different populations. Combination of these tests could be undertaken in the family and on chorionic villus sample to identify the affected fetus, followed by counseling and termination of pregnancy, if needed.

IN A NUTSHELL

1. Hemophilia is a genetic X-linked disorder, transmitted to males via female carrier.
2. It primarily affects the joints but manifests in the early age as easy bruising and mucosal bleeds.
3. The management of an acute bleed not only involves the use of factor but also appropriate first aid using RICE therapy and physiotherapy.
4. The factor support is complemented with physiotherapy and joint rehabilitation techniques in consultation with the physiotherapist.
5. Factor concentrate prophylaxis has to start early (as soon as possible after first bleed if not earlier) to avoid permanent irreversible joint damage.
6. Prophylaxis therapy is preferred to on demand factor support, as the latter does not prevent joint damage.
7. Several factor concentrates are available of which factors produced by recombinant techniques are preferred over plasma-derived concentrates owing to perceived lower risk of transmitting infection.
8. Prevention of hemophilic births depends on prenatal diagnosis using molecular techniques in pregnant carriers.

Table 7 Carrier determination in hemophilia

Obligate carriers	Possible carriers
1. All daughters of a father with hemophilia;	1. All daughters of a carrier;
2. Mothers of one son with hemophilia and who have at least one other family member with hemophilia (a brother, maternal grandfather, uncle, nephew, or cousin);	2. Mothers of one son with hemophilia but who do not have any other family members who have hemophilia (or are carriers);
3. Mothers of one son with hemophilia and who have a family member who is a known carrier of the hemophilia gene (a mother, sister, maternal grandmother, aunt, niece, or cousin);	3. Sisters, mothers, maternal grandmothers, aunts, nieces, and female cousins of carriers.
4. Mothers of two or more sons with hemophilia.

Chapter 38.18

Other Clotting Factor Deficiencies

Sunil Gomer, Archana Kashyap

Common coagulation abnormalities include deficiency of factor VIII and factor IX. These have been discussed earlier. Other clotting factor deficiencies are rare and their diagnosis thus is suspected only on high index of suspicion. This chapter will primarily discuss deficiencies of factors V, VII, X, and XIII.

EPIDEMIOLOGY

Among 600 children with coagulation disorder, hemophilia A was most common coagulation disorder (70.80%), followed by von Willebrand disease (vWD) (14.1%), and hemophilia B (8.4%). Other deficiencies noticed were factor V, factor IX and factor XII deficiencies which were rare.

Deficiency of vitamin K causes hemorrhagic disease of newborn (HDN), which may present with mild-to-severe disease. Many of these newborns may have vitamin K deficiency which goes undetected or asymptomatic. So, predicting its incidence is equivalent to tip of an iceberg. The incidence of the disease shows widely variable figures ranging from 4 to 170 per 100,000 births. Review of number of studies of Europe and Asia showed incidence of late HDN as 4.4–7.2 per 100,000 births in vitamin K unsupplemented groups. The incidence in vitamin K supplemented groups was 1.4–6.4 per 100,000 births. The von Willebrand disease is seen in about 10% of cases with hereditary bleeding disorder. The common subtypes are type 1, type 2a, type 2b and type 3 vWD.

The prevalence of factor XIII deficiency in general population is 1 in 200,000 births. It is a rare coagulation disorder. Its prevalence is higher in countries with consanguinity. The prevalence of inherited coagulation factor disorders is shown in **Table 1**.

LABORATORY EVALUATION

Once a coagulation disorder is suspected, laboratory evaluation is done to confirm the diagnosis. The laboratory tests include screening tests and confirmatory tests.

Screening Tests

These include bleeding time (BT), platelet count, platelet function tests, prothrombin time (PT) and acquired partial thromboplastin time (aPTT). PT tests the efficiency of extrinsic pathway and common pathway. It uses calcium and tissue thromboplastin for the formation of thrombin. Normal PT: 10–12 s (11–16 s). Causes of prolonged PT are deficiency of factor II, V, VII, X; vitamin K deficiency; acquired causes: disseminated intravascular coagulation (DIC), liver disease, oral anticoagulants intake. aPTT assesses the intrinsic pathway. This test depends on contact factor, prothrombin, fibrinogen, factor VIII, factor IX, X, and V. Normal aPTT: 25–35 s. Difference between test and control should be less than 6 s. If it is more than 10 s, it is abnormal. Causes of prolonged aPTT are deficiency of factor VIII, IX, X and factors of intrinsic pathway, vitamin K deficiency, liver disease, DIC, massive transfusion with stored blood, heparin, and oral anticoagulants.

Confirmatory Coagulation Tests

Thrombin Time

It is the time taken for formation of fibrinogen to fibrin induced by thrombin. It is prolonged when the levels of fibrinogen are reduced or absent or there is presence of fibrin degradation products. Dysfibrinogenemias can be diagnosed by this test. Normal thrombin time (TT): within 2 seconds of control, >24 seconds is abnormal.

Mixing Studies

Mixing studies also called as correction studies are done to define abnormality once the initial screening tests like PT, partial thromboplastin time with kaolin (PTTK) are prolonged. These tests are done to identify the specific abnormality. Mixing studies are also helpful in differentiating the factor deficiency from circulating inhibitor.

Table 1 Prevalence of inherited coagulation disorders

Factor deficiency	Genetics	Prevalence	BT	APTT	PT
Afibrinogenemia	AR	1:1 million	N	P	P
Dysfibrinogenemia	AR		N	N/P	P
II	AR	1:2 million	N	P	P
V (Parahemophilia)	AR	1:1 million	N	P	P
VII	AR	1:500,000	N	N	P
VIII (Hemophilia A)	XLR	1:10,000	N	P	N
von Willebrand disease	AD	1:1,000	N/P	N/P	N
IX (Hemophilia B)	XLR	1:60,000	N	P	N
X	AR	1:1 million	N	P	P
XI (Hemophilia C)	AR	1:1 million	N	P	N
XII	AD		N	P	N
XIII	AR	1:1 million	N	N	N
Prekallikrein	AD		N	P	N
HMW kininogen	AR		N	P	N

Abbreviations: AD, autosomal dominant; AR, autosomal recessive; XLR, X-linked recessive; APTT, activated partial thromboplastin time; BT, bleeding time; PT, prothrombin time; N, normal; P, prolonged

Principle Mixing studies are used to evaluate prolonged aPTT or PT. Patient plasma is mixed with equal amount of normal plasma. Correction of initial screening test such PTT immediately indicates factor deficiency. If it does not get corrected, circulating inhibitor is suspected. Various incubation times like 30, 60, 120 minutes are used. Various plasmas which are used are normal plasma, aged plasma, and adsorbed plasma.

Aged plasma is deficient in factors I, V and VIII and contains II, VII, IX, X, XI, XII. Adsorbed plasma contains I, V, VIII, XI, XII. Plasma from patients with isolated severe deficiency (<1 IU/dL) of FVIII or FIX are very useful for mixing studies. The interpretation of mixing studies is given in **Tables 2A and B**.

Diagnosis of factor VIII inhibitors In presence of factor VIII inhibitor, aPTT initially normalizes by mixing studies but again gets prolonged after 1–2 hours of incubation. History of previous bleeding episodes is asked. Sometime factor VIII inhibitor can develop transiently after pregnancy and surgery with no prior history of bleeding. Confirmation is done by Bethesda titer.

Clotting Factor Activity Assays

The amount of clotting factors normally in plasma varies from 50% to 150%. The factor assays are used to differentiate and identify the deficient clotting factor. The severity of disorder is assessed by the amount of factor.

Severe deficiency	<1% of normal plasma
Moderate deficiency	1–5% of normal plasma
Mild deficiency	>5% of normal plasma

The von Willebrand Factor (Ristocetin Cofactor Activity)

It is the functional assay for von Willebrand factor. It is performed when vWD is suspected, BT is prolonged, or platelet function test is abnormal.

Urea Clot Lysis Test

It is used to assess factor XIII deficiency. Normally, clot is formed by conversion of fibrin to cross-linked fibrin in presence of activated factor XIII. This clot is stable for at least 1 hour in monochloroacetic acid solution or 5 molar urea. In absence of factor XIII, clot dissolves rapidly when incubated with 5 molar urea.

A diagnosis can be arrived at by a stepwise approach to history, physical examination, and screening test. Finally, minimum test is

applied to reach to a definitive diagnosis. This approach is cost-effective and minimizes the possibility of misdiagnosis and missed diagnosis. Common scenarios are summarized in **Table 3**.

VITAMIN K DEFICIENCY BLEEDING DISORDER

Pathogenesis

Vitamin K is a group of compounds that have a common naphthoquinone ring structure. Three type of vitamin K are seen. Vitamin K₁ or *phylloquinone* is present in dietary sources like green leafy vegetables, vegetable oils, etc. It is used for food fortification. This form of vitamin is given prophylactically to neonates as aqueous and colloidal solution. Vitamin K₂ or menaquinones are produced by gut flora, also present in meat, liver, and cheese. Vitamin K₃ or *menadione* is a synthetic form of vitamin K and is not used medically because it can cause hemolytic anemia. Vitamin K is a cofactor for gamma-glutamyl carboxylase, involved in post-translational carboxylation. It is a fat soluble vitamin and requires bile salts for its absorption. Causes of vitamin K deficiency are shown in **Table 3**.

Classification

Early vitamin K deficiency bleeding disorder (VKDBD): Formerly called classic hemorrhagic disease of the newborn. It is seen usually in 1–14 days of life. Causes of this early deficiency include poor placental transfer of vitamin K, sterile gut of neonate, and inadequate oral intake in initial few days of life. It mostly occurs in breastfed infants due to low vitamin K content in breastmilk (1.5 µg/L).

Late VKDBD It is mostly seen at 2–12 weeks of age. It can also be seen up to 6 months of age. Causes of late VKDBD include low vitamin K level in breastfed infants, malabsorption, liver disease (biliary atresia, alpha-1 antitrypsin deficiency).

Third form can be seen any time after birth of later. It usually occurs secondary to maternal ingestion of drugs such as warfarin, phenytoin, phenobarbitone which following placental transfer interfere with vitamin K absorption.

Conditions associated with vitamin K dependent factor deficiency are listed in **Box 1**.

Clinical Features

Vitamin K deficiency bleeding disorder presents with bleeding most commonly from gastrointestinal tract, umbilical stump bleed, circumcision site bleed, mucosal and cutaneous bleed. Intracranial bleed is most commonly seen in late VKDBD. Vitamin K deficiency due to fat malabsorption can occur at any age. Some of the important aspects should be asked in history such as gestation at delivery, drug intake, feeding history including breastfeed and bottlefeed.

Investigations

Prothrombin time is prolonged. aPTT is usually prolonged, but it can be normal in early deficiency. In mild vitamin K deficiency, sometimes, PT may be normal. To detect mild deficiency, the undercarboxylated forms of proteins which are normally carboxylated in presence of vitamin K [proteins induced in vitamin K absence (PIVKA)] are increased.

Table 2A Interpretation of mixing studies

Defect in test plasma	Normal plasma	APTT	Aged or factor VIII deficient	Adsorbed or factor IX deficient
Factor VIII	Correction	Abnormal	No correction	Correction
Factor IX	Correction	Abnormal	Correction	No correction
Factor XI/XII	Correction	Abnormal	Correction	Correction
Inhibitor	No correction	Abnormal	No correction	No correction

Table 2B Interpretation of mixing studies

Defect in test plasma	Normal plasma	PT	APTT	Aged plasma	Adsorbed plasma
Factor II	Correction	Abnormal	Abnormal	Correction	No correction
Factor V	Correction	Abnormal	Abnormal	No correction	Correction
Factor VII	Correction	Abnormal	Normal	Correction	No correction
Factor X	Correction	Abnormal	Abnormal	Correction	No correction

Table 3 Laboratory diagnosis of coagulation disorders

<ul style="list-style-type: none"> • Normal screening test with bleeding disorder <ul style="list-style-type: none"> – Factor XIII deficiency – Mild clotting factor deficiency – Vascular disorders – Scurvy – Henoch-Schloein purpura – Senile purpura – Alpha-1 antiplasmin deficiency

<ul style="list-style-type: none"> • Prolongation of PT, aPTT, TT <ul style="list-style-type: none"> – Hypofibrinogenemias, dysfibrinogenemia – Heparin – Liver disease.

BOX 1 Conditions associated with vitamin K dependent factor deficiency

- *Dietary deficiency*: Low vitamin K levels in human milk (1.5 µg/L)
- *Malabsorption*: Celiac disease, biliary atresia, cystic fibrosis
- *Drugs*: Maternal intake of warfarin, valproate, carbamazepine, antitubercular drugs
- *Antibiotics*: Prolonged use
- *Liver diseases*: Cholestasis, acute hepatitis, Wilson disease, cirrhosis, Reye syndrome.

Treatment

When VKDBD is suspected, injection vitamin K (1 mg) is given as soon as possible. It should not be given intramuscular because of risk of hematoma formation. Babies with severe bleed (intracranial and other massive bleed) should be given fresh frozen plasma along with vitamin K to stop the bleed. Children with underlying malabsorption require high doses of oral vitamin K (2.5 mg twice a week to 5 mg/day). PT usually decreases by 6 hours. In exclusive breastfed infants, single intramuscular administration at birth is effective in preventing VKDBD.

von WILLEBRAND DISEASE

von Willebrand disease is an autosomal inherited congenital disorder. It is caused by missing or defective von Willebrand factor (vWF), a clotting protein. von Willebrand factor binds to factor VIII and platelet in blood vessels, helps in platelet plug formation during the clotting process. It is a large multimeric glycoprotein produced in megakaryocytes and endothelial cells as pre-pro form. vWF is produced by sequential cleavage. It is present in normal amount in plasma. Deficiency of vWF causes mucocutaneous bleed and bleed following trauma and surgery. It is one of the common bleeding disorders, seen in 0.1% of population (both biochemical evidence and clinical history). **Table 4** shows types of vWD.

Clinical Features

Patients usually present with nose bleed, increased bleeding during surgical procedures like dental procedures, easy bruisability, and menorrhagia.

- *Type 1 vWD* It is the most common disorder among all types (70–80%). There is qualitative deficiency of vWF, with levels of vWF in blood being 20–50% of normal. This presents with mild symptoms.
- *Type 2 vWD* It is seen in 15–30% of patients. There is qualitative defect in vWF. There are four subtypes of type 2 vWD, viz., type 2A, type 2B, type 2M and type 2N. Symptoms are usually mild to moderate in this type.
- *Type 3 vWD* These patients have qualitative deficiency of vWF. This presents with severe bleeding disorder, such as spontaneous bleeding in joints, and muscles. The level of factor 8 and vWF in plasma are almost undetectable in these patients.
- *Platelet type pseudo-vWD* It is a platelet disorder, which is phenotypically similar to type 2B vWD. There is mutation defect in *GP1BA* gene leading to abnormal *GP1b-1X* in platelet receptors. Increased binding of vWF to platelet receptors causes activation of platelet and as a result, vWF is removed from circulation. So, there are decreased levels of vWF in plasma.

Table 4 Mode of inheritance, relevant investigations to differentiate types of von Willebrand disease (vWD)

	Type 1	Type 2A	Type 2B	Type 2N	Type 2M	Type 3	Platelet type pseudo-vWD
Genetic transmission	AD	AD	AD	AR	AD	AR	AD
Frequency (%)	70–80	10–12	3–5	1–2	1–2	1–3	1–3
Factor VIII	↓	N	N	↓↓	N	Absent	N
Platelet count	N	N	N/↓	N	N	N	↓
Bleeding time	N	↓	NR/↓	N	↓	NR	NR
Response to DDAVP, factor VIII, vWF Ag test	↑	↑	↑	↑	↑	NR	↑
vWF Ag	↓	↓	N/↓	↓	N	Absent	N/↓
vWF activity	↓	↓	N/↓	↓	↓	Absent	N/↓

Abbreviations: AD, autosomal dominant; AR, autosomal recessive; N, normal; NR, nonreactive; ↑, increased; ↓, decreased

- **Acquired vWD** It is seen in a person who does not have lifelong bleeding disorder, but presence with decreased level of von Willebrand antigen. Conditions which may be associated with acquired vWD are Wilms tumor, systemic lupus erythematosus (SLE), polycythemia vera, heart diseases, angiodysplastic lesion, lymphoproliferative disorders and drugs. The proposed mechanisms are formation of autoantibodies, adsorption onto malignant cell clones, and specific hemostatic disorders.

Management

After detailed clinical history and family history, tests are performed to evaluate the clotting time and ability of patient to form clot. Clotting factor assay and platelet function tests are done. vWF antigen test measures the amount of vWF in patient plasma. Patient with vWD will have less than 50% of normal vWF in plasma.

Mainstay of treatment of vWD disease is desmopressin acetate (DDAVP). It acts by stimulating the release of vWF from the cells which also increases factor A. It is available in two forms: injectable and nasal spray. Antifibrinolytic drugs like aminocaproic acid, tranexamic acid are used to prevent the breakdown of blood clots. These drugs are usually used before dental procedures, menorrhagia, nasal and mouth bleeds.

Type 1 vWD DDAVP is helpful in most of these patients. It normalizes factor VIII, vWF and BT. Response to DDAVP is individualized in these patients and repeat dosing may be required. Care should be taken when repeat doses are used, and it can cause tachyphylaxis.

Type 2A vWD Treatment with DDAVP increases the factor VIII levels with improvement in BT in some of the patients. Most of these patients are treated with DDAVP but some patients require treatment with clotting factor concentrates containing both vWF and factor VIII.

Type 2B vWD Clotting factor concentrates containing both factor VIII and vWF are mainstay of treatment in these patients. DDAVP is not used because it can cause transient thrombocytopenia following clearance of abnormal vWF.

Type 2N vWD DDAVP infusion is used in these patients as factor VIII levels increase after the infusion but the released factor VIII has short half-life because of impaired binding to vWF. So, for major surgery and bleeds, factor VIII concentrates with high levels of vWF are used.

Type 2M vWD The heterozygous variants of this subtype respond well to standard doses of DDAVP. But in homozygotes, the vWF released by DDAVP is defective and poor response occurs; so, vWF replacement therapy is used.

Type 3 vWD Treatment with vWF containing factor 8 concentrates is used. Since the levels of vWF in plasma are undetectable, so no releasable stores of vWF are available for DDAVP to act. Patients who have developed alloantibodies to vWF due to repeated transfusion are given recombinant factor VIII (devoid of vWF), as anaphylaxis can occur with vWF in them. The half-life of factor VIII in absence of vWF is short; so continued or repeated infusions are given.

Platelet type pseudo vWD These patients are treated by platelet transfusion.

Acquired vWD DDAVP and plasma-derived factor VIII/vWF are used in these patients. The underlying cause is treated.

Removal of antibodies is done by intravenous immunoglobulin, plasmapheresis, and immunosuppressive therapy.

FACTOR XIII (FIBRIN STABILIZING FACTOR) DEFICIENCY

It is the rarest factor deficiency. It is inherited as autosomal recessive pattern. Activated form of factor XIII leads to formation of cross-linked polymers of fibrin, which help in clot formation. It provides stability to the clot. It presents with umbilical stump bleed in up to 80% of patients, spontaneous intracranial bleed, nasal and mouth bleed, muscle bleed, hematuria, postsurgery bleed. Diagnosis is made by factor XIII assay and clot solubility test (5 M urea). Clotting tests may be normal, as patient with factor XIII deficiency forms clot.

These modalities can be used for treatment like factor XIII concentrates, fresh frozen plasma, and cryoprecipitate.

IN A NUTSHELL

1. Common coagulation abnormalities include deficiency of factor VIII and factor IX. These have been discussed earlier. Deficiencies of factors V, VII, X, and XIII are rare.
2. Mixing studies are done to identify the specific deficiency of clotting factors.
3. Among the other factor deficiencies, vitamin K deficiency is frequent, especially in infants. It can present in first 2 weeks of life (Early VKDBD—formerly called classic hemorrhagic disease of the newborn), between 2 to 12 weeks of age (late VKDBD), or later.
4. Single dose vitamin K administration at birth is effective in preventing VKDBD.
5. von Willebrand factor binds to factor VIII and platelet in blood vessels, helps in platelet plug formation during the clotting process. Patients with vWD usually present with nose bleed, increased bleeding during surgical procedures like dental procedures, easy bruisability, and menorrhagia. Mainstay of treatment of vWD disease is DDAVP.
6. Factor XIII deficiency presents with umbilical stump bleed in up to 80% of patients, spontaneous intracranial bleed, nasal and mouth bleed, muscle bleed, hematuria, and postsurgery bleed. Diagnosis is made by factor XIII assay and clot solubility test.

Chapter 38.19

Thrombocytopenia

Amita Trehan

Thrombocytopenia is defined as a platelet count below $100,000/\text{mm}^3$. Its prevalence is variable in newborn, infancy and childhood. Clinical features include variable clinical symptoms depending upon the age of the child and underlying diagnosis. Detailed family history of drugs intake during pregnancy, maternal platelet count and mother's illness are helpful in establishing the diagnosis. Algorithms are helpful as an approach to a bleeding neonate or child (**Flowcharts 1 and 2**). A megakaryoblast is a product of hematopoietic stem cell differentiation. The megakaryoblast matures into the megakaryocyte, which is a large cell. This cell has a nucleus with many lobes. Platelets are fragments of cytoplasm from the megakaryocyte. Platelets have a life span of 9–10 days. Old platelets undergo phagocytosis primarily in the spleen.

A platelet count of less than $100,000/\text{mm}^3$ is termed as thrombocytopenia. Platelets are primarily responsible for maintenance of hemostasis in the body (see chapter 38.15). There are many ways to approach a child with thrombocytopenia. This may be (1) depending on the size of the platelets; (2) inherited or acquired causes; and (3) the pathogenic mechanism behind thrombocytopenia: decreased production, increased destruction and splenic sequestration (**Box 1**).

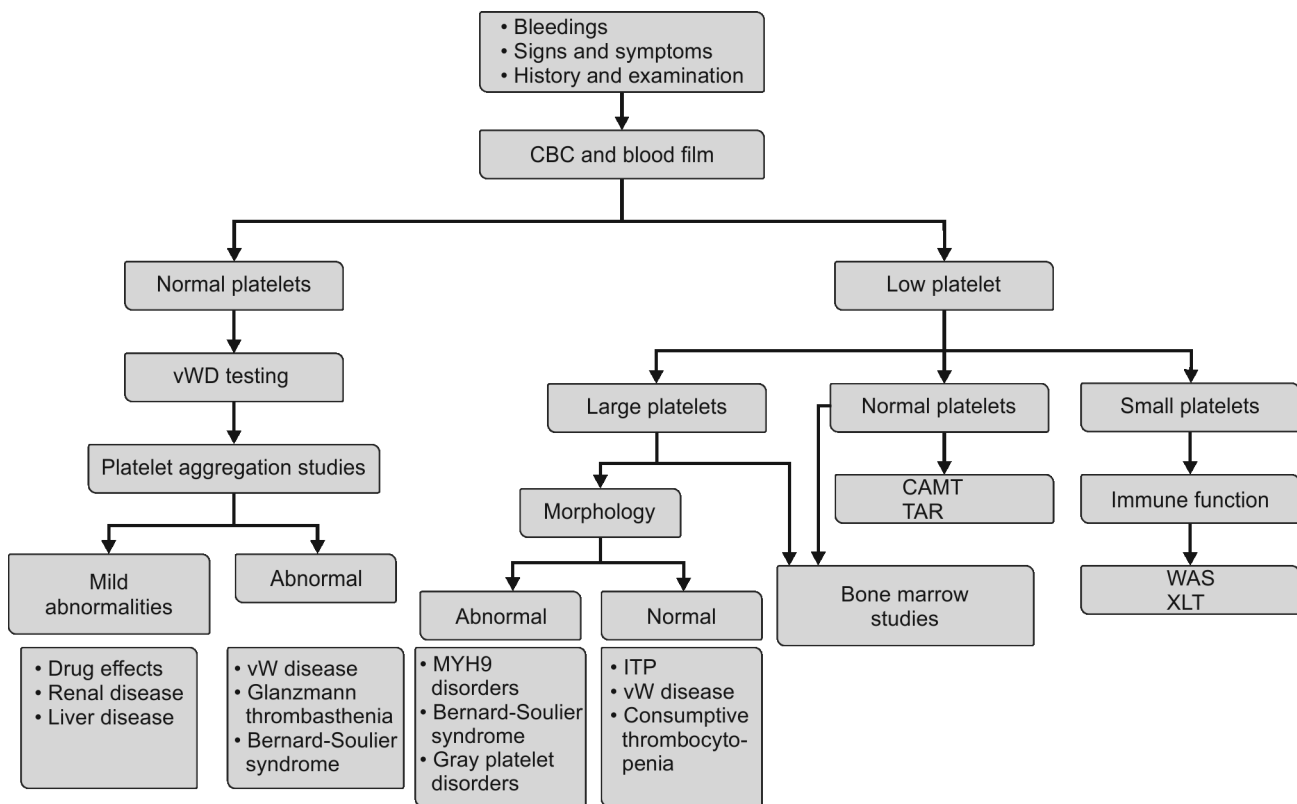

CLINICAL FEATURES

Petechiae, bruises or purpura, mucus membrane bleeding; epistaxis; gingival bleed, acute gastrointestinal bleeding, menorrhagia, hematuria, intracranial hemorrhage (ICH), etc. It is unusual for patients to bleed unless platelets fall to less than $70,000/\text{mm}^3$. Spontaneous bleeds can occur when platelets are less than $50,000/\text{mm}^3$. Major bleeding manifestations and life-threatening hemorrhages usually occur with a platelet count of less than $10,000/\text{mm}^3$.

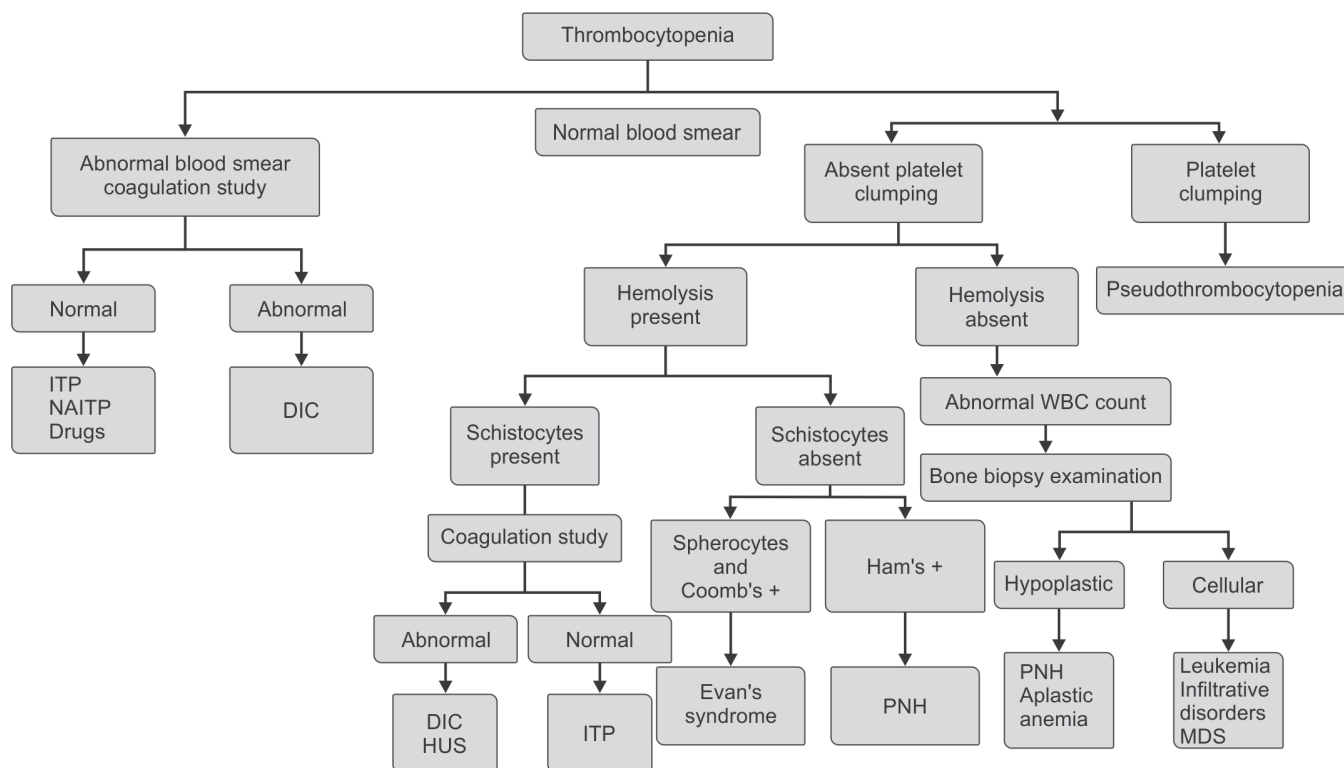

EVALUATION

A good history is mandatory and helps in establishing the etiopathogenesis of the disorder. One must look for a history of constitutional symptoms (fever, weight loss, etc.) which would be present in case of a malignancy/infection. The source of bleeding and the amount of blood lost needs evaluation. Any associated symptoms of diarrhea, respiratory infection, oliguria, vaccination, medications and family history of a similar disorder can provide vital clues to the etiology of bleed. Umbilical stump bleeding, cephalhematoma, bleeding after circumcision, conjunctival hemorrhage, hematuria are important clues in a child. The physical examination must include a thorough systemic and neurological examination. The location and severity of the bleed needs attention. Patients with thrombocytopenia typically experience mucocutaneous bleeding. Joint and soft tissue bleeding is usually seen in the presence of coagulation abnormalities.

 - Disseminated intravascular coagulopathy (DIC)
 - Severe sepsis resulting in consumptive thrombocytopenia (without DIC)
- Splenic sequestration
 - Portal hypertension secondary to chronic liver disease.

INVESTIGATIONS

Blood samples should be taken before commencement of any therapy. These tests are very sensitive and a faulty sample collection will result in false results. For platelet quantitative assessment, blood anticoagulated with ethylenediaminetetraacetic acid (EDTA) is required. Tests for coagulation, the individual coagulation factors, and D-dimers are measured using blood anticoagulated with citrate. Vacutainers are preferred. The ratio of citrate to blood should be 1:9. Any faulty ratio will result in an erroneous result.

Platelet Estiation

A quantitative platelet disorder should be looked in all patients with a bleeding disorder. A platelet count is essential which may be analyzed either manually, with semiautomated counters or with a fully automated cell counter. Examination of a blood smear allows for quick estimation of platelet numbers. In automated counters, platelet clumping can result in artifactually low counts. A decreased platelet count should always be corroborated on a peripheral blood film examination. The count may also be repeated on a freshly drawn blood sample. A high platelet count may be seen in the presence of microspherocytes, leukemia cell fragments and Pappenheimer bodies. Peripheral blood film is the most important investigation which directs in the diagnostic approach in a patient with thrombocytopenia. All three blood lineages should be assessed carefully. A critically ill patient needs urgent evaluation for leukemia, disseminated intravascular coagulation (DIC), and thrombotic microangiopathy.

Bleeding Time

This is the rate at which a stable platelet plug is formed. It does not differentiate between thrombocytopenia and platelet dysfunction. In addition, as no two skin areas are the same and a standard

wound cannot be produced, the bleeding time is considered a very poor test. The American Society of Clinical Pathologists has concluded that this is not a good screening test and its usage has been abandoned.

Additional Investigations

Thrombocytopenia may be the end result of a pathogenic mechanism, therefore renal function tests, liver function tests and a coagulogram with D-dimers is required. Investigations are based upon clinical history, physical findings, clinical diagnosis and the results of the peripheral blood smear. A bone marrow aspirate may be needed to rule out a primary bone marrow disorder. In inherited disorders, mean platelet volume is helpful for further investigation. Automated counts are less accurate in the presence of micro/macro thrombocytopenia and a Wrights or May-Grunwald-Giemsa stained peripheral smear is essential regarding size, quantitative assessment, clumping and granularity.

INHERITED CAUSES OF THROMBOCYTOPENIA

In children, inherited disorders are uncommon but have to be considered as a cause of thrombocytopenia. These conditions arise as a result of a genetic defect in the megakaryocytic production. The easiest way to distinguish inherited causes is based on the size of the platelets, as small and large platelets occur in some important inherited thrombocytopenias.

Small Platelets

Wiskott-Aldrich syndrome This is a congenital X-linked disorder. It is characterized by thrombocytopenia (small platelets 3–5 fL in size), eczema and immunodeficiency. It usually presents in infancy or early childhood.

X-linked thrombocytopenia This is a less severe form of *Wiskott-Aldrich syndrome* caused by mutations in the same gene. Infectious complications and eczema are not seen in this situation.

Normal-Sized Platelets

Congenital amegakaryocytic thrombocytopenia This presents early in life as an isolated thrombocytopenia. This condition may progress to a bone marrow failure syndrome.

Thrombocytopenia absent radii (TAR) syndrome There is markedly diminished megakaryopoiesis. This manifests early in life and spontaneous recovery may occur by one year of age. TAR has a predisposition to a myeloid malignancy.

Amegakaryocytic thrombocytopenia with radioulnar synostosis This has moderate-to-severe thrombocytopenia with fusion of the radius and ulna. The thrombocytopenia persists with age.

von Willebrand disease It is an inherited disorder of von Willebrand factor (vWF). Type 2B is associated with mild thrombocytopenia. Mucocutaneous bleeding is the hallmark of this condition. Epistaxis and easy bruising is a typical history. Laboratory test for ristocetin cofactor activity and VWF multimer assay is required. Thrombocytopenia is seen in type 2B and platelet type non-Willebrand disease. In von Willebrand disease, thrombocytopenia is because of increased binding between larger non-Willebrand factor multimers and platelets. This results in the formation of platelet aggregates which get phagocytosed from the circulation resulting in a low count.

Giant Platelet Disorders

These are rare disorders in which platelets are very large (>12 fL).

Bernard-Soulier syndrome This is an autosomal recessive disorder characterized by mild thrombocytopenia, marked platelet dys-

function and bleeding symptoms which includes easy bruising and hemorrhage following an injury. The bleeding is disproportionate to the thrombocytopenia, as there is concomitant platelet function abnormality.

MYH9-related disorders Mutations of the nonmuscle heavy chain gene (*MYH9*) result in a hereditary macrothrombocytopenia with somatic abnormalities. Mild-to-moderate thrombocytopenia is observed. Nephropathy and deafness may occur and are related to the same gene mutation.

Paris-Trousseau syndrome This is a rare condition with mild-to-moderate thrombocytopenia with large platelets. It is associated with mental retardation, head and face dysmorphism, cardiac and renal defects.

X-linked thrombocytopenia with dyserythropoiesis This is due to *GATA-1* mutations on the chromosome which results in defective maturation of megakaryocytes.

NEONATAL THROMBOCYTOPENIA

Neonatal thrombocytopenia occurs in 1–3% of healthy term infants and in 20–30% of sick neonates. In a sick neonate, thrombocytopenia is usually secondary to severe illness such as sepsis, DIC, respiratory distress syndrome or due to maternal factors such as intrauterine growth retardation (IUGR), pregnancy-induced hypertension and gestational diabetes (**Box 2**).

Neonatal Alloimmune Thrombocytopenia

Neonatal alloimmune thrombocytopenia (NAIT) is a consequence of the transfer of platelet antibodies from the mother to the fetus. It is one of the commonest causes of thrombocytopenia in

BOX 2 Causes of neonatal thrombocytopenia

the newborn and is seen in 1/1,000 births. It invariably resolves within 2–4 weeks. This occurs as mothers who do not have the platelet-specific surface antigen develop alloantibodies to the paternally derived antigens when they are expressed on fetal platelets. Maternal alloantibodies attack the fetal platelets which have the platelet-specific antigens inherited from the father on their surface. Seventy five percent cases of NAIT are because of the platelet-specific antigen (P1A1), human platelet antigen (HPA-1a), followed by HPA-5b in 15–20% cases. The pathophysiology is similar to erythroblastosis fetalis. Antibodies develop by 20th week of gestation. Alloimmunization develops during the first pregnancy and recurs in more than 80% cases in subsequent pregnancies. Usually, succeeding pregnancies have more severe disease.

Clinical Features

Babies with NAIT are usually full-term babies. They are seen to develop generalized petechiae soon after birth or are born with petechiae and ecchymosis. They may have cephalhematomas, bleeding from the umbilicus and skin puncture sites in addition to visceral bleeding such as gastrointestinal or renal tract. A high incidence of ICH (up to 10–20%) is seen in babies. This is characteristically an intraparenchymal bleed. Mortality of 6–14% has been seen. These babies have a low platelet count at birth, invariably being less than 50,000/mm³.

Diagnosis

Neonatal alloimmune thrombocytopenia should be considered in all newborns with thrombocytopenia. Most cases (90%) have a platelet count of less than 50,000/mm³. A definite diagnosis needs presence of platelet antigen incompatibility in parents.

Neonatal Autoimmune Thrombocytopenia

Mothers with isolated immune thrombocytopenia (ITP) have autoantibodies. These antibodies can cross over passively through the placenta to the fetus. The same phenomenon occurs as in autoimmune disorders like systemic lupus erythematosus (SLE). These babies are well at birth. A maternal platelet count helps in clinching the diagnosis and distinguishes this from NAIT. In addition, the history and platelet count should be available before/during pregnancy. This condition is less severe than NAIT, with only 10–15% babies having a platelet count of less than 50,000/mm³. The bleeding manifestations are fewer and the risk of ICH rare. In this condition, maternal antibodies are transferred passively across the placenta and attack the fetal antigens. The antigens commonly involved are the glycoprotein (GPIIb/IIIa or GB1b/IX) complexes. Babies with significant bleeds require therapy. In addition, therapy is recommended in asymptomatic babies with a count below 30,000/mm³.

Management

Platelet transfusion at 10–20 mL/kg is given. Random donor platelets are sufficient. Matched platelets have not been seen to offer any added advantage. Intravenous immunoglobulin 1 g/kg/day for 1–3 days may be given. Methylprednisolone (1 mg IV) 8 hourly is administered along with IVIG. Follow-up till normal platelet counts are achieved is mandatory.

Thrombocytopenia Associated with Erythroblastosis Fetalis or Exchange Transfusion

Babies with erythroblastosis may have skin bleeds soon after birth. The pathophysiology is related to an immune mechanism. It may also be secondary to a very high bilirubin level which can affect the platelet survival. Often, there may be thrombocytopenia following an exchange transfusion secondary to decreased platelets in the blood used.

Thrombocytopenia Secondary to Intrauterine Growth Retardation, Hypoxia, Maternal Diabetes and Pregnancy-induced Hypertension

Any condition which has placental insufficiency can result in thrombocytopenia. This will include pregnancy-induced maternal diabetes mellitus, hypertension, IUGR and perinatal asphyxia. The pathophysiology is impaired megakaryopoiesis which also results in an elevated thrombopoietin level. Increased platelet destruction has also been seen in these conditions. Thrombocytopenia is invariably self-limited needing no therapy. The nadir is likely to occur around day four with recovery by the end of the first 2 weeks of life.

Thrombocytopenia Secondary to Congenital Infections

A perinatal infection is the commonest cause of severe thrombocytopenia that occurs within 72 hours, especially in a sick neonate. Infections needing exclusion include: group B *Streptococcus*; *Listeria monocytogenes*; *Escherichia coli*; toxoplasmosis, rubella, cytomegalovirus, herpes simplex (TORCH) infections and HIV. Amongst the TORCH infections, cytomegalovirus (CMV) infection is the commonest to be associated with severe thrombocytopenia. Jaundice, pallor and hepatosplenomegaly may be present and are considered to be a hallmark in infants with congenital infections. The described *blueberry muffin* rash is secondary to extramedullary hematopoiesis.

Thrombocytopenia is seen secondary to sepsis because of:

- Disseminated intravascular coagulation resulting in consumptive thrombocytopenia
- The phagocytic system clears the bacteria, viruses and immune complexes in any infection. Platelets stick to all three and as a result get phagocytized also.
- There is suppression of the bone marrow secondary to sepsis. This contributes to thrombocytopenia which reverts when the infection is controlled.

Late-onset thrombocytopenia secondary to late-onset or hospital-acquired infections Thrombocytopenia seen after the first week of life is usually secondary to sepsis. Decreased immunoglobulin level as a result of prematurity per se contributes to these processes.

Thrombocytopenia due to Aneuploidy

Nearly 85% cases of Down's syndrome may have thrombocytopenia. This may be due to transient myeloproliferative syndrome which is seen in Down's syndrome. Thrombocytopenia may also occur in trisomy 13, trisomy 18, Turner's syndrome and triploidy. Associated congenital anomalies in these cases are a clue to the diagnosis.

Inborn Errors of Metabolism/Rare Disorders

These include osteopetrosis, metastatic neuroblastoma, Gaucher disease, Niemann-Pick disease, hemophagocytic lymphohistiocytosis, afibrinogenemia and congenital leukemia.

Metabolic Causes

Hyperglycinemia with ketosis and methylmalonic acidemia present with lethargy, vomiting and ketosis during the neonatal period. These disorders may cause episodic thrombocytopenia and neutropenia during infancy. Isovaleric acidemia is associated with generalized marrow hypoplasia resulting in thrombocytopenia and neutropenia.

Platelet Destruction

Immune-mediated Platelet Destruction

Drug-induced thrombocytopenia This is a result of a drug-dependent antibody which forms against an antigen on the surface of the platelet. Thrombocytopenia in this situation is moderate to

severe with clinical manifestations corresponding to the platelet count. It invariably develops a few days to 1–3 weeks of starting the drug. This condition can be easily confused with ITP, thereby highlighting the importance of a drug history. It usually resolves within a week to ten days of stopping the drug. The diagnosis is essentially clinical, a laboratory diagnosis being possible only by demonstration of the drug-dependent antibody. Common drugs which result in thrombocytopenia are given in **Box 1**.

Heparin-induced thrombocytopenia A small percentage (0.5–5%) of heparin-treated subjects develop heparin-induced thrombocytopenia (HIT). A fall in platelet count by $\geq 50\%$ from the baseline should alert one to the diagnosis of HIT. The thrombocytopenia is usually moderate with a varied clinical picture which includes venous and arterial thrombosis and necrotic skin lesions. This condition usually develops 5–10 days after initiation of heparin therapy. HIT is a consequence to development of antibodies against the heparin PF-4 complex, and C-serotonin release assay is diagnostic of the same. In such a situation, it is advisable to use other anticoagulants if required.

Immune thrombocytopenia The commonest acquired bleeding disorder in childhood universally is ITP. It is generally self-limiting but may have a chronic or recurrent course. Eighty to ninety percent children have an acute transient episode of thrombocytopenia which resolves in a few weeks. Children with immune thrombocytopenia usually present between 2 and 10 years of age. They generally present with an acute history of presence of petechiae/purpuric spots in an otherwise fit child. A history of a recent viral illness is often forthcoming. The clinical manifestations, diagnosis, and management of ITP in children are discussed in a separate chapter.

Systemic lupus erythematosus Thrombocytopenia may be the presenting feature in SLE. The other symptoms may appear much later. Three to fifteen percent of patients with thrombocytopenia may develop SLE. Mild thrombocytopenia is seen in patients with SLE. A very small percentage of patients have a moderately low platelet count of less than $50,000/\text{mm}^3$. The pathophysiology of thrombocytopenia in SLE is generally immune-mediated platelet destruction. In SLE, platelet consumption may also occur as a result of microangiopathic hemolytic anemia with ensuing thrombocytopenia.

Nonimmune-mediated Platelet Destruction

Certain conditions like hemolytic uremic syndrome (HUS), thrombotic thrombocytopenic purpura (TTP) and DIC have thrombocytopenia as a result of platelet activation, aggregation and consumption. Kasabach-Merritt syndrome results in thrombocytopenia as a result of coagulation and platelet trapping in the hemangioma.

Disseminated intravascular coagulation It is a condition where there is activation of intravascular coagulation. This results in the formation of microvascular thrombi. In addition, there is thrombocytopenia and reduction of clotting factors. The acute form of DIC can also be seen in severe sepsis, septic shock, neurotrauma, ABO incompatible blood transfusion and in acute promyelocytic leukemia. Thrombocytopenia is moderate to severe and the bleeding manifestations are usually severe.

Chronic disseminated intravascular coagulation It is usually seen with solid tumors, large aortic aneurysms and cyanotic heart disease. The thrombocytopenia in chronic DIC is mild to moderate and the bleeding manifestations milder than in an acute DIC.

Thrombotic thrombocytopenic purpura This is a syndrome characterized by hemolytic anemia, thrombocytopenia, renal dysfunction, fever and neurological symptoms. In TTP, there

is thrombotic occlusion of the microcirculation. This is a result of deficient activity of vWF factor clearing protease caused by mutations of a *disintegrin-like and metalloprotease with thrombospondin motifs* (ADAMTS 13) gene. Severe bleeding from thrombocytopenia is unusual, though skin bleeds are common. The thrombocytopenia ranges from a mild to severe state and it has been covered in detail in other section.

Hemolytic uremic syndrome Microangiopathic hemolytic anemia, thrombocytopenia and acute kidney injury constitute HUS. The thrombocytopenia is usually moderate and active bleeding is infrequent. Platelet transfusions are usually required only when an invasive procedure is required.

Giant hemangioma Thrombocytopenia as a result of consumption and platelet trapping has been seen in giant hemangiomas. This is a form of localized intravascular coagulation. Any giant hemangioma associated with consumptive thrombocytopenia is referred to as the Kasabach-Merritt syndrome. Usually, hemangiomas are cutaneous in nature. However, any child with cutaneous hemangioma needs evaluation for any deep seated visceral hemangioma, e.g., liver, spleen. In addition, infants with baffling thrombocytopenia need evaluation for visceral hemangiomas.

Mechanical destruction Extracorporeal therapies, viz., extracorporeal membrane oxygenation, cardiopulmonary bypass hemodialysis and apheresis can result in thrombocytopenia secondary to mechanical destruction.

Sequestration/trapping The spleen sequesters one-third of platelet mass. This increases in conditions associated with hypersplenism, resulting in thrombocytopenia. Leukopenia and anemia may also accompany a low platelet count.

Decreased Production of Platelets

Nutritional Deficiency

This is especially important in a country like India where there is a high incidence of folate and vitamin B₁₂ deficiency which results in impaired bone marrow production and often results in pancytopenia.

Bone Marrow Failure

A bone marrow dysfunction may be as a consequence of a malignancy of the bone marrow, e.g., leukemia. Dysfunction of the marrow also results when the marrow is invaded by a solid tumor, e.g., neuroblastoma. There may be shut down of the marrow as is seen in aplastic anemia which results in pancytopenia and thrombocytopenia. Cytotoxic drugs and radiotherapy also result in bone marrow suppression with ensuing pancytopenia. In addition, the hereditary disorders of thrombocytopenia are secondary to decreased production (described earlier).

Cyanotic Heart Disease

It has decreased production of megakaryocytes, the exact mechanism not being clear.

Infections

The common infections which may result in thrombocytopenia include Epstein-Barr virus, CMV, parvovirus, varicella, HCV and rickettsia. This thrombocytopenia is transient and recovery is usually seen within a period of a few weeks. HIV-associated thrombocytopenia was a frequent finding in patients with retroviral infection in the era prior to the development of antiretroviral therapy and 40% were seen to have thrombocytopenia during the course of their illness. This correlated with the degree of immunosuppression. Thrombocytopenia is also encountered as an initial manifestation of HIV infection in 10% patients. HIV must be ruled out in the evaluation of a child with thrombocytopenia. Immune dysregulation akin to immune thrombocytopenia is considered

as the pathogenesis for thrombocytopenia in HIV patients and is termed primary HIV-associated thrombocytopenia. In addition, there is reduced platelet count secondary to medications, infection, or thrombotic microangiopathy. Hypersplenism secondary to coincident liver disease and/or cirrhosis is another common cause of thrombocytopenia in patients with HIV infection.

IN A NUTSHELL

1. Thrombocytopenia is defined as a platelet count of less than 100,000/mm³.
2. Spontaneous bleeding is unlikely till the platelet count falls below 20,000/mm³.
3. Intracranial hemorrhage is a dreaded but rare complication.
4. Thrombocytopenia is caused by increased destruction, decreased production (congenital, infectious, marrow dysfunction) or sequestration of platelets.
5. Evaluation has to be done by an initial complete blood count with examination of the peripheral blood smear.
6. Further investigations are done depending upon the clinical evaluation of the patient.
7. Immune thrombocytopenia is the most common diagnosis of isolated thrombocytopenia in preschoolers and school-going children.
8. There is no absolute threshold for treatment, which should be decided based on clinical evaluation and an estimate of risk of significant hemorrhage.
9. Platelet transfusions have limited utility in immune-mediated disorders.

Chapter 38.20

Immune Thrombocytopenic Purpura

Jagdish Chandra, Dinesh Yadav

Immune thrombocytopenic purpura is an acquired immune-mediated disorder characterized by isolated thrombocytopenia. The abbreviation, ITP, has been variably used to define *idiopathic thrombocytopenic purpura* or *immune thrombocytopenic purpura*. ITP is an autoimmune disorder characterized by destruction of otherwise normal platelets, most commonly occurring in response to an unknown stimulus. ITP may occur in isolation (primary) or in association with other disorders (secondary).

Recently, an International Working Group (IWG) has reviewed the recommendation on nomenclature and treatment which is widely being followed. This group defined thrombocytopenia as platelet count less than $100 \times 10^9/L$ based on three considerations: (1) a study demonstrating that only 6.9% patients presenting with a platelet count between 100 and $150 \times 10^9/L$ developed a persistent platelet count less than $100 \times 10^9/L$ over 10 years of follow-up; (2) recognition that in non-Western ethnicities normal values in healthy individuals may be between 100 and $150 \times 10^9/L$; and (3) the hypothesis that a cutoff value of $100 \times 10^9/L$ would reduce concern over the mild *physiologic* thrombocytopenia associated with pregnancy. This group suggested the term *immune thrombocytopenia* as many patients with ITP do not have purpura. The 'P' in ITP, has been retained to avoid altering the traditional acronym.

In place of traditional classification (acute and chronic), ITP has been reclassified as newly diagnosed, persistent and chronic ITP based on duration. These and other terminologies are defined in **Table 1**. The distinction of primary from secondary ITP is important as therapy in secondary ITP is targeted at treatment of underlying disorder. Various causes of secondary ITP are enumerated in **Table 2**.

EPIDEMIOLOGY

Childhood primary ITP has an incidence of approximately 4.0 per 100,000 children per year and usually has a self-limiting course. In a large series [Intercontinental Cooperative ITP Study Group (ICIS)] of over 2,000 cases, mean age of presentation

reported was 5.7 years. In this series, 70% were children between 1 year and 10 years, 20% from 10 to 16 years and 10% were infants (3–12 months). In young age, children of both genders are equally affected. However, slight female predominance is reported in older children (>10 years of age). Nearly 50–65% cases have a preceding viral infection, usually an upper airway infection. In addition, cases occurring after known infections such as rubella, varicella, mumps, rubeola, infectious mononucleosis and cytomegalovirus have been described. In a minority, ITP may also occur after vaccination with a live attenuated vaccine. Yet the only vaccine for which there is a demonstrable cause-effect relationship is the measles, mumps, and rubella (MMR) vaccine with one to three children every 100,000 vaccine doses developing ITP. Most children with ITP have remission with or without treatment. Only 10–20% of children have persistent thrombocytopenia 1 year after the initial diagnosis.

PATHOPHYSIOLOGY

Immune thrombocytopenic purpura is characterized by immune-mediated destruction of platelets. These antiplatelet antibodies were identified as IgG directed against glycoprotein IIb/IIIa and Ib/IX in particular. Antibodies that react with glycoprotein Ia/IIa, IV and V and other platelet determinants have also been identified and the presence of antibodies against multiple antigens is typical in ITP, presumably because of epitope spread. Once produced, these autoantibodies bind to platelets, causing their destruction by either phagocytosis or possibly complement activation and lyses. However, these autoantibodies are documented in only 75% of ITP patients. Other pathophysiological mechanisms, such as T-cell-mediated cytotoxicity, may thus be involved in platelet destruction.

Production of antiplatelet antibodies by B cells is facilitated by CD4+ T cells. Proliferation of CD4+ T cells is controlled by activated antigen presenting cells. Of the two helper T-cell cytokine profiles, ITP shows a Th1 cytokine response [elevated interleukin 2 (IL-2) and interferon- γ (IFN- γ), and reduced IL-10 levels] and a reduced Th2 response, a pattern similar to autoimmune disorders. Ongoing antibody production is necessary for chronicity of the disease.

For more than 50 years, loss of self-tolerance leading to production of autoantibodies against platelet antigens has been recognized as the underlying problem of ITP, and it was assumed that thrombopoiesis was maximized in response to the increased platelet clearance. However, evidence has emerged recently that thrombopoiesis is impaired in at least some patients. Kinetic analyses using autologous platelets demonstrated that 73% of ITP patients had normal or decreased platelet production. Platelet-associated antibody levels correlated inversely with

Table 1 ITP nomenclature (suggested by International Working Group 2009)

Newly diagnosed ITP	All new cases at diagnosis are labeled by this term up to 3-month duration.
Persistent ITP	Refers to thrombocytopenia persisting for 3–12 months from diagnosis. This category includes patients not achieving spontaneous remission or not maintaining their response after stopping therapy between 3 months and 12 months from diagnosis.
Chronic ITP	Refers to thrombocytopenia lasting for more than 12 months.
Recurrent ITP	Defined as return of thrombocytopenia/symptoms after at least 3 month of remission, sustained without treatment.
Primary ITP	Defined as isolated thrombocytopenia (immune-mediated) in the absence of underlying disorders that may be associated with thrombocytopenia. It is a diagnosis of exclusion.
Secondary ITP	Includes patients, where a specific etiology for thrombocytopenia is identified [e.g., systemic lupus erythematosus, HIV, drugs].
Severe ITP	Patients who have <i>clinically relevant bleeding</i> , i.e., bleeding symptoms that warrant treatment. It does not necessarily imply a very low platelet count.
Refractory ITP	Patient with ITP who has failed first-line therapy as well as splenectomy, and continues to experience clinically significant bleeding. More useful in adults with ITP.

Table 2 Causes of secondary immune thrombocytopenic purpura

Antiphospholipid syndrome
Systemic lupus erythematosus
Autoimmune thrombocytopenia (e.g., Evan's syndrome)
Common variable immunodeficiency
Drug administration side effect
Infection with cytomegalovirus, HIV, <i>H. pylori</i> , hepatitis C, varicella zoster
Lymphoproliferative disorders
Bone marrow transplantation side effect
Chemotherapy-induced

platelet production, suggesting that platelet antibodies impair platelet production as well. Platelet antibodies are known to bind to megakaryocyte membranes of ITP patients, and such antibodies may interfere with megakaryocyte maturation, platelet production and release. Morphologic features consistent with apoptosis have been reported to be more common in megakaryocytes of ITP patients than healthy controls. However, impaired megakaryocytopoiesis is inconsistent. Thus, ITP likely presents a mixed picture of impaired platelet production and accelerated platelet destruction. In addition, thrombopoietin (TPO) levels are normal or only slightly increased. Hence, the rate of thrombopoiesis is inadequate to counterbalance the increased rate of platelet destruction.

CLINICAL FEATURES

Immune thrombocytopenic purpura commonly presents as a sudden onset bleeding in an otherwise well child. It typically affects children in the age group of 2–6 years. Most children present with skin bleed (97%) and few have epistaxis (12–30%). Very few children (3–5%) develop severe bleeding, defined as episodes requiring hospitalization and/or blood transfusions. Intracranial hemorrhage (ICH) is a rare (incidence ~ 0.2%), though a real and potentially life-threatening complication. Circulating platelets in ITP patients, although few in number, tend to be particularly effective at hemostasis, perhaps because most will have been recently released from the marrow and are fresh, large, and granular. As a result, ITP patients are far less likely to have serious bleeding than patients with similarly low platelet counts caused by other processes such as marrow failure. Even in cases with ITP having severe thrombocytopenia, arbitrarily defined as platelet count $<20,000/\text{mm}^3$, bleeding other than skin bleeds have occurred only in 12–20% cases. Majority of children who present with or develop ICH have severe thrombocytopenia, bleeding manifestations beyond petechiae and ecchymosis (particularly hematuria) and a high rate of reported head trauma. Spleen is palpable in 5–10% of children. Malaise, bone pains and lymphadenopathy should raise concern for another cause such as acute leukemia.

Childhood ITP is a benign, self-limiting disease. The ICIS group concluded that remission occurred in 37% of the patients between 28 days and 6 months after the initial diagnosis, in 16% between 6 and 12 months and in 24% between 12 and 24 months. Several studies have identified one or more of the following factors to be associated with a shorter duration of thrombocytopenia: younger age at diagnosis (<10 -year-old), abrupt onset (<2 weeks) of symptoms, preceding viral infection, extremely low platelet count ($<5 \times 10^9/\text{L}$) and the presence of wet purpura. Also, male gender and elevated serum IgG levels at diagnosis have been associated with a good prognosis. Data from natural history suggests that adolescents are more likely to develop persistent or chronic ITP.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Diagnosis of ITP is made on clinical features, supported with laboratory parameters. Typically, the clinical features include:

- Abrupt onset of skin bleeds in a previously well child.
- *Pallor proportionate to bleeds*: Observed in 15% of children, particularly in those with epistaxis, hematuria or gastrointestinal (GI) bleed. In India, coexisting nutritional anemia is not uncommon.
- Absence of fever, lymphadenopathy, hepatosplenomegaly or bone pains.

Immune thrombocytopenic purpura is a diagnosis of exclusion. Leukemia and aplastic anemia are close differentials, which should be excluded by detailed history, physical examination and relevant laboratory investigations. Inherited thrombocytopenia should be reliably excluded in children younger than 12 months. Other differential diagnoses of thrombocytopenia in children are described in **Table 3**.

INVESTIGATIONS

There are no diagnostic tests to confirm ITP. A review of hemogram and peripheral smear by pathologist is essential. Pseudothrombocytopenia caused by platelet agglutination due to ethylenediaminetetraacetic acid (EDTA) should be reliably excluded. Typical findings include isolated (often severe) thrombocytopenia, with a normal leukocyte and differential count. Peripheral smear shows few large platelets. A low Hb with reduced mean corpuscular volume may indicate concomitant iron deficiency anemia. Macrocytosis points toward megaloblastic or aplastic anemia. Acute bleeding may result in moderate neutrophilia with occasional immature forms. Mild eosinophilia can be observed. A distinctive lymphocytosis is alarming, though it may be secondary to a resolving viral infection. Tests for HIV

Table 3 Differential diagnosis of thrombocytopenia in children

Pseudothrombocytopenia	EDTA-induced platelet clumping
Gestational/neonatal causes	Maternal pre-eclampsia, HELLP* Neonatal alloimmune thrombocytopenia Maternal drug ingestion
Inherited disorders	Thrombocytopenia absent radius syndrome Amegakaryocytosis Wiskott-Aldrich syndrome
Infectious causes	Sepsis, congenital TORCH infection Viral infections, rickettsial disease, <i>H. pylori</i> , HIV, HCV
Impaired thrombopoiesis	Aplastic anemia, Fanconi anemia Paroxysmal nocturnal hematuria, myelofibrosis Myelodysplastic syndrome, osteopetrosis
Giant platelet disorders	May-Hegglin anomaly Bernard-Soulier syndrome
Malignancy	Leukemia, lymphoproliferative disorders
Platelet sequestration/consumptive coagulopathy	Hypersplenism, Kassabach-Merritt syndrome, DIC, TTP, HUS, type 2B von Willebrand disease, purpura fulminans
Collagen vascular disorders	Systemic lupus erythematosus, antiphospholipid syndrome

*HELLP: Hemolysis, Elevated Liver enzymes, Low Platelet count

Abbreviations: EDTA, ethylenediaminetetraacetic acid; TORCH, Toxoplasma gondii, rubella virus, cytomegalovirus, and herpes simplex virus; DIC, disseminated intravascular coagulation; TTP, thrombotic thrombocytopenic purpura; HUS, hemolytic uremic syndrome

and HCV are also recommended. Exclusion of *Helicobacter pylori* is advisable in adults, if there is clinical suspicion or high local prevalence. Detection of antiplatelet, antithyroid and antinuclear antibodies is neither sensitive nor specific and has no role in the diagnosis of ITP.

The purpose of a bone marrow (BM) examination is not to diagnose ITP, but to exclude an ominous etiology of thrombocytopenia, particularly leukemia and aplastic anemia. It is unusual to overlook these disorders, if the peripheral smear has been reviewed by an experienced pathologist and not found to be atypical. It has been customary to perform a BM prior to administering steroids, for fear of masking an underlying leukemia. However, recent guidelines advocate against this practice in a typical case of acute ITP. A BM can particularly be avoided if decision has been taken for conservative management or for administering intravenous immunoglobulin (IVIG) or anti-D. A BM examination will definitely be required in presence of fever, lymphadenopathy, hepatosplenomegaly, bone/joint pains; pallor disproportionate to bleeds, and/or high or low leukocyte count, atypical cells in blood smear or macrocytosis. The recommendations on BM examination should be viewed with caution in India and other developing countries where concomitant nutritional anemia may complicate the clinical picture. Moreover, most cases will be managed by pediatricians who may be treating ITP only infrequently. In chronic ITP patients, BM evaluation should be considered, if not already done. Screening tests for immunodeficiency, systemic lupus erythematosus (SLE) and other autoimmune diseases [antinuclear antibody (ANA), direct Coombs test, antiphospholipid antibody, thyroid function tests] and serologic testing for HIV and HCV should also be considered. Obtaining blood counts and peripheral smears from the parents may help to exclude the familial disorders. Routine testing for *H. pylori* and TORCH group of infections is not recommended.

MANAGEMENT

In the modern day management of ITP, the dilemma is to balance attempts at preventing severe bleeds versus avoiding therapy-related toxicities and reducing cost of therapy. It is important to remember that: (1) majority of patients will not have life-threatening bleed; (2) disease has a self-limiting nature; (3) therapy does not modify the course of the disease; and (4) platelet count alone has never been shown to predict the severity of bleeding and (5) there is no evidence that medical therapy reduces the incidence of ICH. The principle is to treat clinically relevant bleeding episodes and not to treat the low platelet count. Hospitalization is appropriate for treatment of a child with severe bleeding episode, but otherwise not required in an uncomplicated case. The principles of treatment are shown in **Box 1**.

Observation Alone Approach

In 1966, Zuelzer and Lusher described 152 children with ITP seen between 1956 and 1964, and advised that the child, not the platelet count, should be treated. This discussion whether to treat ITP patients based on platelet count or bleeding symptoms alone, continues even after 60 years of this initial description of ITP. Earlier (1996) American Society of Hematology (ASH) guidelines recommended treatment of ITP patients based on platelet counts. However, the United Kingdom has adopted a minimalistic treatment approach to children with little or no bleeding at diagnosis of ITP since the early 1990s, with only 16% of children now receiving drug therapy compared with 61% in 1995. The ICIS group also reported the emerging trend toward reserving drug therapy for patients with major bleeds or troublesome impairment of quality of life. The United States has not experienced this same trend, but recent ASH guidelines (2011) suggest ITP treatment based on the severity of

bleeding, reliability of family for close follow-up, and potential loss of quality of life and advised *observation alone* for children with no or mild bleeding, irrespective of the platelet count.

An internationally accepted classification of various bleeding manifestations is presented in **Table 4**. Observation alone is recommended in grade 1 and most of the grade 2 bleeds, while platelet raising therapy needs to be initiated in grade 3 and grade 4 bleeds. However, fear of ICH among parents as well as treating physicians is a major hindrance in employment of these recommendations. Although there have been no randomized trials using prevention of ICH or other significant bleeding events as a clinical end point, data extrapolated from natural history studies indicate that the vast majority of children do not experience significant bleeding at follow-up. A registry of 2,540 children followed for 6 months reported three episodes (0.17%) of ICH. All 3 patients had a platelet count less than $20 \times 10^9/L$ at diagnosis and 2 of the 3 had received treatment at diagnosis. A more recent study followed 1,682 children for a minimum of 6 months and determined that only 3 (0.2%) developed ICH. There is no evidence that medical therapy, such as administration of glucocorticoids or IVIG reduces the incidence of ICH and it may occur despite prior or concomitant therapy.

The decision to manage with *observation alone* requires a detailed discussion with the family about health-related quality of life, medication side effects and efficacy, and anticipatory guidance about preventing and monitoring for bleeding. Treatment may be appropriate in children if follow-up cannot be assured or child stays at a remote place. Children with high activity level and upcoming invasive procedure with risk of bleeding should also be considered for treatment. Though evidence suggests that adolescents are more likely than younger children to develop persistent or chronic disease, there have been no studies investigating a benefit to altered treatment in this age group or the age at which this effect is likely to be most present. Therefore, the management of adolescents should follow the usual management of children with ITP.

BOX 1 Treatment principles

- Treat the patient and not the platelet count
- Grading for severity of bleeding should be employed to decide management of a particular patient
- The first-line platelet raising drugs include corticosteroids, IVIG and IV anti-D
- Second-line drugs include high-dose dexamethasone or methylprednisolone; IVIG or IV anti-D, rituximab and immunosuppressive agents
- Splenectomy should only be considered in patient with chronic ITP with significant bleeds, who fail to respond to usual first- and second-line drugs
- Emergency measures in life-threatening bleeds includes use of more than one drug (methyl prednisolone with IVIG or IV anti-D), along with frequent platelet transfusions
- Thrombopoietin agonists (eltrombopag and romiplostim) have shown encouraging results in adults, but their long-term safety and efficacy is yet to be established in children

Table 4 Grade of severity in immune thrombocytopenic purpura patients

Grade	Bleeding/quality of life
Grade 1	Minor bleeding, few petechiae (≤ 100 total) and/or ≤ 5 small bruises (≤ 3 cm diameter); no mucosal bleeding
Grade 2	Mild bleeding, many petechiae (> 100 total) and/or > 5 large bruises (> 3 cm diameter); no mucosal bleeding
Grade 3	Moderate bleeding, overt mucosal bleeding, troublesome lifestyle
Grade 4	Mucosal bleeding or suspected internal hemorrhage

First-line Therapies for Newly Diagnosed Immune Thrombocytopenic Purpura

The three first-line drugs include corticosteroids, IVIG and anti-D. The goal of all platelet raising strategies for patients with ITP is to achieve a platelet count that is associated with adequate hemostasis, rather than a *normal* platelet count.

Corticosteroids

They act through several mechanisms: (1) inhibition of phagocytosis and antibody synthesis; (2) improved platelet production, and (3) increased microvascular endothelial stability. The latter effect aids in controlling bleeding even prior to an increase in platelet count. In randomized trials, prednisolone therapy has been shown to induce more prompt normalization of platelet count than placebo does. The most traditional regimen for treating children with ITP is oral prednisolone at a dose of 2 mg/kg/day (60 mg/m²/day) for 3–4 weeks. Higher doses of parenteral steroids have also been tried and result in a rapid increase of platelet counts. Various regimens of oral and parenteral steroids, response rate and adverse effects are mentioned in **Table 5**. If corticosteroids are chosen as treatment, there is no evidence to support any dosing regimen over the other. Yet, long-term corticosteroids should be avoided in children because of the side effects.

Intravenous Immunoglobulin G

Intravenous immunoglobulin blocks Fc-receptors on the macrophages of the reticuloendothelial system and thereby slows the clearance of antibody-coated platelets. Effects on cytokines might also be important for their therapeutic effect and IVIG may also influence the number and function of regulatory T-cells. IVIG produces more rapid increase in the platelet count than traditional doses of oral prednisolone (2 mg/kg/day), as documented in controlled trials and meta-analysis. The long course of IVIG (0.4 g/kg/day for 5 days) has now been superseded by shorter course (1 g/kg/day for 2 days or a single dose of 0.8 g/kg). Recent ASH guidelines recommend single dose of IVIG (0.8–1 g/kg), if a rapid increase in platelets is desired. Both splenectomized and nonsplenectomized patients may respond to IVIG and these responses are generally reproducible. However, platelet counts fall below acceptable level after 2–6 weeks in one-third of the patients.

Cost is a major limiting factor for the use of IVIG, as it is considerably more expansive compared to steroids or anti-D. Frequent side effects of IVIG therapy include flu-like symptoms, which may be alleviated by pretreatment with antihistaminics and analgesics. Approximately 10% patients may experience aseptic meningitis, which may result in additional diagnostic studies (CT scan) and prolonged hospital stay. Anaphylaxis is another serious, but rare side effect of IVIG therapy and seen more commonly in IgA deficient patients.

IV Anti-D

It has emerged as an additional treatment for ITP over last 30 years in Rh (D) positive individuals. These anti-D antibodies coat red blood cells and engage macrophage Fc-receptors. Thus, preferential red cell destruction takes place in the reticuloendothelial system sparing the platelets. The prerequisites for anti-D treatment in ITP are that the patient should be Rh (D) positive with a hemoglobin level greater than 10 g/dL. Patient should not have undergone splenectomy and coexisting hemolytic anemia should be ruled out.

The use of anti-D in the first-line treatment of newly diagnosed ITP in children remains controversial. Randomized studies in children with ITP have reported comparable or lower efficacy of various dosing regimens of anti-D to IVIG. Similarly, studies comparing an anti-D dose of 50 µg/kg and 75 µg/kg also report contradictory results. ASH 2011 guidelines suggest use of single dose IV anti-D in Rh-positive, nonsplenectomized patients, with negative direct antiglobulin test (DAT); however, there is inconclusive evidence to recommend a specific dose. The therapeutic effect of anti-D lasts for 1–5 weeks. Less cost, shorter administration time and shorter duration of hospitalization makes the medication more convenient to use compared to IVIG.

Adverse events like headache, nausea, chills, dizziness and fever have been reported in 3% of infusion. Some degree of hemolysis is inevitable, because of binding of antibody-coated Rh-positive RBCs to phagocytes. The average decline in hemoglobin ranges from 0.5 to 1 g/dL. More significant intravascular hemolysis, hemoglobinemia/hemoglobinuria and acute renal failure have been reported in few (–0.1–1.5%) patients.

All these first-line therapies are compared in **Table 5** in terms of approximate response rate, time to recovery and adverse effects. Response to different therapies has been variably defined in previous studies. A recent classification has been proposed by IWG, which has been adapted by ASH (2011) for better and uniform reporting of response to different therapies in ITP and is presented in **Table 6**. Except in the rare situation of a life-threatening bleed, there is no indication for administering a combination of the first line drugs. Temptation for adding a second drug without giving adequate time for the response to occur following the first therapy should be avoided.

First-line Therapies for Persistent and Chronic Immune Thrombocytopenic Purpura

The goal of treatment for children with persistent or chronic ITP is to maintain a hemostatic platelet count with first-line therapies and to minimize the use of prolonged corticosteroid therapy. Approximately two-thirds of patients with ITP experience at least a short-term increase in platelets after receiving corticosteroids, IVIG, or IV anti-D. High-dose dexamethasone (20–28 mg/m²/day) and high-dose methylprednisolone (30 mg/kg/day for 3 days,

Table 5 First-line therapies for pediatric immune thrombocytopenic purpura

Therapy	Approximate response rate	Time to recover	Adverse events
IVIG (0.8–1 g/kg single dose)	>80% patients	1–2 days	Headache, fever, flu-like symptoms, aseptic meningitis
IV anti-D (50–75 µg/kg)	50–77%	1–2 days	Headache, fever, chills, rarely intravascular hemolysis and acute renal failure
Prednisolone 1–2 mg/kg/day x 14–21 days; 4 mg/kg/day x 7 days, taper and stop by D21; 2 mg/kg/day x 7 days, tapered and stopped by D21; 4 mg/kg/day x 4 days, no tapering	<75% patients depending on dose	2–7 days	Weight gain, gastritis, hypertension, mood changes, osteoporosis, cataract, glaucoma
Methylprednisolone 30 mg/kg/day (max 1 g/day) IV or PO x 3 days			

Table 6 Definitions of response to treatment of immune thrombocytopenic purpura

<i>Complete response (CR)</i>	A platelet count $\geq 100 \times 10^9/L$ measured on two occasions >7 days apart and the absence of bleeding.
<i>Response (R)</i>	A platelet count $\geq 30 \times 10^9/L$ and greater than twofold increase in platelet count from baseline measured on two occasions >7 days apart and the absence of bleeding.
<i>No response (NR)</i>	A platelet count $<30 \times 10^9/L$ or $<$ twofold increase in platelet count from baseline or the presence of bleeding. Platelet count must be measured on two occasions 24 hours apart.
<i>Loss of complete response</i>	A platelet count $<100 \times 10^9/L$ measured on two occasions more than 24 hours apart and/or the presence of bleeding.
<i>Loss of response</i>	A platelet count $<30 \times 10^9/L$ or a less than twofold increase in platelet count from baseline or the presence of bleeding. Platelet count must be measured on two occasions more than 24 hours apart.

Based on recommendations of the International Working Group 2009

followed by 20 mg/kg/day for 4 days) have been used in persistent and chronic ITP and reported to be effective in 60–80% patients. However, both are associated with worse side-effect profile compared with prednisolone.

High-dose Dexamethasone

The safety and efficacy of high-dose dexamethasone was evaluated in recent trials in adults as well as children with acute ITP. A recent multicenter Italian study (GIMEMA ITP Working group) evaluated dexamethasone administered in four cycles at 40 mg daily for 4 days every two weeks. Responses were seen in 85.6% (complete response in 64.5%, partial response in 20% and minimal response in 1.1%). The overall response rate was similar in children and adults [<18 years, 36/42 (85.7%); >18 years, 41/48 (85.4%)]. Similar results were reported by our prospective study in children with chronic ITP. Thirteen patients with severe/chronic ITP, who had received multiple platelet enhancing therapies previously, were given short-course high-dose dexamethasone (HDD-SC) (20 mg/m² IV daily for 4 days, four cycles repeated every 14 days). Complete response was observed in 66.6% and moderate response in 17% patients, whereas 17% patients had no response.

Periodic Doses of Intravenous Immunoglobulin and Anti-D

They may also be used as maintenance therapy to defer splenectomy in young children with chronic ITP. Low-dose, alternate-day prednisone therapy can be used as an adjunct to maintenance IVIG therapy. In Rh (D) positive patients with chronic ITP, periodic anti-D is preferred over IVIG because of ease of administration, comparable efficacy and lower cost.

Second-line Treatment Options in Immune Thrombocytopenic Purpura

Approximately 5% of all ITP patients either fail to respond to first-line therapies or their condition relapses following cessation of therapy. Second-line drug therapies include high-dose dexamethasone or methylprednisolone; high-dose IVIG or IV anti-D, which are useful for rapid elevation of platelet counts; vinca alkaloids, the immunosuppressants such as azathioprine,

and cyclosporine, danazol which are used in less urgent cases; and the anti-CD20 monoclonal antibody rituximab, a relatively new therapy for ITP patients for which safety and efficacy data are still emerging. Splenectomy has been shown to provide long-term efficacy, although safety issues remain a concern. With the development of effective noncytotoxic therapies for ITP, immunosuppressive approaches have become less popular. The ASH guidelines support rituximab or high-dose dexamethasone as a preferred second-line therapy, alternative to splenectomy.

Rituximab

Rituximab is a humanized monoclonal antibody directed against CD20, an antigen expressed on the surface of B lymphocytes but not present on most plasma cells. After binding to the CD20 antigen, the Fc-domain of rituximab facilitates B-cell lysis and rapid clearance of pre-B cells and B cells that lasts for 6–12 months. In addition, rituximab prevents the activity of Th1-autoreactive cells by increasing the number of regulatory T cells.

There are no randomized trials for rituximab in children with ITP, but in 4 cohort studies and 10 case reports, there is evidence that children with chronic ITP have an overall response rate of 61%. Lack of sustained response to rituximab in all patients is explained by persistence of autoreactive B cells in the germinal centers and the BM. In addition, the majority of plasma cells are preserved in patients receiving anti-CD20 Ab therapy. Recent ASH guidelines suggest use of rituximab for children or adolescents with ITP who have significant ongoing bleeding despite treatment with IVIG, anti-D, or conventional doses of corticosteroids and as an alternative to splenectomy in children and adolescents with chronic ITP or in patients who do not respond favorably to splenectomy. Several dosing regimens for rituximab have been described, but most of the children received 375 mg/m² weekly intravenous transfusions for four consecutive weeks. The safety of rituximab in chronic ITP patients has not been established and increased risk of reactivated viral infections (hepatitis B, cytomegalovirus and varicella zoster) is an important concern.

Splenectomy

Splenectomy has been recognized for nearly a century as being effective treatment for ITP. As a reticuloendothelial organ rich with Fc receptor-expressing phagocytes, the spleen is the major site wherein antibody-coated (opsonized) platelets are actively removed from the circulation. Thus, removal of the spleen leads to prolonged survival of opsonized platelets in the circulation. The spleen may also house plasma cells that produce antiplatelet antibodies; therefore, splenectomy may help eliminate the source of the errant autoantibodies as well that cause ITP. Splenectomy is definitive treatment for most children with ITP, raising their platelet counts to normal or at least to levels that support liberalization of physical activities. In one pediatric study, splenectomy resulted in significant platelet increase in 85% of patients with chronic ITP. The ASH suggests that splenectomy should be considered for patients with chronic or persistent ITP who have significant bleeding symptoms, intolerance of medical therapy, or the need for improved quality of life. With advances in surgery, laparoscopic splenectomy is considered safe, even in smaller children. However, bleeding is possible, particularly if platelet counts are less than $20 \times 10^9/L$ at the time of surgery. Nonetheless, some patients will fail to respond, and some initial responders may have recurrence of thrombocytopenia after splenectomy and some these relapses have been correlated with the presence of accessory spleens.

Splenectomized patients have lifelong enhanced risk of thrombosis and infection. The asplenic patients are at risk of *Haemophilus*, *Neisseria*, and pneumococcus sepsis and incidence of overwhelming sepsis postsplenectomy is on the order of 1–2%. Asplenic patients are also at heightened risk of certain protozoal

infections, especially malaria and babesiosis. As infectious risk is particularly high among very young children, many authorities advocate deferring splenectomy until a minimum of 5 years of age. Immunization against *Haemophilus influenzae* type B, *Meningococcus*, and pneumococcus is recommended preoperatively, and oral prophylactic antibiotic therapy (typically penicillin) is recommended postoperatively, as is appropriate sepsis evaluation for fever. Portal vein thrombosis in the immediate postoperative period has also been reported in children.

Immunosuppressive Agents

A number of immunosuppressive agents other than steroids have been used to treat refractory ITP. These drugs are compared in **Table 7** in terms of doses, response rates and adverse effect profile.

Newer and Emerging Therapeutic Agents

Recombinant Thrombopoietin and Thrombopoietin-Receptor Agonists

An important advancement in the management of ITP is the introduction of TPO receptor agonists. The impact of this discovery has been just as important for the advancement of current understanding of pathophysiology, as it has been for expanding treatment options for patients with refractory disease. With increasing evidence that platelet production may be impaired in ITP, factors that stimulate the proliferation, survival, and differentiation of megakaryocytes have become potential therapeutic agents. Several TPO receptor agonists have been studied. The first were recombinant forms of human TPO, but development of these

Table 7 Immunosuppressive agents used in immune thrombocytopenic purpura

Drug	Mechanism of action	Dose	Response rate	Adverse effects	Important points to remember
Azathioprine	Acts on lymphocytes	50–200 mg/m ² /day orally, combination with steroids synergistic and allow steroid dose reduction	Approx 45%	Dose-related leukopenia, opportunistic infections, malignancy	Continuous therapy for 4–6 months is required before a patient is considered unresponsive
Cyclophosphamide	Alkylating agent, acts on lymphocytes	Oral: 1–2 mg/kg/day × 16 weeks IV: 0.3–1 g/m ² 1–3 doses every 2–4 weeks	24% to 85%	Myelosuppression, alopecia, nausea, infertility, teratogenicity, hemorrhagic cystitis and increased risk for malignancy	Used for patients refractory to corticosteroids and/or splenectomy
Cyclosporin A	Disrupts T-cell function through calcineurin inhibition	5 mg/kg/day divided oral doses, (maintaining a serum cyclosporine level of 200–400 ng/mL)	>80% of patients resistant to 1st line therapy, 42% complete response	Fatigue, renal insufficiency, hypertension, hirsutism and liver dysfunction	The drug should be discontinued if no response after 4 weeks
Tacrolimus	Disrupts T-cell function through calcineurin inhibition	0.15–0.3 mg/kg/day in divided oral doses (maintain trough serum concentration of 5–20 ng/mL)		Hypertension, tremors, headache and hyperglycemia	
Danazol	Attenuated androgen, unknown mechanism in ITP	Orally 300–400 mg/m ² /day, in divided doses (10–15 mg/kg/day)	60–67%	Acne, hirsutism, fluid retention, deepening of voice in women, headache, nausea, rash, breast tenderness and irregular menstrual bleeding	Two months therapy is required before a response is seen. Older females and splenectomized patients have the highest response rate
Dapsone	Moderate steroid-sparing agent	Orally at a dose of 75–100 mg/day		Male patients at risk for G-6-PD deficiency should be screened before starting treatment, monitor for hemolysis and methemoglobinemia	Splenectomized patients have a low response rate
Mycophenolate mofetil	Antiproliferative immune-suppressant, inhibits both T- and B-cells	Progressively increasing doses (250 to optimally 1,000 mg/day twice a week over 3 weeks)	Approx. 39% in refractory ITP	Generally well tolerated	Effective in steroid-resistant ITP patients
Vinca alkaloids (Vincristine and vinblastine)	Bind tubulin and inhibit microtubule polymerization, disrupt phagocytosis	Vincristine: 1.5 mg/m ² (max 2 mg), vinblastine 6 mg/m ² (max. 10 mg) IV weekly	Approx. 47%	Vincristine-peripheral neuropathy, constipation and alopecia. Vinblastine-dose related myelosuppression	A 4-week trial is required, before considering the drug ineffective
Interferon Alpha	Unknown mechanism of action	3 million U/m ² subcutaneous thrice a week for 4 weeks	25% in chronic, refractory adult ITP	Flu-like symptoms and neutropenia	Not tested in children

agents was halted after one form caused thrombocytopenia due to autoimmune destruction of endogenous TPO in several patients. The so-called second-generation thrombopoietic growth factors have been designed to avoid antigenicity. A number of studies with recombinant TPO and TPO receptor agonists have shown encouraging results in adults, and following two synthetic TPO molecules are now licensed for treatment of severe chronic adult ITP.

Romiplostim (AMG 531)

Romiplostim has been FDA-approved since 2008, and the majority of patients have had a very good response with an initial dose of 1 µg/kg given subcutaneously weekly. Two randomized studies investigating romiplostim reported an increase of the platelet count to over $50 \times 10^9/L$ in more than 80% of the children. The platelet response was maintained for a median of 7 weeks and romiplostim seemed to be safe. Further studies in children are definitely needed, but initial results suggest that romiplostim may have a role in the treatment of severe chronic ITP in children.

Eltrombopag

A phase 2 study in chronic ITP patients provides evidence that eltrombopag can both increase platelet count and possibly reduce bleeding symptoms. Another recent open label study evaluated the safety and efficacy of eltrombopag in adults. Both splenectomized and nonsplenectomized patients achieved platelets $>50 \times 10^9/L$ at least once (80% and 88%, respectively) in this study. Long-term treatment with eltrombopag was reported safe, well tolerated, and effective in maintaining platelet counts in the desired range. Increased risk for thrombosis, rebound thrombocytopenia and formation of BM reticulin are potential safety concerns being evaluated with use of TPO receptor agonists.

Rozrolimupab

Rozrolimupab is a recombinant mixture of 25 fully human Rh D-specific monoclonal antibodies, represents a new class of recombinant human antibody mixtures. In a recent dose escalation study, 61 RhD+ adult patients with primary immune thrombocytopenia received a single intravenous dose of rozrolimupab ranging from 75 µg/kg to 300 µg/kg. At the dose of 300 µg/kg platelet responses were observed after 72 hours and persisted for at least 7 days in 8 of 13 (62%) patients. The most common adverse events were headache (20%) and pyrexia (13%). Rozrolimupab was well tolerated, but yet to be tested in pediatric patients.

Emergency Treatment in Immune Thrombocytopenic Purpura

Emergency treatment is required for severe, life-threatening bleeds, e.g., ICH or organ-threatening bleeds. The aim of treatment is to control the bleeding and salvaging the organ as early as possible. This can be achieved with following measures:

First-line Therapies in Combination

High-dose methylprednisolone is administered in combination with IVIG or anti-D. IVIG and methylprednisolone may be repeated for at least 1–2 days, based on response.

Platelet Transfusions

Transfusions are indicated in the setting of life-threatening bleeds to buy time for drug therapy to have an action. At least 2–3 fold higher dose of platelets is administered to temporarily increase the circulating platelet count. Survival of transfused platelets may be improved with concurrent IVIG therapy. Continuous infusion of platelets may be beneficial in selected cases.

Splenic Artery Embolization or Splenectomy

Splenic artery embolization or emergency splenectomy is indicated in life-threatening bleeds unresponsive to first-line drugs or in a patient who is acutely ill and will benefit from an immediate rise in platelet count. Splenic artery embolization is typically performed by interventional radiologist and may be life-saving. The splenic artery is cannulated through the femoral artery and polyvinyl alcohol particles, coils or gelatin sponges are utilized for embolization. There is often a prompt rise in platelet count, as in splenectomy. However, the infarcted spleen has to be surgically removed within the next few days to avoid complications of pain and fever. If expertise is available, splenic artery embolization is a faster and safer bridge procedure prior to splenectomy. Data regarding the use of splenic artery embolization in ITP related life-threatening bleeds is limited and availability of expertise is a major limitation.

Emergency Splenectomy

It is indicated if facilities for splenic artery embolization are not available. Despite first-line therapies, several patients still have very low platelet count at the time of splenectomy. The feasibility and safety of laparoscopic splenectomy in patients with severe thrombocytopenia has been reported, hence, emergency splenectomy should not be delayed in view of severe thrombocytopenia.

Recombinant Vlla

It has been used in ICH refractory to platelet enhancing agents as *off-label use*. It is used in a dose of 90–120 µg/kg infusions every 2–3 hourly, till the cessation of bleeding.

Adjunctive Therapies

Control of bleeding from mucosal surfaces, particularly epistaxis, gum bleeding and menorrhagia can be aided with antifibrinolytic agents. Two agents, aminocaproic acid and tranexamic acid are available. Tranexamic acid is preferred due to longer half-life, higher potency and lower toxicity. Tranexamic acid is given in a dose of 25–50 mg/kg every 6–8 hours. It is absorbed from the buccal mucosa and subsequently secreted in the saliva. Hence, in oral bleeding, hemostasis is better achieved with a mouthwash or local application of crushed tablets in younger children. Aminocaproic acid is administered as 100–200 mg/kg (maximum 10 g) stat, followed by 50–100 mg/kg/dose every 6 hourly (maximum 5 g). This supportive therapy is safe, cheap and effective. Antifibrinolytic agents are contraindicated in hematuria, as ureteric clot formation can result in colic and obstruction of urine outflow.

Site-Specific Management of Bleeds

Epistaxis

Caretakers should be educated regarding the simple maneuver of nasal pinching. Sustained pressure should be applied by pinching the soft part of the nose below the nasal bones, on the ala nasi, which corresponds to Kiesselbach plexus (Little's area), between the thumb and index finger for 20 minutes, continuously. Nasal packing should be done if bleeding persists for more than 20 min with continuous digital pressure, besides starting first-line drugs.

Menorrhagia

Menorrhagia in an adolescent with ITP is commonly managed with oral contraceptive pills containing estrogen and progesterone (levonorgestrel) or cyclic high-dose progestins, e.g., norethisterone. If unresponsive, GnRH agonists, including leuprolide can be used for short period, as this group of drugs has adverse effect on bone mineral density, besides being expensive. Severe acute bleeding will require therapy with intravenous estrogens and platelet enhancing

drugs. Supportive management with tranexamic acid and iron supplementation is important. Nonsteroidal anti-inflammatory drugs (NSAIDs), including mefenamic acid and intramuscular injections (e.g., depot medroxyprogesterone acetate) should be avoided.

Intracranial Hemorrhage

Intracranial hemorrhage should be managed in an intensive care unit with maintenance of airway, breathing and circulation; head end elevation (30°) and osmotherapy (mannitol or 3% saline) for raised intracranial pressure. Neurosurgery consultation should be sought for definitive management. Besides these, emergency measures to raise the platelet counts at hemostatic levels should be initiated.

Supportive Care

One of the most challenging aspects to the management of a child with ITP is restricting participation in normal play and sports activities because of concerns over bleeding risk. In cases where the ITP persists for weeks or months, activity limitations must be balanced with an appreciation of the consequences of *sheltering* a child with chronic ITP, including weight gain and sick child syndrome. Participation in any activity associated with a significant risk of trauma (especially head injury) should be avoided when platelet counts fall below 50×10^9 to $75 \times 10^9/L$. This includes avoiding stairs and other climbing structures such as playground equipment for younger children, and avoiding contact sports for older children and adolescents. Safety gears including helmets, knee pads, etc. should be used for outdoor play and cycling. Regardless of approach, medications that inhibit platelet function, most notably NSAIDs and aspirin, and intramuscular injections should be avoided.

Vaccination for Children with Immune Thrombocytopenic Purpura

Children may develop ITP after vaccinations with a live attenuated vaccine. However, the incidence of ITP is significantly lower than that observed during the natural diseases that the vaccine prevents. Consequently, vaccination is not contraindicated in children with a history of ITP. Hence, ASH 2011 guidelines recommend that children with a history of ITP who are unimmunized receive their scheduled first MMR vaccine. In children with either nonvaccine or vaccine-related ITP who have already received their first dose of MMR vaccine, vaccine titers can be checked. If the child displays full immunity (90–95%), then no further MMR vaccine should be given. If the child does not have adequate immunity, then the child should be reimmunized with MMR vaccine at the recommended age.

PROGNOSIS

The outcome of children with ITP is generally good. Most cases have only skin bleeds. Severe bleeding manifestations are described in 3–5% cases. With appropriate therapy, most cases with severe bleeding recover. Complete remission with or without drug therapy occurs in 60–70% cases within initial few months from diagnosis. According to ICIS observations, incidence of chronic ITP is higher than generally reported figure of 10%. However, large majority of them achieve remission in second year of their illness.

IN A NUTSHELL

1. Immune thrombocytopenic purpura is a self-limiting disorder and most children (70–80%) undergo spontaneous remission over a period of 6 months.
2. Skin and other minor bleeds do not need any specific platelet raising therapy, irrespective of the platelet count.
3. There is a small but definite risk of ICH (~0.2%) which persists till the resolution of thrombocytopenia. Treatment has not been proven to reduce the incidence of ICH, nor does it reduce the chances of progression to chronic ITP.
4. Corticosteroids, IVIG and IV anti-D, are the first-line therapy for ITP. Second-line treatment options include rituximab, high-dose dexamethasone, splenectomy and immunosuppressive agents.
5. Routine transfusion of platelets is not required as transfused platelets are also destroyed by circulating antiplatelet antibodies.
6. Supportive therapy (i.e., fibrinolytic agents and local care) plays as important role as the main therapy in management of ITP.
7. To avoid trauma, particularly head injury, use of helmets during outdoor play, cycling, etc. should be advised. NSAIDs (aspirin, ibuprofen, etc.) and intramuscular injections should be avoided.
8. Patient should be brought to physician's notice in case of headache, hematuria or GI bleed, as it is an indication for systemic therapy.

Chapter 38.21

Platelet Function Defects

Neelam Varma

Platelet function defects (PFDs) are a heterogeneous group of rare diseases. The degree of functional abnormality of platelets and thrombocytopenia determines the clinical manifestations. PFDs are important, as severe defects may cause excessive bleeding beginning in early childhood, although most of PFDs have mild bleeding tendencies which present late and therefore it is not always easy to make distinction among inherited and acquired quantitative and qualitative platelet disorders.

However in clinical practice, most of the platelet disorders are due to acquired factors including drugs and metabolic diseases. The diagnosis of PFD requires extensive laboratory investigation. Routine laboratory tests are not satisfactory for differential diagnosis in some cases, and most of the specific tests are not readily available. Although PFDs are rare, elucidation of their pathogenesis has contributed enormously to current knowledge. The identification of molecular pathology in patients with PFD has improved our understanding of normal megakaryocyte and platelet physiology, as well as the mechanisms of hemostasis and thrombosis.

EPIDEMIOLOGY

Population prevalence is estimated to be approximately 1 in 1,000,000 for Glanzmann thrombasthenia (GT) and Bernard-Soulier syndrome (BSS) and 1 in 40,000 for nonsevere hereditary platelet function defects (HPFD), although nonsevere HPFD may be underrecognized in most clinical diagnostic centers.

Accurate diagnosis of the severe phenotype disorders like BSS and GT is essential in order to direct specific treatments, to provide accurate prognostic advice and for genetic counseling. To fulfil these objectives, it is necessary to identify both the functional platelet defect at protein level and the causative genetic variation(s).

Quantitative and qualitative integrity of platelets can be checked by screening tests like platelet count, skin bleeding time or platelet-vWF function analyzer-100 (PEA-100) tests. However, these tests underestimate some platelet disorders. In the setting of suggestive clinical/family history and normal vWF function, further tests should be planned.

PATHOGENESIS

Classification of inherited platelet disorders based on platelet count, size, function, or underlying genetic abnormality is depicted in **Table 1**. Both quantitative and qualitative abnormalities of platelets lead to signs and symptoms suggestive of defects of primary hemostasis, i.e., mucocutaneous bleeds, epistaxis, menorrhagia, and small ecchymoses over skin.

It is rare for patients to present with spontaneous life-threatening bleeding (e.g., intracranial hemorrhage, massive gastrointestinal or genitourinary bleeding). Menorrhagia and bleeding during pregnancy and labor are a problem in female patients. Unexpected excessive bleeding after trauma or surgery may be the first symptom in milder cases of PFD. Rarely, PFD is a part of a complex of multisystem disorder such as Fanconi anemia, Chediak-Higashi syndrome, or May-Hegglin anomaly (**Table 1**). Platelet count, size and morphology must be assessed before embarking upon further investigations. *Low platelet count* must always be cross-checked by examination of a peripheral blood film. Platelet aggregates and platelet satellitism (binding to neutrophils) induced by ethylenediaminetetraacetic acid or agglutinins, can

Table 1 Classification of inherited platelet disorders

1. Decreased production of platelets
 - a. CAMT

 - d. Integrin $\alpha_2\beta_1$ (GP Ia/IIa) defects
 - e. Integrin $\alpha_5\beta_1$ (VLA-5) defects
 - f. Integrin $\alpha_6\beta_1$ (VLA-6) defects
 - g. Integrin $\alpha_v\beta_3$ defects
6. *Miscellaneous*: GATA-1 related thrombocytopenia, Wiskott-Aldrich syndrome, mediterranean macrothrombocytopenia, Montreal platelet syndrome, familial platelet disorder with propensity to myeloid malignancy (FDP/AML)

Abbreviations: CAMT, congenital amegakaryocytic thrombocytopenia; TAR, thrombocytopenia with absent radius; MYH9, mutations of nonmuscle heavy chain gene; vWD, von Willebrand disease; GP, glycoprotein

easily be detected as a cause of pseudothrombocytopenia. Large platelets are found in BSS and increased peripheral platelet destruction; gray vacuolated platelets in α -granule deficiency and microplatelets in Wiskott-Aldrich syndrome.

APPROACH TO DIAGNOSIS

When to Suspect

Platelet function defects should be suspected whenever there is bleeding with normal platelet count or when the bleeding is disproportionate to the severity of thrombocytopenia. Positive family history of platelet type bleeding with normal platelet count and presence of congenital malformations/physical stigmata indicate toward PFD. The following points should be evaluated:

- Family history for consanguinity, bleeding in family members/siblings
- Type and severity of bleeding [questionnaire-based bleeding assessment tools (BATs)]
- Platelet count determination

- Exclusion of drugs—nonsteroidal anti-inflammatory drugs (NSAIDs), secondary causes such as uremia, liver disease
- Examination of platelet morphology:
 - Giant platelets
 - Inclusions within neutrophils
 - Absence of platelet clumps on peripheral blood smear
 - Gray platelets.
- *Clot retraction test*: Useful in GT and fibrinogen disorders
- *Platelet-vWF function analyzer-100 (if available for screening)*: Measures closure time of aperture in collagen/epinephrine or collagen/adenosine 5'-diphosphate (ADP) cartridges at high shear rates.
- Platelet aggregometry on platelet rich plasma (PRP) with agonists. Commonly used agonists are: (1) epinephrine; (2) ADP; (3) collagen; (4) thrombin; (5) arachidonic acid; (6) low (< 0.4 mg) and high-dose ristocetin.

Pre-requisites for Platelet Function Testing

- Stop aspirin/NSAIDs for minimum 7 days
- Platelet count has to be greater than $100 \times 10^9/L$.
- Fasting sample and a normal control sample are required.

Characteristic Findings

- *Bernard-Soulier syndrome* Absence of aggregation with ristocetin and normal aggregation with other agonists. Not corrected on testing after mixing with normal pooled plasma (NPP).
- *Glanzmann thrombasthenia* Absence of aggregation with epinephrine, ADP, collagen and arachidonic acid. Aggregation-disaggregation response can be seen with ristocetin.
- *Disorders of granule secretion/storage pool defect* Show absence of secondary wave of aggregation.

Investigations

- *Flow cytometry (FCM)* To confirm deficiency of platelet membrane glycoproteins. Platelet aggregation studies can also be performed with FCM.
 - *Electron microscopy (EM)* In cases of deficiency of alpha/delta granules.
- Platelet function tests (PFTs) are listed in **Table 2**.

Bleeding Time

Bleeding time is a poor predictor of platelet dysfunction and bleeding complications. The test involves making a superficial skin incision on the patient's forearm using a standardized device and the blood from the wound is blotted intermittently until the bleeding stops. The time taken from the incision to cessation of bleeding (formation of hemostatic plugs) is noted as bleeding time. It depends upon the platelet count and the ability of platelets to adhere to subendothelium and form aggregates. Prolonged bleeding time is observed in patients with thrombocytopenia, platelet function disorders, von Willebrand disease (vWD), vascular abnormalities and rarely severe deficiency of factors V/XI/fibrinogen.

Bleeding time has many confounders, is poorly reproducible and difficult to standardize. Presently, it has been mostly discontinued in clinical practice and is replaced by other simpler screening tests.

Platelet Function Analyzer-100

This is a rapid whole blood analyzer capable of screening for PFT. Whole blood is passed through a hole in a membrane coated with collagen and ADP (CADP) or collagen and epinephrine (CEPI). Under the combined effects of high shear rates and vWF, platelets when encountered with the membrane spontaneously adhere to collagen and aggregate due to stimulation by ADP or epinephrine.

Table 2 Platelet function tests

Abbreviations: ADP, adenosine 5'-diphosphate; ATP, adenosine 5'-triphosphate; PFA-100, platelet-vWF function analyzer-100

The time taken for a platelet plug to form, occlude the aperture and stop the flow of blood is measured as closure time (CT). Markedly prolonged PFA-100 CT is observed in GT and BSS and IIb/IIIa glycoprotein receptor inhibitors (abciximab, tirofiban, etc.). More severe types of vWD (types 2 and 3) are easily detected by PFA-100. Sensitivity is quite low for mild-to-moderate bleeding disorders like storage pool disease and secretion defects.

Platelet-vWF function analyzer-100 CT can be affected by hematological variables unrelated to platelet function. Severe thrombocytopenia (platelet count < $50 \times 10^9/L$) and anemia (hematocrit < 25%) result in abnormally prolonged CT. PFA-100 CT also is prolonged in patients with vWD and in normal O blood group individuals (known to have low vWF levels).

Platelet Aggregometry

Two methods using different blood preparations are practiced for study of platelet aggregation: PRP by optical method or whole blood by impedance method.

Platelet Rich Plasma Aggregation by Optical Method

The patient and control individuals should not ingest any drugs, food items or beverages that are known to affect aggregation for a minimum of 10 days. Overnight fasting is advisable as presence of chylomicrons may disturb aggregation patterns. Panel comprises of following agonists:

- **Adenosine 5'-diphosphate** Low concentrations of ADP (< 0.5–2.5 $\mu\text{mol/L}$) cause primary or reversible aggregation. Higher concentrations lead to secondary or irreversible aggregation.
- **Collagen** Lower concentrations cause a short *lag* phase succeeded by a single wave of aggregation resulting from activation of arachidonic acid pathway and release from granules. Higher concentrations cause a sudden increase in intraplatelet calcium concentration and may lead to release reaction without activating the prostaglandin pathway.
- **Ristocetin** This agonist does not cause aggregation but induces platelet *agglutination* by binding to vWF and membrane receptor.
- **Arachidonic acid** This agonist induces thromboxane A₂ (TXA₂) generation and granule release even if there is a defect of agonist binding to the surface membrane or of the phospholipase-induced release of endogenous arachidonate. When further steps in the pathway are impaired such as absence or inhibition of cyclooxygenase (aspirin effect), arachidonic acid does not produce normal aggregation response.
- **Epinephrine/adrenaline** Its response resembles that of ADP; however, aggregation is not preceded by shape change. Severely reduced response to epinephrine may be shown by some clinically normal persons.

It is a gold standard test for platelet function, but is time-consuming, labor intensive and requires adequate expertise in technical procedure and interpretation. Results are modified by lipemia, hemolysis or red-cell contamination. All these factors cause lot of interlaboratory variability in aggregometry interpretation.

Whole Blood Aggregation by Impedance Method

This is a simple and fast method which obviates the need of preparing PRP. Impedance method is thought to be more sensitive in the study of hyperactive platelets and effects of aspirin and clopidogrel on platelets. An aggregation curve is generated, resistance to the electric flow being proportional to platelet aggregation. Reduced or absent aggregation response to one or more agonists clinches the diagnosis or provides important leads (**Table 3**).

Platelet Secretion Assays

Platelet secretion can be measured by luciferin-luciferase assay (easy to perform) and ¹⁴C-labeled serotonin release assay.

Platelet Flow Cytometry

Flow cytometer is a very sensitive tool to assess the expression of glycoprotein (or other molecules) on the platelets. In expert hands, it finds use in diagnosis of following conditions: Bernard-Soulier syndrome, GT, acquired GT (multiple monoclonal antibodies used to detect autoantibody blockade of GP IIb/IIIa), storage pool defect, heparin-induced thrombocytopenia, platelet activation and reactivity, and monitoring thrombopoiesis.

Platelet function disorders are a rare and underestimated cause of bleeding in hematological practice. The inherited variety includes defects in platelet adhesion, aggregation, secretion and platelet procoagulant activities. Affected individuals seek medical opinion depending upon personal perception of seriousness of the bleeding manifestations. Milder phenotypes may pass off unrecognized in childhood and may even be missed later in life, unless specially tested for PFT. Many mild platelet function disorders in females present as menorrhagia. Plan of investigations includes a coagulation screen, which may show a prolonged bleeding time, followed by platelet aggregation tests with a panel of agonists. Flow cytometry for platelet surface markers, membrane glycoprotein analysis and identification of the genetic defects must be done later. Extra care should be taken while drawing the venous blood, preparation of samples, and interpretation of results of PFT.

MANAGEMENT

The majority of patients with PFD do not need treatment on a regular basis, but require it after injury, during surgical procedures, and during bleeding episodes. Patients have to be educated about maintaining dental hygiene, avoiding contact sports and activities carrying bleeding risk, and avoiding the use of antiplatelet drugs. Bleeding from minor cuts, nose, and gingiva can be stopped by applying pressure. Minor bleeding symptoms can be decreased by using topical hemostatic agents such as gelatin sponges, fibrin sealants, and antifibrinolytic drugs such as tranexamic acid.

The data on the efficacy and safety of desmopressin [1-desamino-8-D-arginine vasopressin (DDAVP)] in the treatment of intermittent peritoneal dialysis (IPD) patients are limited because the literature includes only small case series with different

Table 3 Comparative results of platelet aggregometry and PFA-100

Disorder	Platelet aggregation					PFA-100 CT		Remarks/further tests
	ADP/epinep		Col	AA	Ri	CADP	CEPI	
	1 ^o	2 ^o						
Inherited

SPD	N/d	a	N/d	N/d	N	N/P	N/P	ATP/ADP pool
Acquired								
Aspirin	N/d	a	D	a	N	N	P	Stop drug and retest
ADP-RA	d	d	N/a	N	N/a	N/P	N/P	
GP IIb/IIIa inh	d	d	D	a	N/a	P	P	

1⁰ = primary wave, 2⁰ = secondary wave

Abbreviations: a, absent; ADP-RA, ADP receptor antagonists; BS, Bernard-Soulier syndrome; CT, closure time; d, decreased; GPIIb/IIIa inh, GPIIb/IIIa inhibitors; GT, Glanzmann thrombasthenia; i, increased; N, normal; P, prolonged; SPD, Storage pool disease; vWD, von Willebrand disease

results. Desmopressin is indicated for the prevention or treatment of bleeding episodes in patients with type-1 VWD and in patients with hemophilia A with factor VIII levels >2–5%. It stimulates the release of vWF from endothelial cells and increases factor VIII levels in plasma.

Both gynecologic and hematologic treatments are required for management of menorrhagia in patients with PFD. Oral contraceptives or hormonal intrauterine devices along with tranexamic acid can be used to reduce bleeding during menses. Patients with severe bleeding after trauma, surgery, or delivery may require platelet and RBC transfusions.

IN A NUTSHELL

1. Severe platelet function defects can present early in childhood with bleeding manifestations.
2. Signs and symptoms suggestive of defects of primary hemostasis can be caused by both quantitative and qualitative abnormalities of platelets.
3. Platelet count, size and morphology must be assessed before performing further investigations.
4. Further tests should be planned in the setting of suggestive clinical/family history and normal vWF function.
5. Platelet-vWF function analyzer-100 is a rapid whole blood analyzer capable of screening for PFT, however currently not available in India.
6. Platelet aggregometry is the gold standard test for platelet functions and provides direction for planning further tests.
7. Platelet FCM, if expertise and equipment are available, can be conveniently used for investigation of specific disease entities like BSS, GT, etc.
8. Adequate care must be taken for giving instructions to the patient and controls to avoid ingestion of items likely to interfere with platelet aggregation, drawing the venous blood, and preparation of samples.
9. Abnormal results of PFT should be interpreted carefully and repeated at least once.

Chapter 38.22

Thrombotic Disorders

Sidharth Totadri, Deepak Bansal, RK Marwaha

With increasing clinical awareness and availability of imaging modalities, pediatric thrombotic conditions are being increasingly diagnosed and treated. Prothrombotic states, which may be primary or secondary, include venous thromboembolic events, arterial thrombosis, arterial ischemic stroke and cerebral venous sinus thrombosis. Advances in the field of anticoagulant therapy have made it possible to reduce the morbidity and mortality resulting from these conditions.

EPIDEMIOLOGY

Data available from international registries and databases suggest that thromboembolic events have increased fivefold to tenfold, from 5 per 10,000 to 18–58 per 10,000 hospitalized children, over the past 20 years. This increased incidence may be attributed to the advances in neonatology and pediatric medicine. There has been progress in neonatal care and survival of preterm and low birth weight babies who have a physiological hypercoagulable state. There is improvement in critical care of sick children and extensive use of central venous access devices, which are the most common cause of pediatric thrombosis. There has been increased treatment and survival of children with chronic illnesses, including nephrotic syndrome, lupus and cancers. Progress in radiology and availability of modalities, including Doppler, computed tomography (CT) and magnetic resonance imaging (MRI), has led to increased diagnosis of thromboembolic events. There is increased awareness and screening for inherited thrombophilic states and antiphospholipid antibody syndrome.

PATHOPHYSIOLOGY

The pathological tendency to develop excessive and unwanted thrombosis is called thrombophilia. This may be the result of inherited genetic changes involving the physiological anticoagulant proteins, or secondary to acquired risk factors. The normal anticoagulant mechanism is illustrated in **Figure 1**. The tissue factor initiated extrinsic pathway and the surface dependent intrinsic pathway converge to produce thrombin from prothrombin. This is regulated by dynamic inhibitory systems. Protein C is activated by the thrombin-thrombomodulin complex, leading to inactivation of factors Va and VIIIa. This action is catalyzed by protein S. Antithrombin, which is present in the normal plasma, neutralizes the procoagulant serine proteases, namely, factors XIa, IXa, Xa and IIa. Tissue factor (TF) pathway inhibitor blocks the TF-factor VIIa complex.

Inherited Thrombophilias

Inherited mutations affecting the proteins involved in anticoagulant mechanisms may lead to unregulated production of thrombin in inappropriate locations. The common inherited thrombophilias are summarized in **Table 1**.

Protein C and Protein S Deficiency

Hereditary deficiency of protein C or S may be homozygous, heterozygous or compound heterozygous. Compound heterozygous or homozygous deficiencies manifest in the first few days of life as life threatening disseminated intravascular coagulation and purpura fulminans. Purpuric lesions form on pressure points and progress into painful black eschars. There is

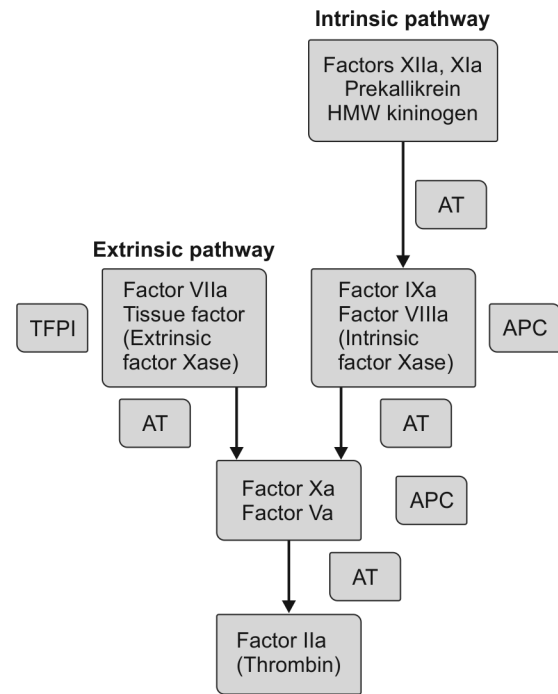

Figure 1 Coagulant and anticoagulant factors in the normal physiological pathway. Antithrombin (AT) inhibits activated factors XI, IX, X and thrombin. Activated Protein C (APC) in conjunction with Protein S inhibits activated factor V and VIII. Tissue factor protein inhibitor (TFPI) inhibits the extrinsic pathway

increased risk of recurrent thromboembolic phenomena in older children and adolescents, such as deep vein thrombosis (DVT) of lower extremities and pulmonary embolism (PE). Severe deficiency states are diagnosed by protein activity of less than 1% on clotting or immunological assays. Heterozygous states need repeat assay after 6 months, as there may be a false decrease in protein levels during the thrombotic episode secondary to consumption.

Homozygous/compound heterozygous patients require fresh frozen plasma 10–20 mL/kg or protein C concentrate, twice daily, till resolution of the purpuric lesions followed by lifelong anticoagulation with low molecular weight heparin (LMWH) or warfarin to prevent thrombosis.

Antithrombin Deficiency

This condition also manifests with thromboembolic disease, most commonly DVT and PE. The risk increases with age; the presentation being uncommon before puberty. In some patients, functional deficiency with mutation affecting the heparin binding site may make them refractory to conventional doses of heparin.

Table 1 Inherited thrombophilic conditions

Condition	Inheritance
Antithrombin deficiency	AD
Protein C deficiency	AD
Protein S deficiency	AD
Factor V Leiden mutation	AD
Prothrombin G20210A	AD
MTHFR mutations	AR
Dysfibrinogenemias	AD

Abbreviations: MTHFR, Methylene tetrahydrofolate reductase; AD, autosomal dominant; AR, autosomal recessive

Factor V Leiden and Prothrombin G20210A Mutations

These are point mutations, which respectively render factor V and II resistant to protein C induced inactivation, causing a hypercoagulable state. There is predisposition to venous thromboembolism (VTE). They can be diagnosed by polymerase chain reaction for the specific mutations.

Methylenetetrahydrofolate Reductase Mutations

Mutations affecting the methylenetetrahydrofolate reductase (MTHFR) enzyme (e.g., *MTHFR* C677T) results in hyperhomocysteinemia, which in turn leads to endovascular dysfunction and thrombophilia. Hyperhomocysteinemia is an independent risk factor for VTE, cerebral venous sinus thrombosis and arterial ischemic stroke. Diagnosis is suspected by elevated fasting homocysteine levels. Folate supplementation can decrease the risk of thrombotic events.

Acquired Thrombophilic States

The classical Virchow's triad of thrombosis includes: (1) stasis, (2) hypercoagulable state, (3) endothelial injury. Acquired thrombophilic states induce one or more of these components. The pathophysiology of these conditions is outlined in **Figure 2** and **Table 2**. **Figure 3** exemplifies an acquired thrombophilic state in a patient with thalassemia major.

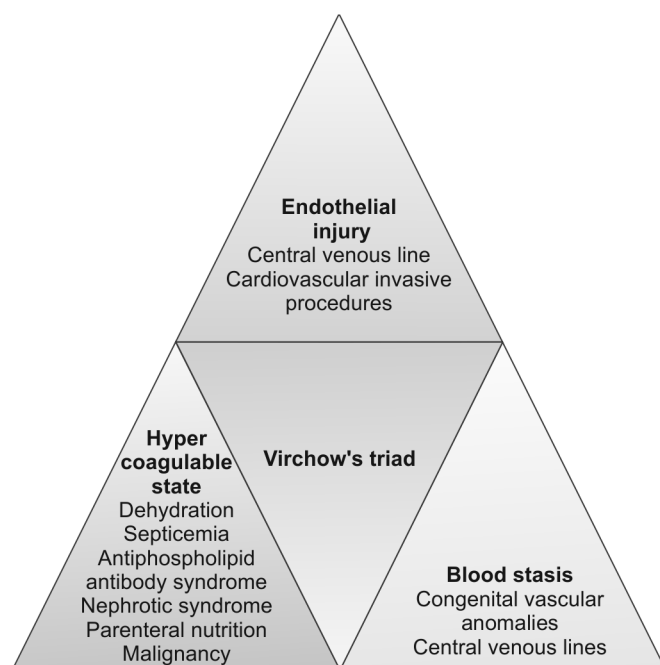

Figure 2 Image showing common acquired thrombophilic states. Acquired thrombophilic states affect one or more components of the classical Virchow's triad, which include endothelial injury, hypercoagulable state and blood stasis

Table 2 Pathophysiology underlying common acquired thrombotic states

Condition	Pathogenesis of thrombotic state
Central venous line	Stasis of blood, venous wall injury
Cyanotic congenital heart disease	Polycythemia with hyperviscosity of blood, presence of stents and prostheses
Gram-positive septicemia	Bacterial mucopolysaccharides activate platelets and serine proteases

Contd...

Contd...

Condition	Pathogenesis of thrombotic state
Gram-negative septicemia	Bacterial endotoxins cause cytokine cascade and endothelial injury
Dehydration secondary to diarrhea, ketoacidosis, poor intake, burns, high fever	Increased hematocrit and hyperviscosity of blood
Total parenteral nutrition	Dextrose and phosphate cause prothrombotic state
Nephrotic syndrome	Hyperfibrinogenemia, thrombocytosis, hemoconcentration, relative immobilization with urinary loss of antithrombin, proteins C and S
Malignancy	Thrombin production by tumor, hyperleukocytosis in leukemia leading to hyperviscosity of blood
Drugs	Oral contraceptive pills, L-Asparaginase, steroids
Inflammatory diseases (Systemic lupus erythematosus, inflammatory bowel disease, Behçet's disease)	Tissue factor release, vascular injury, antiphospholipid antibodies
Paroxysmal nocturnal hemoglobinuria	Alteration of platelet surface glycoproteins
Anemia	Iron-deficiency associated with thrombocytosis; sickle cell disease causes stasis and hyperviscosity; patients with hemolytic anemia—postsplenectomy
Miscellaneous	Injury secondary to trauma or surgery, prolonged immobilization leading to blood stasis

Figure 3 A 12-year-old boy with thalassemia major presented with left upper quadrant pain and tender splenomegaly. CT abdomen revealed splenic infarct (arrow). Hemoglobinopathies including thalassemia major and sickle cell disease are associated with a hypercoagulable state

CLINICAL PRESENTATION

Venous Thromboembolism

Idiopathic VTE is very rare. Majority of children have a definite underlying risk factor. An indwelling central venous line is found in 50–60% of thrombotic events. While 70% of children with VTE have a chronic medical condition such as malignancy, inflammatory

diseases or nephrotic syndrome, most of the remaining have a transient underlying insult, including infection or trauma.

Extremity Deep Vein Thrombosis (DVT)

It presents as unexplained pain and swelling of the limb. There may also be warmth, erythema of overlying skin and tenderness (**Fig. 4**). Forceful dorsiflexion of the foot can elicit pain in the calf (*Homan's sign*) and side to side squeezing of calf can elicit pain (*Moses' sign*) in DVT of lower limb. If the clot extends further proximally, bilateral limb swelling may occur. In the upper half of the body, a clot proximally extending into the superior vena cava can be associated with head and neck swelling, periorbital edema and headache.

Pulmonary Embolism

It is usually secondary to deep vein thrombosis. It manifests as sudden onset dyspnea, dry cough, hemoptysis, pleuritic chest pain and sometimes fever. Severe episodes associated with proximal or saddle emboli, lead to hypoxemia, cyanosis and collapse. A massive pulmonary embolus can obstruct the pulmonary circulation leading to right heart failure with hepatomegaly and peripheral edema.

Cerebral Venous Sinus Thrombosis (CVST)

It can have acute to subacute onset and is almost always associated with an underlying medical condition (**Table 3**). The manifestations include seizures, which are more common in newborns; and focal (cranial nerve palsies, hemisensory loss and hemiparesis) or diffuse neurological signs (headache, nausea, vomiting, blurred vision and papilledema), which are usually seen in infants and children. Any new onset neurological manifestation in the conditions listed in **Table 3** must elicit suspicion of CVST and prompt appropriate imaging.

Renal Vein Thrombosis

It may manifest as hematuria, thrombocytopenia, flank pain and enlarged kidney, which becomes palpable as a flank mass. It is most commonly seen in the newborn period, maternal diabetes being an important risk factor. In older children, it is often associated with nephrotic syndrome. One fourth of cases may show bilateral involvement. There may be uremia and oliguria, particularly with bilateral disease.

Figure 4 A 4-year-old patient with acute lymphoblastic leukemia received vincristine, steroids and L-asparaginase for induction. The patient developed sudden onset swelling of right lower limb. A Doppler ultrasound confirmed a large thrombus extending from the popliteal vein into the right common iliac vein. Malignancy, L-asparaginase and steroids contribute to a prothrombotic state

Table 3 Risk factors for cerebral venous sinus thrombosis

Adverse perinatal events	Maternal hypertension, gestational diabetes mellitus, neonatal sepsis, birth asphyxia, polycythemia, dehydration
Head and neck infections, surgery or trauma	Meningitis, otitis media, mastoiditis, sinusitis, intracranial surgery and shunts
Anemia	Iron-deficiency, sickle cell anemia, thalassemia, paroxysmal nocturnal hemoglobinuria
Autoimmune	Systemic lupus erythematosus, antiphospholipid antibody, inflammatory bowel disease
Renal disease	Nephrotic syndrome, hemolytic uremic syndrome
Cardiac disease	Cyanotic congenital heart disease, catheterization and surgery
Malignancy	Leukemia, lymphoma, L-asparaginase related, brain tumors
Miscellaneous	Dehydration, diabetic ketoacidosis, Down syndrome, homocystinuria

Other rare sites of venous thrombosis and presentation include: *hepatic vein*: right upper abdomen pain and hepatomegaly; *splenic vein*: discomfort in left upper abdomen, splenomegaly and hypersplenism; *portal vein*: abdominal pain, portal hypertension manifested as gastrointestinal bleed, ascites and splenomegaly; *mesenteric vein*: diffuse abdominal pain and ileus. Internal jugular vein thrombosis presents with neck pain and swelling, and may occur as a part of a distinct septic thrombophlebitic syndrome known as *Lemierre's syndrome*, where there is fever, trismus and painful neck movements. Lung embolism can cause dyspnea. The etiology is a parapharyngeal infection caused by *Fusobacterium necrophorum*.

Arterial Thrombosis

Peripheral arterial thrombosis is invariably related to catheterization of the artery. The involved extremity becomes cold and pale to cyanosed due to hypoperfusion. The peripheral pulses in the limb are absent or diminished (**Box 1**). Umbilical artery cannulation in newborns and cardiac catheterization in older children are important risk factors. The other common arterial thrombotic event is ischemic arterial stroke involving the cerebral vasculature, which manifests as seizures, apnea and poor feeding in newborns, and focal neurological deficit in older children.

BOX 1 Signs of arterial occlusion

- Pain
- Pallor
- Paresthesia
- Paralysis of limb
- Pulses difficult to palpate

Peripheral arterial catheters can also be thrombosed. It is important to perform *Allen test* prior to radial arterial puncture to prevent limb threatening thrombus. For this, the radial and ulnar arteries are respectively occluded with the examiner's thumb and index finger and the child's hand is raised above the head. The child is then instructed to make a fist repeatedly till the fingers turn white, following which the ulnar artery is released. If there is a delay of more than 14 sec for color to return to normal, it suggests ulnar artery insufficiency and contraindicates radial artery puncture.

INVESTIGATIONS

A complete blood count and a coagulogram with prothrombin time (PT), activated prothrombin time (aPTT) and international normalized ratio (INR) is essential as baseline prior to initiating therapy and for monitoring the anticoagulation therapy. Radiology is required for confirming diagnosis as well as defining the extent of thrombus and the degree of obstruction.

Coagulation Parameters Relevant to Thrombosis

Prothrombin time is a measure of the extrinsic pathway. Warfarin inhibits the vitamin K dependent proteins (Factors II, VII, IX, X, Proteins C and S), resulting in a prolonged PT. The therapeutic monitoring of warfarin is thus PT based. However, since PT is critically dependent on the tissue derived thromboplastins used in the assay, there is significant interlaboratory variation in reporting PT. For this reason, WHO introduced the concept of *INR*, to compare any given PT from a lab to an established international reference preparation of thromboplastin. It is calculated by the following formula:

$$\text{INR} = [\text{Patient PT} / \text{mean normal PT}]^{\text{ISI}}$$

ISI is a correction factor, which is provided by the commercial suppliers of thromboplastin preparations and is 1 for the international reference preparation. INR is thus used as the standard monitoring parameter during vitamin K antagonist therapy. aPTT measures the intrinsic pathway of coagulation and is used to monitor therapy with unfractionated heparin and other anticoagulants which inhibit thrombin. Low molecular weight heparin predominantly inhibits factor X and does not prolong aPTT. It is better monitored with anti-Xa level, when available.

D-dimer and fibrin degradation products represent ongoing thrombosis and fibrinolysis. They are increased during any thrombus formation. Their diagnostic value is limited in pediatric thrombosis, and they are not recommended as standard investigations. They have a good negative predictive value.

Radiological Investigations

Venography

It has historically been the gold standard imaging modality for VTE. However, with the availability of less invasive modalities, its role is declining. The concerns include technical difficulty, the need to inject iodinated contrast and possible risk of causing thrombus extension.

Compression Ultrasound with Doppler

It is an excellent noninvasive method for confirming and delineating a thrombus involving the distal or proximal lower extremity. The thrombosed femoral vein loses its normal compressibility with the pressure of the ultrasound transducer. Color-flow and pulsed Doppler further outline the extent of thrombus in the vein. It is also useful in renal vein, portal vein and jugular vein thrombosis. Doppler is a good modality for arterial thrombosis too, particularly in the femoral, renal and carotid arteries.

Echocardiography

It is useful in intracardiac and proximal vena caval thrombi. It is also important in diagnosis of coronary artery thrombosis and aneurysm in Kawasaki disease. It is an important aspect of work up in arterial ischemic stroke for detecting cardioembolic source and right to left shunt.

CT/MR Venography

For deeper pelvic or intra-abdominal veins, *CT venography* or if radiation exposure is a concern, *MR venography* can be used. MRI

further helps in differentiating from myositis and diagnosing May-Thurner syndrome, where the iliac vein is compressed by the right common iliac artery. CT or MRI is required to image the subclavian veins, innominate veins and the superior vena cava.

Line-o-grams with injection of radiographic contrast into central venous catheters are used for imaging line related thrombosis. *Dynamic venography* is useful in the diagnosis of Paget-Schroetter syndrome where the subclavian vein is compressed by abnormalities at the thoracic outlet, such as cervical rib. For pulmonary embolism, *helical or spiral CT* with contrast is the modality of choice with high specificity. *Ventilation-perfusion radionuclide scan* has a good negative predictive value; however, the interpretation of result needs expertise. The gold standard modality: *pulmonary angiography* is restricted to cases where intervention is being planned.

Cerebral venous sinus thrombosis is often diagnosed with the classical *empty delta sign*, a filling defect in the superior sagittal sinus on CT. A contrast CT however misses up to 40% of cases. CT venography and MRI with venography are the modalities of choice (**Figs 5A to C**). The imaging modalities are summarized in **Table 4**.

Thrombophilia Screening

Ideally every child who has experienced a thromboembolic event must undergo screening to detect an underlying thrombophilic condition. This is because it helps to identify the etiology of the event. Thrombotic events may be multifactorial and inherited thrombophilia may be uncovered by an acquired risk state for thrombosis. It enables identification of risk of recurrence and appropriate prophylactic measures. Family member counseling and screening can be offered.

Evidence is still lacking for need to screen children with catheter related thrombosis. Screening for thrombophilia must be considered in the following clinical scenarios: when young age at first episode (essentially any child); recurrent episodes of thromboembolism; unusual sites of thrombosis (cerebral veins, mesenteric veins, portal vein); warfarin induced skin necrosis (Protein C or S deficiency); neonatal purpura fulminans (Protein C or S deficiency); resistant to treatment with heparin (qualitative antithrombin defect); recurrent fetal losses and preeclampsia in pregnancy.

The investigations to be performed as part of a basic thrombophilia screening are presented in **Table 5**. During the thrombotic episode, consumption of proteins by the thrombotic process and ongoing anticoagulant therapy may interfere with the tests. Therefore, it is important to repeat following resolution of thrombosis and at least 6 months after cessation of anticoagulant drugs. Since most of the inherited thrombophilias are autosomal dominant, half the family members may be carrying the defect. Thus, screening of asymptomatic family members can be offered.

TREATMENT

The rationale of using anticoagulant therapy is to suppress the hypercoagulable state. This prevents further extension of the thrombus and embolism, and allows the intrinsic fibrinolytic system to dissolve the thrombus over time. Thrombolytic therapy is seldom used in children, unless the situation is life or limb threatening. Due to the lack of large randomized trials in children, majority of the pediatric recommendations are extrapolated from adult data.

Treatment of VTE consists of initial anticoagulation in the acute phase with unfractionated heparin (UFH) or LMWH. This is followed by an extended phase of anticoagulation with warfarin or LMWH.

Heparin

Low molecular weight heparin is increasingly being preferred over UFH due to the relative ease of administration and paucity

Figures 5A to C Neuroimaging findings of a 10-year-old patient undergoing treatment for acute lymphoblastic leukemia (ALL) who presented with altered sensorium and seizures. (A) CT head showing filling defect in the posterior aspect of the superior sagittal sinus (empty delta sign, white arrow) and hyperdense gyri in the left parieto-occipital region (black arrow); (B) T2-Flair MRI brain showing hyperintense signals in the superior sagittal sinus (white arrow) and the left parieto-occipital region (black arrow) suggestive of infarct; (C) MR venography showing gross filling defect in the superior sagittal sinus suggestive of thrombus (arrow). L-asparaginase coupled with the prothrombotic effects of steroids and the underlying malignancy predisposes to thrombosis in patients with ALL

Table 4 Radiological investigations in thrombotic conditions

Modality	Site
Compression ultrasound with Doppler	Lower limb veins, jugular veins, renal vein, portal vein; femoral artery, renal artery and carotids
CT, MRI	Deep veins of abdomen and pelvis, superior vena cava, subclavian vein, innominate vein
Line-o-gram	Central venous line related thrombi
Echocardiography	Proximal vena cava, intracardiac, cardioembolism
Helical or spiral CT, Ventilation-perfusion radionuclide scan	Pulmonary embolism
CT or MRI with venography	Cerebral venous sinus thrombosis
CT or MRI with arteriography	Arterial ischemic stroke

Abbreviations: CT, computed tomography; MRI, magnetic resonance imaging

Table 5 Investigations for thrombophilic conditions

Thrombophilic condition	Test
Protein C, protein S and antithrombin deficiency	Chromogenic or clotting assay
Factor V Leiden, prothrombin 20120A	Polymerase chain reaction
Hyperhomocysteinemia	Fasting homocysteine levels
Antiphospholipid antibody (APLA)	Phospholipid based clotting assays, ELISA for specific antibody detection

of adverse effects. Pros and cons of LMWH and UFH are given in **Table 6**. Initial heparin therapy is usually given for 5–10 days. Prolonged use of UFH in children is discouraged due to the concern of osteoporosis and is preferred in patients with increased hemorrhagic risk and renal insufficiency. During heparin therapy, platelet count should be monitored and maintained above 50,000/ μ L. The schedule for UFH is illustrated in **Figure 6**. Till target aPTT is achieved, 4 hourly aPTT monitoring is done, with dose adjustments as shown in **Table 7**.

Table 6 Comparison of low molecular weight heparin and unfractionated heparin

Parameter	Low molecular weight heparin (e.g., enoxaparin)	Unfractionated heparin (Conventional heparin)
Administration	Subcutaneous. Once or twice a day	Continuous intravenous infusion
Mechanism	Anti-Xa	Anti-Xa and IIa
Target	Anti-Xa levels 0.5–1 U/mL, 4–6 hours postinjection	APTT: 60–85 sec
Monitoring requirement	Less frequent	Intensive
Risk of heparin induced thrombocytopenia	Less	More
Reversibility with cessation	Slow	Rapid
Response to protamine	Not predictable	Predictable
Clinically labile patients and increased hemorrhagic risk	Less preferred	Preferred due to short $t_{1/2}$ and response to protamine
Patients with renal failure	Less preferred due to renal excretion	Preferred due to renal independent elimination

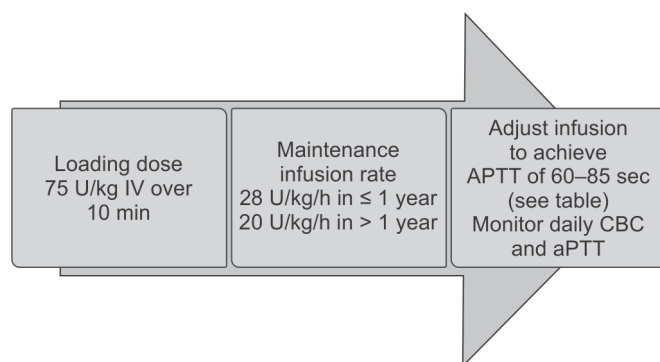

Figure 6 Protocol for administration of unfractionated heparin. Heparin infusion is initiated with a bolus dose of 75 U/kg over 10 minutes. Subsequently, a maintenance rate of 20–28 U/kg/h depending on the age is continued with 4 hourly aPTT monitoring. Infusion rates are titrated based on aPTT as described in Table 7 till the target of 60–85 sec is achieved. Subsequently daily complete blood count and aPTT are monitored as long as the infusion continues

Table 7 Titration of unfractionated heparin dose based on aPTT

APTT (seconds)	Bolus (U/kg)	Withhold for minutes	Change in dose (%)
< 50	50	0	+10
50–59	0	0	+10
86–95	0	0	–10
96–120	0	30	–10
> 120	0	60	–15

Enoxaparin is the commonly available LMWH. It is administered subcutaneously (12 hourly). The initial dose is 1.5 mg/kg/dose (< 2 months age) and 1 mg/kg/dose (> 2 months age). The other LMWH formulation available in India is dalteparin, which can be administered once a day. Ideally, an anti Xa level of 0.5–1 U/mL must be obtained at 4–6 hours after the injection, though it is not a readily available investigation.

Adverse events during heparin therapy include bleeding and heparin induced thrombocytopenia with paradoxical thrombosis. The risk of bleeding on heparin therapy ranges from 1–4%. For mild bleeding, discontinuation of UFH infusion may suffice. Protamine sulphate is indicated for immediate cessation of bleeding. The dose is dependent on time since last exposure to heparin and described in Table 8. Reversal of LMWH effect with protamine is not as predictable as with UFH. Protamine is infused in a dilution of 10 mg/mL, at a rate of not more than 5 mg/min.

Heparin induced thrombocytopenia is a rare but potentially serious complication with a frequency of 2–4% in children. It is suspected in children with a paradoxical fresh thromboembolic episode after 5–15 days of initiation of heparin, accompanied with a fall in platelet count. The pathophysiology is explained by generation of antibodies to the heparin-PF4 (Platelet factor 4) complex. The antibody-heparin-PF4 complex then binds to and activates platelets, leading to a paradoxical hypercoagulable state. Diagnosis is confirmed by detection of the antibodies by immunoassays. Treatment is with direct thrombin inhibitors, such as lepirudin, bivalirudin, argatroban and danaparoid. Warfarin and other vitamin K antagonists are contraindicated in this condition.

Vitamin K Antagonists (Warfarin)

Warfarin is the alternative drug for extended anticoagulation after the initial heparin therapy. Though other analogs such as acenocoumarol and phenprocoumon are also used in children,

Table 8 Protamine dosing in relation to time of receiving last unfractionated heparin dose

Time since last heparin dose (minutes)	Dose of protamine (mg/100 U of administered heparin dose)
< 30	1
30–60	0.5–0.75
60–120	0.375–0.5
> 120	0.25–0.375

the maximum experience and literature is on warfarin. The use of warfarin is fraught with several problems (Box 2). Warfarin initiation must overlap with the initial heparin therapy. The dose on day 1 of treatment is 0.2 mg/kg/day as a single dose (maximum 7.5 mg/day). Subsequently, dose is titrated as described in Table 9, to achieve a target INR of 2–3. Heparin is discontinued on day 6 of treatment or later if the target INR is still less than 2. The reason for the overlap is that warfarin being a vitamin K antagonist also antagonizes protein C and S, which are anticoagulant vitamin K dependent proteins. These proteins are depleted rapidly as they have a short half-life ($t_{1/2}$). This leads to a transient paradoxical prothrombotic state, until the clotting factors with longer $t_{1/2}$ get depleted as well. Infants may require higher doses (up to 0.33 mg/kg) and adolescents may require lower doses (as low as 0.09 mg/kg). Patients must be instructed to be cautious and report if there is bleeding from any site. Warfarin has drug interactions with several drugs which are used commonly, and can potentially lead to increased levels and toxicity or decreased levels and inadequate response (Box 3).

BOX 2 Difficulties with warfarin use in children

- Vitamin K dependent coagulation factors are physiologically low in newborns and increase rapidly to adult levels in infancy. This makes INR monitoring and warfarin dose titration difficult in infants
- Exclusively breastfed infants are deficient in vitamin K and thus sensitive to adverse events with warfarin. Hence require supplementation with 30–60 mL of formula feed per day
- No liquid formulation available. Tablets need to be crushed and dissolved in water for younger children with no data supporting stability in such a form. This reduces compliance as well
- No safety information in babies under 3 months of age
- Intercurrent illnesses, food items and commonly used drugs can interact with warfarin influencing its pharmacological action (Box 3).

The most concerning adverse effect is bleeding, the incidence of which is around 0.5%. Warfarin must be stopped and vitamin K administered immediately. For significant bleeding, fresh frozen plasma can be transfused; prothrombin complex concentrates and recombinant factor VIIa are other alternatives. Other adverse events reported include hair loss and reduced bone mineral density; however, are observed more in adults than in children.

Duration of Anticoagulant Therapy in VTE

The durations of anticoagulant therapy in various clinical scenarios are summarized in Table 10. The following questions are to be answered to decide the duration of therapy in any venous thromboembolic event.

1. Is it a primary or a recurrent event?
2. Is there an underlying identifiable risk factor?
3. Is the risk factor transient (e.g., postoperative or central venous line) or long standing (e.g., Lupus)?
4. Is there an identifiable potent thrombophilic state? (e.g., homozygous deficiencies of anticoagulant proteins or factor V Leiden mutation, Antiphospholipid antibody syndrome)

Table 9 Warfarin dose titration based on INR

INR	Warfarin dose
<i>Loading dose on days 2–4</i>	
1.1–1.3	Same as day 1
1.4–3	50% of day 1 dose
3.1–3.5	25% of day 1 dose
> 3.5	Hold; once INR < 3.5, restart at 50% of previous dose
<i>Maintenance dose from day 5 onwards</i>	
1.1–1.4	Increase previous dose by 20%
1.5–1.9	Increase previous dose by 10%
2–3	No change
3.1–3.5	Decrease previous dose by 10%
> 3.5	Hold; once INR < 3.5, restart at 80% of previous dose

BOX 3 Warfarin drug interactions**Increase in warfarin's effect**

Chloramphenicol, sulfonamides, metronidazole
Cimetidine, omeprazole
Fluconazole
Nonsteroidal anti-inflammatory drugs
Selective serotonin reuptake inhibitors
Zafirlukast
Mega doses of vitamin A and E
Quinidine

**Decrease in warfarin's effect**

Vitamin C
Barbiturates, carbamazepine
Cloxacillin, rifampicin
Griseofulvin
Cholestyramine
Sucralfate
Spironolactone
Oral contraceptive pill
Vitamin K rich foods: Green leafy vegetables, liver, meat.

Thrombolysis in Pediatric Thrombosis

Conventional anticoagulant therapy is the cornerstone of managing pediatric thromboembolic event. However, thrombolytic therapy has role in selected circumstances which are life or limb threatening. The indications and contraindications of thrombolysis in children are described in **Boxes 4 and 5**.

There is no consensus on the choice or administration route of thrombolytic agent. The commonly used agent is tissue plasminogen activator (tPA), followed by urokinase, which is a cheaper option. Use of Streptokinase in children is discouraged due to the risk of severe hypersensitivity reactions and production of long lasting neutralizing antibodies. The conventional method of administration of tPA is as an intravenous infusion (0.1–0.5 mg/kg/ hours for 6 hours). Continuous infusions of lower doses over 24–96 hours and catheter directed thrombolytic administration has also been described. Urokinase is infused at a loading dose of 4400 U/kg over 5 minutes, followed by the slow infusion of same dose over 12–72 hours.

The biggest concern with thrombolytic therapy is hemorrhage. The incidence ranges from 0–40%. It may be life threatening: intracranial bleed, retroperitoneal bleed, bleed requiring surgical intervention and bleed resulting in acute fall of hemoglobin by greater than or equal to 2 g/dL. As such, careful monitoring

Table 10 Duration of anticoagulation in venous thromboembolism (VTE)

Situation	Underlying risk factor	Total duration of therapy
First episode of venous thromboembolism (VTE)	CVD	6 weeks–3 months if CVD removed* As long as in situ if retained
	Transient	3–6 months
	Chronic	12 months–lifelong
Recurrent VTE	Idiopathic	6–12 months
	Transient	6–12 months
	Chronic	Lifelong
Renal vein thrombosis	Idiopathic	12 months to lifelong
		6 weeks to 3 months
		3–6 months
Cerebral venous sinus thrombosis#		6 months
Massive thrombus with organ dysfunction		6 months
Pulmonary embolism		6 months

*CVD: Central venous device, if its patency fails to be established or it is no longer needed it should be removed *after* 3–5 days of anticoagulation to prevent embolism

#Anticoagulation to be given even if there is minimal associated hemorrhage. In case of significant associated hemorrhage reassess after 5–7 days and start anticoagulation if the thrombus shows evidence of extension

BOX 4 Indications for thrombolytic therapy**Life threatening (Strong indications)**

1. Shunt obstruction in complex cyanotic congenital heart disease
2. Massive pulmonary embolism with hemodynamic instability
3. Large atrial thrombus
4. Obstructive superior vena cava syndrome
5. Cerebral venous sinus thrombosis with worsening neurological status
6. Bilateral renal vein thrombosis

Limb threatening

1. Acute iliofemoral thrombosis
2. Inferior vena cava thrombosis
3. May-Thurner syndrome
4. Paget-Schroetter syndrome.

BOX 5 Contraindications to thrombolysis

- Ongoing bleeding
- Seizures in last 2 days
- Invasive procedure in last 2 weeks
- *Major surgery:* CNS surgery, trauma or intracranial bleed in last 2 months
- Systemic sepsis
- *CNS pathology likely to bleed:* Aneurysm, vascular malformation or tumor
- Inability to achieve a platelet count of > 75,000/μL or fibrinogen > 100 mg/dL
- Serum creatinine > 2 mg/dL
- Uncontrolled hypertension.

is required during administration. Adequate platelet count and fibrinogen levels should be ensured prior to initiation and monitored 6–12 hourly during administration. A repeat imaging to assess response can be repeated at 24 hours. D-dimer assay can be done to document evidence of thrombolysis. Conventional anticoagulation must be started with the thrombolysis and continued for an appropriate duration as per the clinical condition.

Other Anticoagulant Drugs

Other anticoagulant inhibitors include direct thrombin or factor Xa inhibitors (**Table 11**). The predominant indication is heparin induced thrombocytopenia, where heparin has to be stopped and warfarin is contraindicated. This is important in patients who are critically dependent on anticoagulation, such as patients on extracorporeal membrane oxygenation or cardiac assist devices. They all carry risk of bleeding.

Other Modalities

Surgical thrombectomy may be used prior to anticoagulation in life threatening massive venous thrombosis, pulmonary embolism and shunt thrombosis in patients with complex congenital heart disease. Inferior vena cava filter is a device inserted through femoral or jugular approach in children more than 10 kg, who have a lower limb DVT and in whom anticoagulation is contraindicated. A temporary filter is preferred over a permanent one, as it can be retrieved following resolution of the thrombus or when anticoagulation can be initiated.

Outcomes after Venous Thromboembolism (VTE)

Thromboembolic events in children are complicated by immediate or short-term complications, and chronic or long-term sequelae. Mortality rates of 1–4% are associated with large venous thrombosis. Up to two times increased in-hospital mortality is observed in children with VTE. This emphasizes the need for prompt initiation of anticoagulant therapy.

The short-term complications are: (1) Pulmonary embolism (occurs in 15–20% of venous thrombosis), (2) Superior vena cava syndrome in DVT of upper venous system, (3) Acute renal insufficiency in renal vein thrombosis, particularly if bilateral and in neonates, (4) Intracardiac thrombus or proximal pulmonary embolus leading to critical hemodynamic instability, (5) Catheter related thrombosis causing catheter malfunction and necessitating removal, (6) Occlusive DVT of lower limbs may lead to venous gangrene, (7) Complications of anticoagulant therapy, mainly bleeding, and (8) Post-thrombotic hemorrhage in brain.

The long-term sequelae are: (1) Recurrent venous thromboembolism: in up to 6–11% of primary VTE (less compared to adults); (2) Post thrombotic syndrome: A syndrome of chronic venous obstruction and valvular insufficiency following limb DVT. It is characterized by limb edema, pain, limitation of activities, visible tortuous and dilated collateral superficial veins, stasis dermatitis and ulcers. It occurs in nearly one third of children with extremity DVT; (3) Chronic hypertension and kidney injury in

Table 11 Other available anticoagulants

Drug	Mechanism of action	Administration	Monitoring parameter
Lepirudin	Antithrombin	Continuous infusion	aPTT, ACT
Bivalirudin	Antithrombin	Continuous infusion	aPTT, ACT
Argatroban	Antithrombin	Continuous infusion	aPTT
Danaparoid	Anti-Xa	Continuous infusion	Anti-Xa activity
Fondaparinux/ Idraparinux	Anti-Xa	Subcutaneous	None
Dabigatran	Antithrombin	Oral	None
Rivaroxaban	Anti-Xa	Oral	None

Abbreviation: ACT, activated coagulation time

renal vein thrombosis; (4) Portal hypertension and variceal bleed in portal vein thrombosis; (5) Neurological sequelae in cerebral venous sinus thrombosis.

Adverse prognostic indicators in thromboembolic events are: (1) Inappropriate, inadequate or delayed anticoagulation; (2) Failure of resolution of the thrombus completely with therapy; (3) Underlying inherited thrombophilia or antiphospholipid antibody; (4) Elevated factor VIII activity and D-dimer concentration at diagnosis, as well as after 3–6 months of anticoagulation.

Treatment of Arterial Thrombosis

The treatment for arterial thrombosis includes antiplatelet drugs, including aspirin and clopidogrel, in addition to heparin and warfarin. Aspirin is administered at 1–5 mg/kg/day for antiplatelet action. Acute femoral arterial thrombosis, if untreated, can progress to unsalvageable limb gangrene. Treatment starts with UFH or LMWH (similar to that described for treatment of VTE) for 5–7 days. If there is no response and/or the thrombus extends further proximally, thrombolysis must be considered. If thrombolysis is contraindicated, surgical intervention must be sought for thrombectomy. If a peripheral artery thrombosis is secondary to an arterial catheter, the catheter must be removed immediately.

In Kawasaki disease, coronary arteries are selectively affected with complications of aneurismal dilation and thrombosis. Aspirin is started at an anti-inflammatory dose of 80–100 mg/kg/day for the initial 2 weeks and continued at antiplatelet doses for 6–8 weeks. Warfarin must be added in case of moderate or giant aneurysms. Coronary artery thrombosis is a life threatening event needing thrombolysis or surgical thrombectomy. The anticoagulation/antiplatelet therapy for arterial ischemic stroke is outlined in **Table 12**.

Table 12 Antiplatelet and anticoagulant drugs in arterial ischemic stroke (AIS)

Age	Situation	Initial therapy	Extended therapy
Newborn	First episode, no cardioembolic source	Supportive care alone	
	Cardioembolic source	UFH/LMWH	LMWH*
	Recurrent AIS	Aspirin/LMWH	Aspirin/LMWH*
Older children	First episode, no embolism or dissection	UFH/LMWH/ aspirin till embolism or dissection ruled out	Aspirin for 2 years
	Recurrent AIS or transient ischemic attacks on aspirin	—	Change to clopidogrel/LMWH/ warfarin*
	Cardioembolic source	LMWH	LMWH/warfarin for 3 months#. Repair right to left shunt
	Dissection	LMWH	LMWH/warfarin for 6 weeks#
	Nonmoyamoya vasculopathy	LMWH	LMWH/warfarin for 3 months#
	Moyamoya vasculopathy	Aspirin	Refer to center with revascularization expertise

Abbreviations: UFH, unfractionated heparin; LMWH, low molecular weight heparin

*Duration of therapy based on clinical and radiological monitoring and response

#The duration mentioned is the minimum needed, it may be prolonged in case of clinical recurrence or persistence of thrombus

IN A NUTSHELL

1. Pathologic tendency to develop excessive and unwanted thrombosis is called thrombophilia.
2. Inherited thrombophilia is due to mutations in genes involved in anticoagulant protein production. Conditions include deficiency of protein C, protein S, antithrombin and mutations involving factor V Leiden, prothrombin and *MTHFR*.
3. Acquired thrombophilia is secondary to the classical Virchow's triad of thrombosis: stasis, hypercoagulable state and endothelial injury. Common etiology: nephrotic syndrome, central venous line, systemic lupus erythematosus and malignancies.
4. Clinical features depend on the site of thrombosis. Few commonly encountered sites include deep vein thrombosis (DVT) in limbs, pulmonary embolism and cerebral venous sinus thrombosis (CVST).
5. Doppler ultrasound is the best modality to detect DVT in the lower extremity. Spiral/helical CT and ventilation-perfusion scans are used for diagnosing pulmonary embolism. MRI with venography is the modality of choice for CVST.
6. A screening for common inherited thrombophilic states is desirable following all noncatheter related thrombosis in children. The investigations are performed following resolution of thrombosis and discontinuation of anticoagulant drugs.
7. Treatment of venous thromboembolism in children involves initial anticoagulation using UFH or low molecular weight heparin (LMWH) followed by an extended phase of anticoagulation with LMWH or warfarin.
8. Low molecular weight heparin is typically preferred over UFH. Enoxaparin the commonly available LMWH. It is administered subcutaneously, 12 hourly, at 1.5 mg/kg/dose in less than 2 months age and 1 mg/kg/dose in older patients.
9. Warfarin is started after an initial overlap with heparin therapy at a dose of 0.2 mg/kg/day and subsequently titrated to achieve an INR of 2–3.
10. The duration of anticoagulation varies, depending on site, underlying risk factors and whether the thromboembolic event is a primary or recurrent event.

Chapter 38.23

Disseminated Intravascular Coagulation

VK Khanna, Tarangini D, Anupam Sachdeva

Disseminated intravascular coagulation (DIC) is a systemic disorder characterized by intravascular activation of the coagulation system leading to intravascular thrombi, compromising an adequate blood supply to the organs, and to bleeding as a consequence of exhaustion of the platelets and coagulation factors. Hence, a patient with DIC can present with features of intravascular thrombosis and hemorrhagic manifestations at the same time. DIC never occurs in isolation and is always secondary to a pre-existing primary pathology.

EPIDEMIOLOGY

The frequency of DIC in hospitalized patients is approximately 1.72%. Sepsis is the most important etiological factor in all age groups. DIC may occur in 30–50% of patients with gram-negative sepsis and may be a predominant feature of severe infection. DIC occurs at all ages with no particular sex predisposition.

ETIOLOGY

Disseminated intravascular coagulation is not itself a specific illness. It is a clinicopathological syndrome which complicates a number of illnesses. All these culprit illnesses have the ability to induce systemic activation of coagulation system either by activating cytokines or by causing the release of, or exposure to procoagulant factors (**Box 1**).

PATHOPHYSIOLOGY

Disseminated intravascular coagulation is the result of several simultaneously occurring mechanisms. The systemic formation of fibrin is a result of tissue factor-mediated thrombin generation and the simultaneous suppression of physiologic anticoagulation mechanisms such as the antithrombin system and the protein C system. In addition, there is delayed removal of fibrin as a consequence of impaired fibrinolysis. In some forms of DIC, fibrinolytic activity may be increased and may further contribute to bleeding. The initial phase of DIC consists of formation of microvascular thrombi in kidneys and lungs with subsequent end organ dysfunction. In the second phase, there is wide-spread activation of fibrinolysis and consumption of coagulation factors and platelets. The resultant severe consumption coagulopathy leads to uncontrolled bleeding from wounds and spontaneous hemorrhage into gut, brain and other tissues (**Fig. 1**).

Several mechanisms which play role in the pathogenesis include (1) Tissue factor (TF) mediated thrombin generation (2) Suppression of physiologic anticoagulant mechanisms (3) Impaired fibrin removal due to depressed fibrinolysis.

Tissue factor can trigger the extrinsic pathway of coagulation. Increased tissue factor production is considered the most important for the onset of DIC. Its activity in peripheral blood is markedly increased following tissue injury and activation of monocytes. The increased tissue factor activity results in the transformation of prothrombin to form fibrin thrombus.

Disseminated Intravascular Coagulation in Sepsis

Septicemia is the most common clinical condition associated with DIC. Although virtually all microorganisms can cause

BOX 1 Conditions associated with disseminated intravascular coagulation

1. *Neonatal causes*
 - Perinatal asphyxia, respiratory distress syndrome, meconium aspiration, amniotic fluid aspiration, necrotizing enterocolitis, metabolic disorders, congenital intrauterine infections, bacterial and fungal infections, congenital homozygous protein C/S deficiency
2. *Infections*
 - Bacterial (e.g., gram-negative, gram-positive infection, rickettsial infection)
 - Viral [e.g., HIV, cytomegalovirus (CMV), varicella-zoster, hepatitis, dengue, influenza]
 - Fungal (e.g., histoplasma)
 - Parasite (e.g., malaria)
3. *Trauma*
 - Neurotrauma
 - Crush injury
 - Severe burn injury
 - Fat embolism
4. *Organ destruction*
 - Pancreatitis
 - Severe hepatic failure
5. *Malignancy*
 - Solid tumors
 - Lymphoproliferative/myeloproliferative malignancies
6. *Immunologic*
 - Acute hemolytic transfusion reaction
 - Transplant rejection
7. *Vascular abnormalities*
 - Kasabach-Merritt syndrome
 - Large vascular aneurysm
8. *Severe toxic reactions*
 - Snake bite
 - Drugs
9. *Heat stroke and hyperthermia*
10. *Hemorrhagic skin necrosis*
 - Purpura fulminans.

DIC, bacterial infection is most frequently associated with the development of DIC. Clinically overt DIC may occur in 30–50% of patients with gram-negative sepsis. DIC in sepsis is mediated by several proinflammatory cytokines. The principal mediator of activation of coagulation is interleukin-6, and it is the principal mediator of the dysregulation of the physiologic anticoagulation pathways and the fibrinolytic defect.

Mechanisms Involved in the Pathogenesis of DIC in Sepsis*Increased Thrombin Generation*

It is predominantly mediated by tissue factor/factor VIIa pathway and reduced antithrombin levels which result from increased consumption, enzyme degradation by elastase released from activated neutrophils, impaired synthesis due to liver failure and increased capillary leakage.

Impaired Function of Physiological Anticoagulant Pathway

Reduced antithrombin levels as previously described along with significant depression of protein C system caused by increased consumption, impaired hepatic synthesis, vascular leakage and downregulation of thrombomodulin expression by pro-inflammatory cytokines like tumor necrosis factor (TNF)- α and interleukin (IL)-1 β .

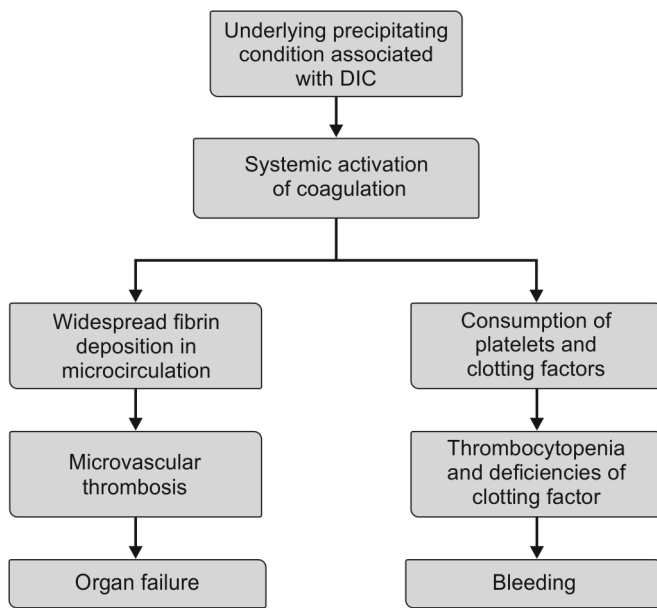

Figure 1 Pathophysiology of disseminated intravascular coagulation (DIC)

Impaired Fibrinolysis

Initial hyperfibrinolytic response due to release of plasminogen activator from endothelial cell is followed by rapid suppression of fibrinolytic activity due to increase in plasma levels of plasminogen activator inhibitor type I (PAI-I) levels. Functional mutation in PAI-I gene is associated with worst clinical outcome in patients with meningococcal sepsis.

Activation of Inflammatory Pathway

It is mediated by activated coagulation proteins and depression of protein C system which has an anti-inflammatory effect through inhibition of endotoxin-induced production of TNF- α , IL-1 β , IL-6 and IL-8.

Polytrauma, because of physical force, burns or heat stroke may result in DIC due to a combination of mechanisms including hemolysis, endothelial activation, release of tissue material into the circulation (fat, phospholipids) and acidosis because of hypoperfusion.

TYPES OF DISSEMINATED INTRAVASCULAR COAGULATION

Disseminated intravascular coagulation can present as acute (decompensated) or chronic (compensated) form.

Acute disseminated intravascular coagulation Acute form presents when there is exposure of blood, over a brief period, to procoagulants (e.g., tissue factor or tissue thromboplastin), which generate intravascular coagulation. As a result of this, there may be profound bleeding due to consumption coagulopathy or diffuse microvascular thrombosis leading to end-organ damage or a combination of both.

Chronic disseminated intravascular coagulation In chronic DIC, the exposure to the triggering factor is slow. The compensatory mechanisms in the liver and bone marrow replenish the factors by increased production. There may be little obvious clinical or laboratory indication of presence of DIC. Chronic DIC is more frequently seen in malignancies, large aortic aneurysms and vasculitis.

CLINICAL MANIFESTATIONS

The clinical presentation and consequences of DIC depend on the etiology and the rapidity of the initiating event. Acute events lead to intravascular coagulation with depletion of platelets and procoagulant factors, production of fibrin degradation products and bleeding. Acute DIC may be fatal unless the condition is diagnosed early and appropriate treatment initiated.

In addition to the symptoms related to the underlying disease process, there is typically a history of blood loss through bleeding in the areas such as the gingivae and the gastrointestinal system. Acutely presenting DIC often manifests as petechiae on the soft palate, trunk and extremities because of thrombocytopenia and ecchymosis at venipuncture sites and traumatized areas. There may be blood loss from intravenous lines and catheters. In postoperative DIC, bleeding can occur in the vicinity of surgical sites, drains, tracheostomies as well as within serous cavities. Bleeding from at least three unrelated sites is particularly suggestive of DIC. Patients with pulmonary involvement can present with dyspnea, hemoptysis and cough. Comorbid liver disease as well as rapid hemolytic bilirubin production may lead to jaundice. Neurological changes (e.g., coma, altered sensorium and paresthesia) are also possible. One should look for symptoms and signs of thrombosis in large vessels (e.g., deep vein thrombosis) and microvascular thrombosis (e.g., in renal failure). As many as 25% patients with DIC present with renal failure. In patients with chronic DIC, the signs of venous thromboembolism may be present because of thrombosis from excessive thrombin formation.

APPROACH TO DIAGNOSIS

No single laboratory assay is pathognomonic of DIC. Hence, it is very important to assess the entire clinical picture, taking into account the clinical condition of the patient, the diagnosis, and all available laboratory results. DIC is an extremely dynamic situation and each laboratory test describes the state at that particular point of time. A combination of tests when repeated in a patient with a clinical condition known to be associated with DIC can be used to diagnose the disorder with reasonable certainty in most cases. However, in clinical practice DIC can be diagnosed on the basis of the presence of an underlying condition known to cause DIC, low platelet count or a rapid fall in the platelet count, prolonged prothrombin time (PT) and activated partial thromboplastin time (aPTT), presence of fibrin degradation products (FDPs) in plasma, low plasma levels of plasma inhibitors of coagulation like antithrombin III and protein C.

A combination of prolonged PT, hypofibrinogenemia and thrombocytopenia in an appropriate clinical setting is sufficient to suspect the diagnosis of DIC in most instances. To confirm the diagnosis of DIC, tests that indicate increased fibrinogen turnover (i.e., elevated fibrin degradation products—FDPs or D-dimer assay) may be necessary. The D-dimer assay has been shown to be highly sensitive and specific for proteolytic degradation of polymerized fibrin.

INVESTIGATIONS

Platelet Count

A low platelet count or a rapid fall at subsequent measurements is a sensitive though not a specific indicator of DIC. A low platelet count strongly correlates with thrombin generation as thrombin induced platelet aggregation is responsible for platelet consumption. A continuous fall even within normal range may indicate the active generation of thrombin, whereas, a stable platelet count suggests cessation of thrombin formation. It is important to note that many conditions that are associated with DIC may also cause a low platelet count in the absence of DIC.

Peripheral Blood Smear

The peripheral blood smear may demonstrate schistocytes, though they rarely exceed 10% of red blood cells. Presentation of schistocytes is neither sensitive nor specific for DIC. It may help in making a diagnosis of chronic DIC when schistocytes are seen with normal coagulation values and increased D-dimer value.

Prothrombin Time, Activated Partial Thromboplastin Time and Coagulation Factors

Prothrombin time and aPTT are generally prolonged. However, normal values or even shortening of either PT or aPTT or both do not exclude the diagnosis of DIC. This prolongation of PT and aPTT is mainly due to consumption of coagulation factors, impaired synthesis, loss of coagulation proteins and vitamin K deficiency. The consumption and depletion of various coagulation factors may be further confirmed by the measurement of coagulation factors such as V, VII and VIII. It is important to note that serial measurements of coagulation tests are more helpful than a single laboratory result in confirming the diagnosis of DIC. Another point to note is that the PT, not the international normalized ratio (INR), should be used in DIC monitoring as INR is recommended only for monitoring anticoagulant therapy.

Tests for Fibrin and Fibrin Degradation Products and D-Dimer

Fibrin generation is the key component of DIC. Hence, demonstration of elevated levels of soluble fibrin, to establish the diagnosis of DIC, seems logical. Most of the studies have shown that soluble fibrin measurement is highly sensitive (90–100%) but has very low specificity. Moreover, there is a major problem in reliable quantification of soluble fibrin and the test is also not routinely available.

An important component of DIC is fibrinolysis. Therefore, there will be evidence of fibrin breakdown, such as elevated levels of FDPs and D-dimer. The specificity of high levels of FDPs and D-dimer is limited as many other conditions such as thromboembolism, trauma, recent surgery and inflammation may be associated with raised levels of FDPs and D-dimer. Impairment of kidney and liver functions may also influence their levels. Testing for FDPs and D-dimer may be useful for differentiating DIC from other conditions which are associated with a low platelet count and prolonged clotting time values. Exact cut off levels of FDPs and D-dimer to grade DIC have not been established.

Fibrinogen

Low fibrinogen levels are only present in about one third of the patients of DIC as a result of consumption. Fibrinogen is an acute phase reactant, it may be high in conditions of inflammation and hence, the levels may be falsely normal. Sequential measurements of fibrinogen levels may point towards consumption coagulopathy occurring in DIC.

Anticoagulants

Proteins C and antithrombin III are the two natural anticoagulants that are frequently decreased in DIC. Their single measurements are neither sensitive nor specific for DIC. Low levels of protein C may indicate severity of DIC. They may be useful as prognostic indicators.

Specialized Tests

Activation markers which are released upon the conversion of the coagulation factor zymogen to an acute protease such as prothrombin activation fragment F1 + 2 (F1+2) are markedly increased in DIC but their specificity is not good.

Serum levels of thrombomodulin are elevated in DIC, which correlate well with severity of DIC and also can serve as a marker for early detection and monitoring of DIC. Thromboelastography (TEG) technique provides information about the coagulability of blood at a particular time. Its diagnostic use in DIC is still being evaluated. An atypical light transmittance profile of aPTT resulting in a biphasic waveform abnormality has been shown to be a good indication of DIC and this often precedes any abnormality in the more conventional parameters used for diagnosing DIC.

Most of the tests show high sensitivity but low specificity. DIC is a rapidly changing process and these tests give an idea of patient's condition at that particular point of time. It is important to remember that repeated tests may, therefore be required to make a more clinical certain diagnosis. Tests like PT, aPTT, platelet count, FDPs and D-dimer are commonly available and are sufficient to make or exclude clinical diagnosis of DIC.

In 2001 the International Society on Thrombosis and Hemostasis (ISTH) proposed a scoring system for the diagnosis of DIC, whose prerequisite is the presence of an underlying disorder known to be associated with DIC. A diagnosis of overt DIC is made with a score more than or equal to 5. This scoring system has sensitivity of 91%, whereas, the specificity is 97%. A positive correlation between an increasing DIC score (**Box 2**) and mortality has been shown by several studies. A major disadvantage of the diagnostic score is that it is a static assessment, which may not capture the dynamically changing scenario of the coagulopathy.

BOX 2 Scoring system for overt disseminated intravascular coagulation

- **Risk assessment:** Does the patient have an underlying disorder known to be associated with overt DIC?
 - *If no:* Do not use this algorithm
 - *If yes:* Proceed, order global coagulation tests (PT, platelet count, fibrinogen, fibrin related marker) and score the test results
 - Platelet count ($> 100 \times 10^9/L = 0$, $< 100 \times 10^9/L = 1$, $< 50 \times 10^9/L = 2$)
 - Elevated fibrin marker (e.g., D-dimer, fibrin degradation products) (no increase = 0, moderate increase = 2, strong increase = 3)
 - Prolonged PT ($< 3 \text{ sec} = 0$, $> 3 \text{ but } < 6 \text{ sec} = 1$, $> 6 \text{ sec} = 2$)
 - Fibrinogen level ($> 1 \text{ g/L} = 0$, $< 1 \text{ g/L} = 1$)
- **Calculate score**
 - > 5 compatible with overt DIC: Repeat score daily
 - < 5 suggestive for nonovert DIC: Repeat next 1–2 days.

DIFFERENTIAL DIAGNOSIS

Conditions that may produce clinical manifestations and laboratory abnormalities similar to those in DIC include liver disease, hemolytic uremic syndrome, thrombotic thrombocytopenic purpura, primary fibrinogenolysis and massive transfusion.

Patients with liver disease may present with coagulation abnormalities and clinical manifestations similar to DIC patients. However, these conditions may be differentiated by measurement of clotting factor activity. In liver disease, factor VII and IX are typically low and factor VIII may be normal or increased. Whereas, in DIC factor VII is mildly decreased and factor VIII is decreased as well. Another useful test is D-dimer assay, which is abnormal in DIC but normal in liver disease.

Hemolytic uremic syndrome is commonly associated with anemia and renal insufficiency. High levels of FDPs may be seen but coagulation abnormalities are not commonly present. Patients with thrombotic thrombocytopenic purpura have anemia, renal abnormalities and neurological changes in addition to thrombocytopenia.

Cases with primary fibrinolysis have hypofibrinogenemia, increased levels of FDPs, abnormal PT, aPTT and thrombin time and deficiency of factor V and VIII. However, platelet count is generally normal and D-dimer level is normal or minimally elevated. Massive transfusion may present with coagulation abnormalities and decreased fibrinogen and clotting factor levels but FDPs and D-dimer are normal.

MANAGEMENT

The cornerstone of the management of DIC is the specific and vigorous treatment of the underlying condition. In most of the cases, DIC will spontaneously resolve when the underlying disorder is appropriately managed. Examples include the administration of antibiotics, antsnake venom or surgical drainage in patients with DIC. Additional supportive therapy in the form of plasma and blood transfusions, platelet substitution therapy, anticoagulants, and administration of physiologic coagulation inhibitors may be required.

Blood Component Therapy

Blood component therapy should be based on whether the patient is bleeding or requiring an invasive procedure, or at risk of bleeding. It should not be instituted on the basis of laboratory results alone.

Replacement of missing blood components should be instituted as necessary. Packed erythrocytes are required if the patient is bleeding profusely. Platelet transfusions should be considered in patients with active bleeding or at high risk of bleeding and a platelet count of less than $50 \times 10^9/L$. In non-bleeding patients with DIC, prophylactic platelet transfusion is not given unless it is felt that there is high risk of bleeding. Replacement therapy for thrombocytopenia is aimed at raising the platelet count to $20\text{--}30 \times 10^9/L$ and to $50 \times 10^9/L$ in patients who need an invasive procedure.

In patients with active bleeding or who require an invasive procedure, and have prolonged PT and aPTT, administration of fresh frozen plasma (FFP) in the dose of 15 mL/kg is recommended. If transfusion of FFP is not possible such as in patients with fluid overload and bleeding, administration of factor concentrates like prothrombin complex concentrate may be useful. These concentrates may partially correct the defect as they contain only selected coagulation factors, whereas, patients with DIC usually have a deficiency of all coagulation factors. Severe hypofibrinogenemia ($< 1 \text{ g/L}$) that persists despite FFP replacement may be corrected by cryoprecipitate or fibrinogen concentrate.

The response to blood component therapy should be monitored both clinically and by repeated assessment of platelet counts and coagulation tests following administration. The efficacy and safety of recombinant factor VIIa in DIC patients with massive bleeding are unknown and this should be used with caution.

Anticoagulants

Heparin has been shown to be beneficial in small and uncontrolled studies of patients with DIC, but not in controlled clinical trials. The administration of heparin is not recommended in DIC patients with bleeding because of the increased risk of bleeding. However, therapeutic doses of heparin should be considered in cases with DIC in which thrombosis is the primary feature. When thrombotic event is associated with DIC (such as arterial, venous or purpura fulminans), heparin should be used in the dose of 10 IU/kg/h. Patients with an increased risk of bleeding may be given unfractionated heparin due to its short half-life. Low

molecular weight heparin and mechanical methods can also be used. The target aPTT in such cases should be around 1.5–2.5 times the normal or 59–85 sec. Monitoring the aPTT in these cases may be complicated and clinical observation for signs of bleeding is important. In critically ill and nonbleeding patients with DIC, prophylaxis for venous thromboembolism with prophylactic doses of heparin or low molecular weight heparin is recommended.

Conceptually, the use of anticoagulant agents effective against tissue factor activity seems to be most logical. Although, phase II trials of recombinant tissue factor pathway inhibitor (TFPI) in patients with sepsis showed encouraging results, a phase III trial did not show an overall survival benefit. Recent trials of recombinant human thrombomodulin suggest that this compound may reduce mortality and may reduce the severity of organ failure significantly.

Concentrate of Coagulation Inhibitors

The use of anticoagulant factors such as antithrombin and activated protein C to restore the dysfunctional anticoagulant pathway in DIC is not recommended in pediatric patients. Antithrombin concentrate has been available since 1980s and most trials with this compound show some benefit in terms of improvement of laboratory parameters but no clinical trial has been able to demonstrate improved mortality. Based on the logic that there is depression of the protein C pathway in DIC, it has been suggested that supplementation of activated protein C might potentially be of benefit. Some studies have shown the ability of activated protein C to normalize coagulation activation during severe sepsis, but it has also been reported to increase the risk of major bleeding. Unlike in adults, use of activated protein C is not recommended in children with DIC. In fact, because of an increased risk of bleeding and lack of efficacy, a randomized clinical trial of activated protein C in children with severe sepsis was terminated early.

Antifibrinolytic Agents

The use of antifibrinolytic agents such as tranexamic acid in patients with DIC is generally not recommended because DIC has hypofibrinolysis and antifibrinolytic agent might worsen the condition by prothrombotic effect. The only exception may be made in patients with primary or secondary hyperfibrinolysis (e.g., coagulopathy associated with promyelocytic leukemia or in some cases of DIC secondary to other malignancies), where antifibrinolytic treatment has been shown to control coagulopathy. The use of procoagulant factor concentrate like prothrombin complex or recombinant factor VIIa is not recommended for the treatment of DIC patients with coagulopathy as they may worsen the condition.

PROGNOSIS

In general, presence of DIC worsens prognosis in all disorders. Development of complications such as shock, hemorrhage, thrombosis and renal failure are associated with increased mortality. DIC is an independent predictor of mortality in patients with sepsis and trauma. It is difficult to state the mortality and morbidity of DIC as both DIC and its underlying condition contribute to these. Overall mortality of severe acute DIC ranges from 50–70%. However, if the underlying condition is self-limiting or can be controlled, DIC will disappear and the coagulation status will be normalized. With the early recognition of systemic abnormalities and the introduction of new therapies, the prognosis for many patients with DIC has improved over the last several years.

IN A NUTSHELL

1. DIC is an acquired thrombohemorrhagic syndrome in which a patient can present with thrombotic and bleeding problems at the same time.
2. DIC never occurs in isolation and is always secondary to a pre-existing primary pathology.
3. Sepsis is the most common etiological agent of DIC. Administration of appropriate antibiotics is of paramount importance.
4. Thrombin generation, suppression of physiological anticoagulants (such as antithrombin III, protein C and tissue factor pathway inhibitor) and decreased fibrinolysis play key role in pathogenesis of DIC.
5. There is no single laboratory test that allows a definite diagnosis of DIC.
6. In a clinical situation, a combination of prolonged PT, aPTT, thrombocytopenia and elevated fibrin degradation products along with a condition known to cause DIC is sufficient to make a diagnosis of DIC.
7. Early recognition and effective control of the underlying disease are paramount to ensure successful management of acute DIC.
8. The treatment of choice for DIC remains vigorously treating the underlying triggering condition along with supporting the hemostatic components.
9. Clinical condition of the patient (e.g., bleeding) should guide replacement therapy rather than laboratory values.
10. Presence of DIC worsens prognosis in all disorders.

Chapter 38.24

Blood Component Therapy

Anupam Verma, Hemlata, Nabajyoti Choudhury

Blood component transfusion is one of the mainstays of treatment across pediatric patients who are one of the intensively transfused patients and also one of the most vulnerable groups of transfusion recipients. Blood transfusion needs in pediatric group especially for infants are different due to small volume of patients and immature organs which necessitate special approaches to component therapy. This chapter deals with a number of specialized pediatric transfusion situations including the technical considerations and biomedical devices required for the transfusions. The goal is to provide a resource for a safe and most effective pediatric hemotherapy. Despite the availability of several clinical guidelines for transfusion practices, transfusion practice often deviates from these established guidelines, resulting in under and over utilization of blood products.

Pediatric transfusion practice is usually divided into two periods: (1) neonates from birth through 4 months and (2) older infants (> 4 months) and children. The transfusion in the fetus (in utero) is the domain of obstetric transfusion medicine, while pediatric health care providers are primarily concerned with postnatal transfusion practices involving neonates, infants and children. It is equally important for neonatologists to understand transfusion concerns during the antenatal period as well, as some of the specialized transfusion requirements in postnatal period overlap with those of antenatal period.

TRANSFUSION PRACTICES IN ANTENATAL PERIOD

Intrauterine transfusion (IUT) of red blood cells is indicated most commonly when a fetus is severely anemic due to red cell antigen incompatibility (usually RhD) with maternal blood. IUTs are generally performed by the intravascular route (umbilical vein) or intraperitoneal or combined approach. Infants who received IUT for hemolytic disease of fetus and newborn (HDFN) may have prolonged postnatal transfusion requirement. Erythropoietin has been shown to improve hemoglobin (Hb) and reduce transfusion volume in infants who have a persisting transfusion requirement following IUT. In severe HDFN, IUTs are administered to fetus to prevent or reverse hydrops fetalis and prevent fetal death. IUTs suppress compensatory erythropoiesis in the fetus and after one or more IUTs most of fetal blood is of donor origin. IUT with red blood cells (RBC) lacking the offending antigen is the lifesaving procedure although the treatment is not without risk. Additional maternal red cell antibodies are often formed after IUTs, which can complicate subsequent pregnancies and future transfusions.

The blood for possible IUT must be antigen negative for the offending antibody (generally O RhD negative) and cross-matched against the mother's serum to help rule out any other possible hemolytic antibodies. Additionally, the unit of red blood cells should be cytomegalovirus-negative or leukodepleted, irradiated to prevent transfusion associated graft versus host disease (TA-GVHD), preferably less than 5–7 days old and hematocrit (Hct) level between 70–85%. The rate for red cell IUT is about 5–10 mL/min. In general, volume of 30–60 mL/kg of nonhydropic fetal weight is transfused because volumes higher than this may be difficult for the fetus to tolerate. Once the transfusion is accomplished, a final blood sample is often taken to estimate

the final Hct value of the fetus. If the initial Hb/Hct value is extremely low, a repeat procedure may be necessary within a week. Otherwise, the procedure can be performed every 2–4 weeks based on the post-transfusion Hb value. Intrauterine platelet transfusion procedures are performed to treat fetal thrombocytopenia due to platelet alloimmunization. When fetal platelet count is less than $30 \times 10^9/L$ at 22 weeks of gestation, platelets together with intravenous immunoglobulin at 1 g/kg body weight are administered.

TRANSFUSION PRACTICES IN INFANTS LESS THAN 4 MONTHS OF AGE

Most preterm infants with birth weight of less than 1000 g will require RBC transfusion. Whole blood may be requested for infants undergoing exchange transfusion or massive transfusion, however, RBC along with plasma components or reconstituted whole blood is now increasingly used in many centers.

Red Blood Cell Transfusion

The increased transfusion need in the first four months of life usually arises from: (1) iatrogenic blood loss due to frequent blood sampling; (2) hemolytic disease of newborn; (3) physiologic anemia of prematurity; and (4) prolonged length of hospital stay for premature infants with very low birth weight. Delayed cord clamping at delivery, minimizing iatrogenic blood loss and judicious use of erythropoietin are some of the strategies that can reduce the need for red cell transfusion.

Neonatal red cell transfusion includes small volume (top up) or large volume transfusions in the setting of exchange transfusion, transfusion in hypotensive shock, transfusion for surgery. The red cell transfusion trigger for small volume transfusion in neonates and infants under 4 months of age can be summarized as: Hb less than 12 g/dL in first 24 hours; Hb less than 12 g/dL with intensive care; Hb less than 11 g/dL with chronic oxygen dependency; Hb less than 7 g/dL in a stable infant; acute blood loss more than 10%; sampling more than 10% blood volume/week.

Most RBC transfusions are small volume and are administered in the first month of life to preterm infants. Fresh red blood cells less than 5–7 days should be transfused due to concern with hyperkalemia in older blood units especially in large volume transfusion and renal failure. Red cell additive saline-adenine-glucose and mannitol (SAGM) is safe for small volume top up RBC transfusions and now increasingly used in large volume transfusions in many centers; however, citrate-phosphate-dextrose (CPD) solution may be preferred over SAGM in case of exchange transfusion as former contains some coagulation factors and albumin in plasma, which may be beneficial for the neonate during exchange transfusion. It is preferable to have dedicated blood aliquots from a unit for serial small volume transfusions to minimize multiple blood donor exposures. The use of pediatric bags (pedipacks) is recommended otherwise sterile connecting device can be used for making small volume aliquots from an adult blood unit without decreasing shelf life of original unit.

Blood for neonatal transfusion is often issued as group O RBC (Hct of 55–60%) with compatible infant Rh type. Alternatively, nongroup O infants may receive nongroup O RBCs if passive maternal anti-A or anti-B is not detected in an infant's plasma. RBC transfusions for infants are issued in bags or syringes may be used if less volume of blood is required. Transfusion should be through a standard blood transfusion set (170–260 μm filter) which holds true for other blood components as well. Where small volumes are drawn into a syringe an appropriate filter should also be used. Small volume transfusion dose is 10–15 mL/kg transfused over 2–4 hours or blood may be transfused intermittently in bolus if

syringed blood is used. Electromechanical infusion devices may be used for slow controlled rate of transfusion in neonatal or pediatric patients. Constant rate syringe delivery pumps can be used for transfusion of red cells through small gauge needles. Syringe pumps are suitable for volumes from 10 mL to 50 mL. Blood aliquots and syringed components expire in 4 hours in an open system due to risk of bacterial contamination. The expected post-transfusion increase in Hb depends upon type of anticoagulant preservative solution (3 g/dL in CPD vs 2 g/dL in SAGM) and Hct of blood.

Small volume transfusions can be given repeatedly over the first 4 months of life without further serological testing, provided that there are no atypical maternal red cell antibodies in the maternal/infant plasma, and the infant's direct antiglobulin test is negative, as the development of antibodies to red cell antigens is very uncommon in the first 4 months of life. Leukodepleted blood (residual leukocytes $< 5 \times 10^6$) is generally accepted as equivalent to CMV seronegative component.

Exchange transfusion (ET) in the neonate represents a massive transfusion (> 25 mL/kg) involving the replacement of one or two whole blood volume. Whole blood or reconstituted whole blood can be used for ET. Irradiation of component is desired although not essential. However, irradiation of all cellular components is essential for the neonates with previous IUT. Similarly irradiation is mandatory in following situations: premature neonate with weight less than 1200 g, immunocompromised, receiving blood from relatives or receiving HLA matched or platelet cross-match compatible components. There is no need to irradiate red cells or other cellular components for infants undergoing cardiac surgery unless clinical or laboratory features suggest co-existing immunodeficiency which can put them at risk. Blood for ET and IUT should be transfused within 24 hours of irradiation. Hematocrit of packed red blood cells (PRBC) is lower (50–55%) compared to top up transfusions. Units should not be transfused straight from refrigerator but rather brought to the room temperature before transfusion. When possible, use of a blood warmer is recommended for rapid or massive transfusion. Washing of red cells by manual or automated methods may be desired in selected cases, for example, washing of irradiated red blood cells for prevention of hyperkalemia, allergic reactions to plasma proteins.

A unique situation which affects about 5% of all newborns during the first week is neonatal polycythemia (Hct $> 65\%$) which may lead to hyperviscosity of blood affecting blood flow to many important organs. Whole blood of neonate is removed and replaced with normal saline by partial exchange. Plasma is not used to replace whole blood because necrotizing enterocolitis has been reported as a complication of the use of plasma.

Platelet Transfusion

Thrombocytopenia is one of the most common hematologic abnormalities in the neonatal period with over 75% of episodes occurring in the first 72 hours of life. Early onset severe thrombocytopenia (Platelet count $< 50 \times 10^9/L$) is mainly due to neonatal alloimmune thrombocytopenia (NAIT) and sepsis is responsible for most cases of late onset thrombocytopenia in a preterm infant.

Single unit or aliquots of platelets prepared from whole blood donations, that is, random donor platelets (RDP) or from plateletpheresis donations (single donor platelets; SDP) can be used for correcting thrombocytopenia. Commonly accepted platelet transfusion triggers for infants under 4 months of age are—stable infant with platelet count less than $20 \times 10^9/L$; critically ill preterm infant with platelet count less than $30 \times 10^9/L$; previous major bleed or an active minor bleed in an infant with platelet count less than $50 \times 10^9/L$; platelet count less than $100 \times 10^9/L$ prior to cardiovascular or neurologic surgeries. Even without

thrombocytopenia platelet transfusion is recommended if there is active bleeding in the setting of qualitative defect in platelets or unexplained excessive bleeding in a patient undergoing cardiopulmonary bypass.

Infants should receive ABO and Rh (D) identical platelets as far as possible. Group O platelets should be avoided in non-group O recipients. Plasma volume reduced platelet concentrates may be preferred in selected neonates with fluid restriction. In NAIT human platelet antigen compatible platelets are preferred; however, RDP or even irradiated maternal platelets can be used in emergency. A platelet volume of 5–10 mL/kg raises platelet count of a neonate by $50\text{--}100 \times 10^9/L$. It is recommended to leuko-reduce and irradiate platelet products for use in neonates whenever possible.

Granulocyte Transfusion

Granulocyte transfusions (GT) are rarely performed as there is not enough evidence for benefit of GT in treatment of neonatal infection. GT have been used as adjunct therapy in bacterial sepsis or disseminated fungal infection unresponsive to antibiotics in infants under 2 weeks of age with absolute neutrophil count (ANC) less than $3 \times 10^9/L$ and in infants over 2 weeks of age with ANC less than $0.5 \times 10^9/L$.

Granulocyte concentrates, can be obtained from apheresis procedure or from pooled buffy-coat units derived from whole blood donations. The granulocyte yield is better in leukapheresis compared to buffy coat preparations. The product should be ABO compatible, cross-match compatible with the recipient, CMV seronegative, irradiated (but not leukofiltered). The usual dose is $1\text{--}2 \times 10^9$ neutrophils/kg body weight in a volume of 10–15 mL/kg. Granulocytes should be transfused immediately after collection or stored at 20–24°C without agitation for a maximum period of 24 hours.

Plasma Transfusion

Physiologically low levels of vitamin-K-dependent factors and the contact factors contribute to prolong prothrombin and partial thromboplastin times seen in infants for which fresh frozen plasma (FFP) transfusion is not indicated if there is no bleeding. The justified usage of FFP that are similar to those for older infants and children can be summarized as—coagulation factor deficiency with bleeding, or prior to invasive procedures/surgery if specific factor replacement is not available; replacement therapy in congenital antithrombin III deficiency, protein C or protein S deficiency; clinical evidence of coagulopathy and reversal of warfarin in an emergency situation in a bleeding infant.

Fresh frozen plasma must be compatible with the infant's red cell antigens (group identical or group AB). However, FFP does not need to be Rh-compatible. It is usually transfused in a dose of 10–15 mL/kg for which an adult unit can be split into aliquots. Frozen plasma must be thawed, usually in a water bath, and infused immediately or stored at 1–6°C for up to 24 hours.

Cryoprecipitate is a product derived from the slow thawing of frozen plasma at 4°C that contains predominantly fibrinogen, factor VIII, von-Willebrand factor and factor XIII. Cryoprecipitate is indicated in patients with active bleeding or undergoing an invasive procedure having von Willebrand disease, hemophilia A (when factor VIII concentrates are unavailable) hypofibrinogenemia, dysfibrinogenemia and factor XIII deficiency. It is also given in consumptive coagulopathy when fibrinogen levels are low. Cryoprecipitate should be ABO-compatible with the infant's red cells. A typical cryoprecipitate bag is 10–15 mL in volume which is sufficient to achieve hemostatic level in an infant. It is usually transfused in a dose of 5 mL/kg. Thawed cryoprecipitate is kept at

Table 1 An overview of technical aspects of hemotherapy for small volume transfusions in neonates and infants (modified from AABB)

Component	Dose	Expected rise	Component administration*	Special consideration
Red blood cells	10–15 mL/kg	2–3 g/dL in hemoglobin	Standard blood administration (BA) set	Leukodepleted, irradiated if previous IUT or at risk candidate
Platelets	5–10 mL/kg	50–100 × 10 ⁹ /L in platelet count	Standard BA set or platelet administration set	Leukodepleted, irradiated if previous IUT or at risk candidate
Granulocytes	10–15 mL/kg (1–2 × 10 ⁹ neutrophil)	Variable increase in ANC, clinical response	Standard BA set	Irradiated but no leukodepletion by filtration
Fresh frozen plasma	10–15 mL/kg	15–20% in factor levels	Standard BA set	Nil
Cryoprecipitate	5 mL/kg (usually single unit)	60–100 mg/dL in fibrinogen level	Standard BA set or cryoprecipitate infusion set	Nil

* In infants standard blood administration sets with 170–260 micron filter may be used; however, pediatric blood administration set with integral 3-way tap should be preferred for small volume transfusion. Similarly platelet administration sets having smaller priming volume are to be preferred over standard set if available.

room temperature and should be transfused as soon as possible after thawing.

A summary of practical aspects of transfusion for various blood components can be found in **Table 1**.

TRANSFUSION IN INFANTS MORE THAN 4 MONTHS OF AGE AND CHILDREN

The principles of transfusion support and transfusion needs for older infants and children are similar to those for adults, though recipient's blood volume is still an important issue while administering blood products in older infants. However, unlike neonates, there is no concern over choice of anticoagulant preservative solution in the blood. Serum grouping for ABO confirmation is required in this group unlike in infants less than 4 months of age. Serological testing is mandatory after each transfusion including screening for the presence of clinically significant antibodies. Neonates rarely develop febrile non-hemolytic transfusion reactions with less chances of alloimmunization; however, children can have adverse reactions due to leukocytes if blood unit is not leukodepleted and easily form red blood cell alloantibodies.

Children can tolerate lower hemoglobin levels without symptoms as compared to adults thus a lower transfusion trigger may be preferred in many children. Most transfusions are required for children with hemoglobinopathies, coagulopathies, bone marrow failure syndromes, hematological malignancies, transplants, surgeries and massive blood loss. Red cells are indicated for correction of significant preoperative anemia, acute blood loss with hypovolemia, intraoperative blood loss of more than 15% of blood volume, Hb less than 8 g/dL in perioperative period/chemotherapy/congenital or acquired symptomatic chronic anemia, Hb less than 13 g/dL with severe cardiopulmonary disease. The volume for red blood cell transfusion in children can be calculated as below: Volume (mL) of RBC to be transfused = Desired Hb rise (g/dL) × weight (kg) × 3.

Thalassemia and hemophilia are two important inherited disorders which are traditional users of red blood cells and plasma products respectively. Sick cell disease, which is prevalent in central and western India also puts burden on the limited blood resource. Patients with sickle cell disease are managed with top up and exchange transfusion with red blood cells. Thalassaemic patients are managed with regular PRBC transfusions along with chelation therapy; however, blood transfusion is not without risks in this population. Many patients develop acute and chronic adverse effects of blood transfusion. In thalassemia, a pretransfusion Hb of 9–10 g/dL should be maintained. All patients in this age

group who are transfusion dependent should be phenotyped for red cell antigens other than ABO and RhD (extended red cell phenotype) as soon as possible to minimize red cell alloantibody production and provide compatible units in the event of formation of alloantibodies. Similarly Hepatitis B vaccination should be initiated for children who are candidate for chronic transfusions.

Bone marrow transplant (BMT) is a specialized procedure which is performed mainly in children with leukemia, lymphoma, aplastic anemia and thalassemia. In allogeneic BMT when recipient and donor are of different ABO and Rh blood groups a new protocol on the specifications and selection of blood products is followed. Irradiated and leukodepleted blood components are mainstay of treatment in BMT. Post-transplant children and adult patients should continue to receive irradiated blood components until the patients have recovered immunologically.

Cryoprecipitate and FFP transfusions may be used for treatment for hemophilia A and B patients if factor concentrates are not available, however, hemophilia patients should preferably be treated with plasma derived/recombinant factor concentrates. The indications and selection of platelets and plasma components in children are based on transfusion practices used for adults. Due to larger body weight doses for blood components are different from that of neonates. Thus the platelet dose for children over 10 kg body weight is 1 unit of RDP/10 kg weight or 10–15 mL/kg. Similarly minimum granulocyte dose for larger children is 1×10^{10} cells/kg.

Massive transfusion can cause dilutional thrombocytopenia and coagulopathy, which may require large quantities of platelet and plasma components. Use of rFVIIa may be considered in patients where bleeding is uncontrolled by conventional blood components.

Platelet transfusions are indicated especially in aplastic anemia, acute leukemia, hemopoietic stem cell transplant, platelet function disorders, massive transfusion, consumptive coagulopathy and immune thrombocytopenia. Immune thrombocytopenic purpura (ITP) is among the most frequent causes of childhood thrombocytopenia. Platelets are only indicated in patients with ITP who are having major, life-threatening bleeding. Platelets are generally not indicated in thrombotic thrombocytopenic purpura and heparin induced thrombocytopenia.

The decision to transfuse any blood component in a pediatric patient requires critical clinical evaluation supported by laboratory investigations. Newer viscoelastic tests of coagulation, for example, thromboelastography may be used especially during perioperative period in guiding the component use in children. However, guiding principle in blood component therapy should be to achieve a clinical goal rather than to correct abnormal laboratory values.

IN A NUTSHELL

1. The principles of transfusion support for children and adolescents are similar to those for adults.
2. Younger infants have many special transfusion considerations, which have been outlined here namely: syringed components, relatively fresh blood, CMV safe/leukodepleted blood components, irradiated cellular components, red cells with high hematocrit, volume reduced blood products and aliquoting of a blood unit.
3. Although it may not be possible to meet all the *special* requirements for blood components in a pediatric patient, every effort should be made to provide the safest and most effective transfusion.
4. There are many patient characteristics, e.g., age, weight, diagnosis, procedure and severity of illness that contribute to the likelihood of receiving a blood component therapy in pediatric populations.
5. Each pediatric center should have own manual or standard operating procedures for guiding clinical practice.

Chapter 38.25

Stem Cell Transplantation

Mammen Chandy

Hematopoietic stem cell transplantation (HSCT) is widely used to treat various malignancies and a number of hematologic, immune and genetic diseases. The annual rate of allogeneic HSC transplants now exceeds 40,000. HSCT is an effective treatment for acute leukemias and bone marrow failure syndromes such as aplastic anemia and myelodysplastic syndromes. In thalassemia major, HSCT now provides a cost effective alternative to transfusion/chelation therapy (**Box 1**). Graft versus host disease, interstitial pneumonia, leukemic relapse and infection remain the major complications.

TYPES OF STEM CELL TRANSPLANT

Allogeneic Transplant

Where the donor is a histocompatible sibling or family member (related) or from a donor registry (unrelated), it is allogeneic transplantation. Another source can be umbilical cord blood, which is a rich source of hematopoietic stem cells. This is illustrated in **Figure 1**. The bone marrow and immune system of patient who has a human leukocyte antigen (HLA) matched donor is destroyed (this is called conditioning) and the stem cells of the donor are harvested either from the bone marrow or the peripheral blood and transfused.

Syngeneic Transplant

In this type, donor is an identical sibling. These transplants are easier to perform because engraftment is faster and graft versus host disease (GVHD) is rare, and if present, mild. However, relapse is much higher in syngeneic transplants for leukemia because there is no graft versus leukemia effect.

Autologous Transplant

Here, the patient acts as his own donor. Usually done in diseases where the marrow is free of tumor and the dose limiting toxicity of chemotherapy is marrow suppression. The patient's own marrow can be harvested, cryopreserved and then returned back after ablative chemotherapy (**Fig. 2**). In some situations, the marrow will be treated (purging) with either drugs or monoclonal antibodies to remove any minimal tumor in the harvest.

Graft Source

Bone marrow has traditionally been the graft source but increasing number of transplants are being done with mobilized peripheral blood stem cells (PBSCT), however, because of larger number of T-cells there is some increase in chronic graft versus host disease. The stem cells can be *pushed* into the peripheral blood using growth factors or a mobilizing agent called preixafor. Alternatively cyclophosphamide is given and as the counts are rising, there is an increase in number of stem cells in the peripheral blood which can be harvested using a cell separator.

The Donor

Once the decision to have a bone marrow transplant has been made, the next step is to perform HLA typing on the patient, sibling and parents. Most centers would perform a transplant only if a full six antigen HLA A, B and DR matched related donor is available. Bone marrow transplantation can be done even if the donor and recipient are not ABO blood group matched unlike solid organ transplants. If there are no matched siblings who can serve as a donor then an extended family search can be done in which

BOX 1 Indications for allogeneic transplantation

- **Malignant diseases:**
 - Acute myeloid leukemia—presence of > 15% blasts after 1st course of chemotherapy, absence of favorable genetic abnormalities, presence of adverse genetic abnormalities, e.g., -5, -7, del (5q)
 - Acute lymphoblastic leukemia (ALL)—high risk ALL in CR1, early relapsed ALL in CR2
 - Juvenile chronic myeloid leukemia
 - Lymphomas
- **Bone marrow failure:**
 - Severe aplastic anemia, Diamond-Blackfan anemia, Fanconi anemia, myelodysplastic syndromes
- **Genetic disorders:**
 - *Immune:* Severe combined immunodeficiency
 - *Granulocyte disorders:* Kostmann syndrome, chronic granulomatous disease, Chediak-Higashi syndrome
 - *Platelet disorders:* Wiskott-Aldrich syndrome, Glanzmann thrombasthenia
 - *Red cell disorders:* Thalassemia major, sickle cell disease
 - *Enzyme deficiency disorders:* Gaucher disease, leukodystrophies, Lesch-Nyhan syndrome, etc.
 - Osteopetrosis.

Abbreviation: CR, complete remission

Figure 1 Principle of an allogeneic stem cell transplant

parents or cousins are tested but the probability of finding a donor is small except where the parents are consanguineous. If there is only one child then the family can plan to have another child and HLA typing can be performed on the DNA sample that has been obtained from a chorionic villus sample. When this child is born either a cord blood transplant can be done or a regular transplant can be done when the baby is 2 years old.

TRANSPLANT PROCEDURE

At the time of transplant the patient and donor undergoes a series of tests after which the patient is admitted to the ward. The patient is then taken to the operating room where a dual lumen Hickman catheter is inserted under anesthesia: this catheter is

Figure 2 Principle of an autologous stem cell transplant

used thereafter for blood tests, transfusions and administration of medication and fluids. It is removed when the patient is ready to go home. The catheter is dressed twice weekly and flushed with heparin saline when not in use. The patient is transferred to the bone marrow transplant unit prior to initiation of the conditioning regimen and is kept in the positive pressure HEPA (High efficiency particulate air) filtered unit till engraftment has occurred and the absolute neutrophil count is over 500/cu mm. The HEPA filters are high efficiency filters with a size of 0.3 microns and a trapping efficiency of 99.97%. The air quality is monitored using air quality monitors and air pressures are assessed using a pressure-testing device. Settle plate cultures are also done every month to look for microbiological contamination.

Conditioning

This refers to the treatment given to the patient, which permits engraftment of donor marrow and involves the creation of space by destroying the patient's own marrow (cytoreduction) and immunosuppression to prevent rejection. The choice of conditioning regimen for a given patient is dictated by the underlying disease and donor characteristics. Most transplant centers use chemotherapeutic agents alone for conditioning; busulfan orally at a dose of 16 mg/kg over 4 days is administered followed by cyclophosphamide 50 mg/kg for 2–4 days. Intravenous busulfan is better tolerated and has more predictable pharmacokinetics. Total body irradiation 12 Gy over 3 days is often used for transplant conditioning in patients with acute lymphatic leukemia. In patients with a high risk of rejection such as thalassemia, antilymphocyte globulin may be added to the conditioning regime. In diseases such as aplastic anemia, where the rejection rate is increased, fludarabine is added to the conditioning regime. Fanconi anemia because of the increase sensitivity to chemotherapeutic agents requires special conditioning with reduced doses. Older patients with comorbidities are nowadays conditioned with non-myeloablative or reduced intensity conditioning (RIC) regimens. Here, drugs such as fludarabine are used to suppress the patient's immune system enough to allow engraftment of donor cells and this suggests that it is not necessary to destroy the marrow and create *space* for the donor stem cells.

Bone Marrow Harvest

The donor is admitted a day or two before the harvest. Under general anesthesia marrow is aspirated from the iliac bone using either a harvest needle or even with a sternal aspirate needle. There is no surgical incision. The volume of marrow harvested is dependent on the weight of the patient: a nucleated cell dose of

300 million-marrow cells/kg (3×10^8) of the recipient is required. If the donor is over 25 kg, 8 mL/kg of blood is collected and used as an autologous transfusion during the harvest. If autologous transfusion is not feasible then and the harvest volume is large, irradiated leukodepleted blood is transfused. The donor is discharged the day after the harvest.

Stem cells can also be collected from the donor using an apheresis machine after administration of G-CSF for 4–5 days and this is called a PBSCT. Engraftment is faster following a PBSCT as compared to bone marrow transplantation (BMT) but the incidence of chronic GVHD is also greater with PBSCT. In certain situations such as high-risk leukemia, chronic GVHD can lead to a potential graft versus leukemia effect thus translating to higher cure rates with PBSC than with bone marrow transplant.

The harvested cells are usually not treated and are directly infused into the patient like a blood transfusion. If the patient and donor have different blood groups, the harvest may need to be red cell depleted either using hydroxyethyl starch or using a cell separator.

Transplant

The harvested marrow looks just like blood and is infused to the donor like a blood transfusion. Following the infusion of donor marrow the stem cells home in to the patient's marrow and a rising white cell count over the next 15 days is evidence of engraftment. One may use colony stimulating factors (G-CSF, GM-CSF) to hasten engraftment in sick patients. Red cell genotyping, cytogenetics or DNA fingerprinting will be used post BMT to document engraftment and to look for residual disease. Prior to transplant, the patient and donor DNA is tested using a set of VNTR's to look for specific DNA patterns and this is used post-transplant to see if the hematopoietic cells being produced belong to the donor. The patient is considered to be a full chimera if all the cells in the blood are donor in origin and a mixed chimera if residual host cells are present. Usually patients achieve full donor chimerism 30–45 days following BMT if a myeloablative conditioning protocol is used. The patient is transferred out of the BMT unit when his neutrophil count is over 500/cu mm and discharged when there are no IV medications to be administered.

COMPLICATIONS

Graft versus host disease, infection and regimen related toxicity are the major acute complications of BMT. The late complications include relapse, sterility, cataract and second malignancies (**Box 2**).

BOX 2 Complications following hematopoietic stem cell transplantation

- Acute complications
 - Acute graft versus host disease
 - Infections
 - Graft rejection
 - Veno-occlusive disease
 - Hemorrhagic cystitis
 - Interstitial pneumonia
- Chronic complications
 - Chronic graft versus host disease
 - Relapse
 - Sterility
 - Cataract
 - Second malignancy.

Graft Versus Host Disease

This is one of the most devastating complications of BMT and is termed acute if it occurs in the first 100 days following

transplantation and chronic if it continues or develops after this period. Despite a six-antigen HLA match, the donor T lymphocytes on entry into the patient may recognize minor differences in the recipient's cells, recognizing them as foreign and attack the recipient. Any organ in the body may be affected but the skin; intestine and liver usually bear the brunt of the attack by the donor lymphocytes in acute GVHD. Generalized erythema, maculopapular rash involving palms and soles and in severe cases toxic epidermal necrolysis (TEN) are the main cutaneous manifestations. Intestinal involvement usually manifests as diarrhea while upper gastrointestinal involvement may manifest with vomiting and loss of appetite. Progressive jaundice with minimal elevation of enzymes is seen in hepatic GVHD. Severe GVHD is associated with delayed engraftment and increased propensity to infections particularly with cytomegalovirus (CMV). Acute GVHD develops in 30–60% of patients transplanted with HLA identical marrow and may be an indirect cause of death in 20–30% of affected individuals. Acute GVHD is graded I–IV based on the degree of target organ involvement. Increased host age and transplants from female donors to male recipients particularly if the female is multiparous increases the risk of GVHD.

Chronic GVHD produces a picture similar to scleroderma. In the skin, manifestations range from dry patches or areas of variegated pigmentation to extensive dermal scarring that produces thickened atrophic skin. The GI tract involvement may result in lichenoid lesions in the oral mucosa, xerostomia, dysphagia, diarrhea or malabsorption. Chronic GVHD of the liver usually presents as a cholestatic process, which can progress to a syndrome similar to primary biliary cirrhosis. The other manifestations include sicca syndrome, pulmonary dysfunction and development of autoantibodies. Chronic GVHD is graded as either limited or extensive.

The standard protocols use a combination of 2 drugs, methotrexate and cyclosporine, as prophylaxis for GVHD. Methotrexate is given as an intravenous push in 3–4 doses over the first 10 days following BMT. Cyclosporine is continued for a period of 6–12 months depending upon the disease and the presence of GVHD. This is unlike solid organ transplantation where the drug has to be continued lifelong. Once GVHD develops the main stay of treatment is with corticosteroids. In refractory cases, antithymocyte globulin (ATG), OKT3, mycophenolate, sirolimus and IL2 antibody may be used. Chronic GVHD is managed with prednisolone along with cyclosporine.

Infection

In the initial period following transplantation, profound neutropenia, disruption of anatomic barriers secondary to mucositis and presence of central venous catheters are the most important risk factors resulting in bacterial and disseminated fungal infections with *Aspergillus* and *Candida*. At the earliest sign of infection or fever the patient is started on intravenous antibiotics depending on the sensitivity patterns in the center: piperacillin, tazobactam and amikacin are the usual first line. If there is persistent fever, carbapenems such as imipenem or meropenem and glycopeptides such as vancomycin or teicoplanin are added. With the increasing incidence of carbapenem resistant organisms colistin is added. Prophylactic posaconazole is used and when the patient is not able to tolerate orally this is changed to caspofungin or amphotericin.

Viral infections with herpes, CMV and adenoviruses contribute to the morbidity and mortality of transplantation after engraftment. The presence of GVHD, high intensity of immunosuppression, manipulation of the graft (T cell depletion) and use of fludarabine/ampath (anti-CD45 monoclonal antibody) as part of conditioning are the risk factors for CMV and adenovirus infections. CMV infection commonly targets lungs, liver and intestine. CMV

quantitative polymerase chain reaction is done at 4 weeks and every 2 weeks thereafter. Pre-emptive treatment with ganciclovir is started if the titer is greater than 1,000. The most common manifestation of adenovirus infections is hemorrhagic cystitis, gastroenteritis, pneumonia and liver cell failure. Treatment options are limited with anecdotal reports of success using cidofovir. Patients with chronic GVHD are immunosuppressed and remain at risk for infections with encapsulated organisms such as *Pneumococcus*, *Meningococcus* and *Pneumocystis jirovecii*. Prophylactic penicillin and trimethoprim-sulfamethoxazole in the first year post-transplant is useful in reducing the incidence of these infections.

Interstitial Pneumonia

This complication is observed in 30% of patients where radiation is used for the conditioning and can be crippling. In transplants where radiotherapy is seldom used, busulfan related lung damage, GVHD, CMV and *Pneumocystis jirovecii* are other etiologic agents that have to be considered.

Regimen-related Toxicity (RRT)

Veno-occlusive Disease of the Liver

Veno-occlusive disease of the liver (VOD) is a major problem with conditioning regimens containing busulfan and cyclophosphamide. It is characterized by weight gain, ascites and tender hepatomegaly, which appears within the first week after transplant and usually resolves by the third week. If severe, it can progress to hepatic failure and death. Treatment is supportive with careful fluid management. Defibrotide, recombinant tissue plasminogen activator (tPA) and heparin have also shown some benefit but the latter two carry a risk of hemorrhage. Prophylactic strategies including ursodeoxycholic acid and heparin have been evaluated, but neither has shown consistent benefit. In iron overloaded patients cardiac failure and acute pericardial tamponade can occur.

Hemorrhagic Cystitis

It is a well-known complication of cyclophosphamide but can also arise from infection with adenovirus or BK virus. This is prevented by hydration and MESNA. Severe cases may require continuous bladder irrigation, cystoscopy and clot evacuation. BK virus infection is best treated by reducing the immunosuppression: drugs like ciprofloxacin, leflunomide and cidofovir can be used.

Graft Failure

Graft failure is defined as failure to achieve neutrophil recovery (absolute neutrophil count > 500 per mm^3) by day + 30 after transplant. It results from eradication of the incoming donor cells by recipient's immune system. The risk factors include inadequate conditioning, inadequate cell dose, T cell depletion of the donor cells and HLA disparity between donor and recipient. With appropriate conditioning regimens graft failure is rare.

ABO Mismatched Transplants

ABO identity is not essential for BMT unlike solid organ transplants since stem cells do not carry ABO antigens. Removal of red cells from the harvested marrow with cell separators or gravity sedimentation with hydroxyethyl starch is all that is necessary in order to prevent hemolysis during infusion of the marrow in a group-mismatched transplant. It is much more difficult to remove ABO antibodies from the patient's plasma by plasmapheresis or immunoabsorbent columns. Delayed red cell engraftment can occur in about 20% of major ABO mismatched transplants but most patients recover as the recipient's immune system is replaced by the donors.

Blood Support

Aggressive blood and blood component support is crucial during the mandatory period of aplasia, while awaiting marrow recovery. Red cell transfusions are given to keep the hemoglobin levels above 9 gm% (PCV 27%) and platelets transfusions given to maintain a platelet count above $10 \times 10^9/L$. All blood products are irradiated to prevent transfusion associated GVHD. When possible, the blood should be leukodepleted centrally if that is not possible, leukocyte filters are recommended. Pall filters are used to leukodeplete red cells and platelet products and usually deplete the leukocyte load by 3–4 logs.

POST-TRANSPLANT CARE

Following a bone marrow transplant for a patient who has no graft versus host disease, cyclosporine is given at full doses for six months after which it is tapered and stopped 1 year post-transplant. The tapering is done earlier for malignant diseases. *Pneumocystis jirovecii* prophylaxis and supplemental folic acid is given for 1 year. The child or adult can return to normal activities within 6 months after a transplant and the quality of life is excellent. Most patients do not require any special treatment or care 1 year post-transplant unlike solid organ transplants, where they are on life-long immunosuppression with its associated complications and high cost.

Immunization

All children who have received allogeneic HSCT should be considered for reimmunization program. It should commence 12 months after a HLA-identical sibling donor transplant: this is delayed if there is graft versus host disease (**Table 1**). Child should be off all immunosuppressive treatment including steroids and cyclosporine and should not have evidence of active or chronic GVHD.

AUTOLOGOUS TRANSPLANTATION

Autologous stem cell transplantation (ASCT) is widely used in pediatric malignancies (**Table 2**). The rationale for this treatment is that dose intensification of chemotherapeutic agents increases the response rate of chemo sensitive tumors and if hematopoietic

toxicity is a limiting factor, stem cells are harvested, cryopreserved and reinfused after the chemotherapy is given. Autologous stem cell transplant requires that the patient should be in remission or have minimal disease at the time of transplant.

ALTERNATE DONOR TRANSPLANTATION

Allogeneic transplantation requires the presence of a 6 antigen matched HLA-identical donor. The chances that a sibling will be 6 antigens identical are around 25% and this improves to 30–40% using an extended family search. This means that a large number of patients who require a transplant will not find a HLA identical donor within the family. In this situation, the options of transplant and donor source include

- Matched unrelated donor (MUD)
- Cord blood transplants (CBT)
- Haploidentical transplants.

These transplants may be associated with slower engraftment, higher rejection rates and higher incidence of GVHD and hence necessary modifications in conditioning protocols and manipulation of stem cells may be required to make the transplant a successful one. However, today the results of alternative donor stem cell transplants are improving to the point that they are not inferior to matched related transplants.

Matched Unrelated Donor (URD) Transplants

The absence of a HLA identical sibling donor and the necessity for BMT has led to the formation of a number of bone marrow donor registries around the world. These registries maintain detailed HLA records of donors who are immediately accessible on request. It is estimated that approximately 22 million donors are registered in marrow donor registries around the world thus forming a large donor pool. Once a donor search is initiated, the initial reports of donors identified all over the world may be available within 5–7 days and a single donor is identified subsequently after high resolution HLA molecular typing is done. The average time from initiation of a donor search to transplant can vary between 1–6 months depending upon the country and the marrow registry. The bone marrow is usually harvested in the country where the donor is a resident (usually in a hospital recognized by the Registry) and then transported to the country/place where the patient has

Table 1 Post-HSCT immunization schedule

a. Mandatory 1 year			
1. Tetanus toxoid 0.5 mL IM	0 month	2 months	4 months
2. Inactivated polio vaccine 0.5 mL IM	0 month	2 months	4 months
3. <i>Haemophilus influenzae B</i>	One dose		
4. Pneumococcal vaccine (23 valent)	One dose		
Tetanus and polio vaccines are to be given simultaneously. <i>Haemophilus influenzae</i> and pneumococcal vaccines are to be given 1 month apart, starting 1 month after initiation of the tetanus and polio vaccination.			
2 years			
No graft versus host disease/not on immunosuppression			
1. Measles/Mumps/Rubella	One dose		
b. Optional after 1 year			
1. Hepatitis B			
2. Typhoid			
3. Cholera			
4. Rabies (if indicated)			

Table 2 Diseases treated with autologous stem cell transplantation

Neuroblastoma	Stage 2–4, at any age with <i>MYCN</i> amplified tumor Stage 4 disease in children over 1 year of age Relapse
Soft tissue sarcoma	Primary refractory disease Stage 4 disease at diagnosis
Ewing tumor	> 10% viable tumor in the resected tumor after induction therapy Relapse
Wilms tumor	Primary refractory disease Relapse in case of unfavorable histology 2 or more relapses
Brain tumor	Medulloblastoma in CR2 PNET in CR2
Lymphoma	Non-Hodgkin and Hodgkin lymphoma in second CR
Multiple myeloma	This is the most common indication in adults

Abbreviations: CR, complete remission; PNET, primitive neuroectodermal tumor

been conditioned for transplant. With recent improvements in HLA typing, conditioning regimens and supportive care, MUD transplants in acute leukemia offer as good a chance of cure as with HLA identical sibling transplants.

Cord Blood Transplant

Cord blood is a rich source of hematopoietic cells and because of their increased proliferative capacity, a 1 log lower cell dose is adequate for transplantation. Since the T cells in cord blood are immunologically naïve stringent, HLA matching is not essential and there is a low incidence of GVHD in cord blood transplants (CBT). This has led to the development cord blood banks (UCB) where cord blood units are stored and made available for transplantation. UCB offers the advantage of significantly faster availability of banked cryopreserved UCB units compared with unrelated donor stem cells.

Umbilical cord blood stem cells are the preferred donor source for children who need a stem cell transplant and do not have a matched related donor. In children with acute leukemia the results of CBT are in fact superior to matched related donor transplants particularly if the, cord blood match is good and the cell dose is high. However, in nonmalignant diseases particularly thalassemia and aplastic anemia where the risk of rejection is high, cord blood may not be the preferred donor sources.

Haploidentical Transplant

Virtually all patients who need a stem cell transplant, have at least one haploidentical parent sibling or cousin who could serve as a donor. Originally these transplants were done using mega doses of stem cells to avoid rejection and T-cell depletion to reduce GVHD. However, T-cell depleted grafts are associated with delayed immune reconstitution and associated infections and relapse. T-cell depletion is also expensive and requires specialized equipment. The John's Hopkins group has shown that it is possible to do a T-cell replete transplant using either bone marrow or peripheral blood stem cells and destroy alloreactive T cells by administering large doses of cyclophosphamide on day 3 and 4 after graft infusion. The results are promising but relapse still remains a problem.

BONE MARROW TRANSPLANTATION FOR INDIA

For a developing country like India, it would seem irrational to develop such high technology medical treatment that is likely to benefit only a few when there are more urgent health priorities competing for scarce resources. The current cost of bone marrow transplantation in the United States is about \$150,000 (INR 1 crore). It is possible to transplant patients in India at a cost of about INR 8–12 lakh. The costs involved in alternate donor transplantation will be much higher and can vary between INR 20–25 lakh depending on the type of transplant. These costs will still be much lower than if the patient traveled abroad for a transplant. There are approximately 37 transplant centers in Indian performing allogeneic and autologous transplants and 1,000 transplants were performed in India in 2013. (Data from the Indian Stem Cell Transplant Registry). Inadequate resources and lack of trained personnel are some of the reasons why transplant activity in India is far below current practice in most developed countries. The practice of private cord blood banking should be discouraged and the government should help establish public cord blood banks in India. Hematopoietic stem cell transplantation should be developed in India since it will save valuable foreign exchange, upgrade the quality of medical care in tertiary referral institutions and provide a lifesaving treatment for the patient in his own country.

IN A NUTSHELL

1. Hematopoietic stem cell transplantation is well established technique and is being used for multiple malignant and benign hematological disorders.
2. Commonly used stem cell transplants include allogenic, syngenic and autologous.
3. Current advances in conditioning regimens transplant procedure and advances in management its complications have greatly improved the long-term survivals.
4. The donors for allogenic stem cell transplant are usually available for 30% of cases. Therefore alternative sources of donor for transplantation are being considered which include
 - Matched unrelated donor
 - Cord blood transplants
 - Haploidentical transplants
5. Initially the transplants from alternative donor had slower engraftment higher rejection rate and high incidence of GVHD.
6. Necessary modifications in conditioning regimens and manipulation of stem cells have greatly improved the long-term survivals in patients undergoing stem cell transplantation from alternative donor sources.

Chapter 38.26

Myelodysplastic Syndromes

Tathagata Chatterjee, VP Choudhry

Myelodysplastic syndrome (MDS) comprises of a heterogeneous group of bone marrow (BM) disorders resulting from a clonal stem cell defect characterized by cytopenia despite a relatively hypercellular marrow, ineffective hematopoiesis, morphological dysplasia in the marrow elements, no response to hematinics such as iron, B12 or folic acid and risk of progression to leukemia. MDS in childhood is extremely rare and accounts for less than 5% of all hematopoietic neoplasm in children below the age of 14 years. Differences between adult and childhood MDS are depicted in **Table 1**.

CLASSIFICATION

Myelodysplastic syndrome is classified as primary or secondary. About one-fifth of children with primary MDS may have an underlying genetic defect that predisposes them to develop MDS at a young age. Secondary MDS occurs in patients after chemotherapy or radiation therapy; in such cases it is known as therapy-related MDS or (t-MDS). It may also occur in patients with inherited BM failure disorders, acquired aplastic anemia, or familial MDS. Among the inherited BM failure disorders, 47% of Fanconi anemia patients progress to MDS and acute myeloid leukemia (AML) and 10–25% of patients with Shwachman-Diamond syndrome progress to MDS. However, patients of dyskeratosis congenita hardly ever progress to MDS. Genetic disorders like Down syndrome (DS), Noonan syndrome and neurofibromatosis can also lead to secondary MDS. A clinical classification of myelodysplastic and myeloproliferative diseases in children is shown in **Box 1**. Specific subtypes are discussed in detail below.

BOX 1 Categories of myelodysplastic and myeloproliferative diseases in children

- I. *Myelodysplastic/Myeloproliferative disease*
Juvenile myelomonocytic leukemia (JMML)
- II. *Down syndrome (DS) disease*
Transient abnormal myelopoiesis (TAM)
Myeloid leukemia of DS (ML-DS)
- III. *Myelodysplastic syndrome (MDS)*
Refractory cytopenia (RC) (PB blasts < 2% and BM blasts < 5%)
Refractory anemia with excess blasts (RAEB) (PB blasts 2–19% or BM blasts 5–19%)
RAEB in transformation (RAEB-t) (PB or BM blasts 20–29%).

REFRACTORY CYTOPENIA OF CHILDHOOD (RCC)

Refractory cytopenia of childhood is the most common subtype of MDS in children and adolescents, accounting for approximately half of all MDS cases. It affects boys and girls with equal frequency.

Clinical Features

Blood and bone marrow are always affected; spleen, liver and lymph nodes are generally not affected. The most common symptoms are malaise, bleeding, infection and fever. Hepatosplenomegaly is not a feature. In up to 20% of cases there are no clinical signs or symptoms. Majority of patients present with thrombocytopenia, while anemia and neutropenia are noted in 50% and 25% cases, respectively.

Morphological Features

The peripheral blood (PB) smear shows red cell anisopoikilocytosis and macrocytosis. Anisochromia is present. Neutropenia may be severe in 25% cases with pseudo-Pelger-Huet nuclei and/or hypogranularity of neutrophil cytoplasm. Blasts are absent or account for less than 2% of the white cells. Platelets display anisocytosis and giant platelets may be noted and counts are generally less than $150 \times 10^9/L$.

Bone marrow aspirate shows dysplastic changes which may be present in two different myeloid cell lineages, or exceed 10% in one single cell line. Erythroid abnormalities include nuclear budding, multinuclearity, karyorrhexis and internuclear bridging along with megaloblastoid changes. It is important to note that ring sideroblasts are generally not found. Cells of granulocytic series reveal hyposegmentation with pseudo-Pelger-Huet nuclei, hypogranularity of cytoplasm, giant band forms and less than 5% blasts. Megakaryocytes are low in number; detection of micromegakaryocytes favors the diagnosis of RCC.

About 75% of children with RCC show considerable hypocellularity of the BM. Cellularity may be as low as 5–10% of the normal age matched value. There is a moderate increase in erythropoiesis with accumulation of immature precursors, mainly proerythroblasts. Increased numbers of mitosis indicate ineffective erythropoiesis. Granulopoiesis is decreased with less than 5% blasts, which is verified by CD34 staining. Megakaryocytes are decreased in number but may be normal also. Dysplastic changes include non-lobulated nuclei, micromegakaryocytes and abnormally separated nuclear lobes. There is no increase in reticulin fibers. Multiple sections prepared from the biopsy are helpful in identification of abnormal megakaryocytes and immunohistochemistry to identify micromegakaryocytes is obligatory. This is achieved by the expression of platelets glycoprotein like CD61 (GP 111a), CD 41(GP11b/111a) or von Willebrand factor.

Fatty tissue between the areas of hematopoiesis can mimic aplastic anemia and therefore at least two biopsies at least 2 weeks apart are recommended to facilitate the detection of representative BM spaces containing foci of erythropoiesis. Morphological differences between refractory cytopenia of childhood (RCC) and aplastic anemia (AA) in childhood are depicted in **Table 2**. Differential diagnosis which may present with morphological features indistinguishable from refractory cytopenia of childhood is depicted in **Box 2**.

Management

Hematopoietic stem cell transplantation (HSCT) is the only curative therapy and is the treatment of choice with monosomy 7 or complex karyotype early in the course of their disease. An expectant approach with careful observation may be reasonable for patients in the absence of transfusion requirements, severe cytopenia or infections. Immunosuppressive therapy can be a successful therapy strategy for improving outlook in some children with RCC since early BM failure in such cases can be partly mediated by T-cell immunosuppression of hematopoiesis. Preliminary data have shown a few long lasting responses in children with RCC treated with antithymocyte globulin. Whether immunosuppressive therapy can result in sustained responses in childhood RCC is not known.

Prognosis

Most cases of RCC show a normal karyotype irrespective of BM cellularity though monosomy 7 is the most common cytogenetic abnormality. Patients with monosomy 7 have a significantly higher probability of progression than other chromosomal abnormalities or normal karyotype.

Table 1 Difference between adult and pediatric myelodysplastic syndromes (MDS)

Adult MDS	Pediatric MDS
1. Refractory anemia with ring sideroblasts common	1. Refractory anemia with ring sideroblasts extremely rare
2. MDS associated with isolated del (5q) chromosome abnormality are common with good prognosis	2. MDS associated with isolated del (5q) chromosome abnormality are very rare
3. Isolated anemia is the major presentation in refractory anemia (RA) in adults	3. Isolated anemia is an uncommon presentation. Common presentations are thrombocytopenia and neutropenia
4. Bone marrow are mostly hypercellular	4. Hypocellularity of bone marrow more commonly seen
5. RAEB-t (Refractory anemia with excess blast in transformation) has not been retained in adult MDS in the present WHO classifications as these cases behave like AML	5. RAEB-t has been retained in childhood MDS. Children with RAEB-t have stable peripheral blood counts for weeks or months and do not behave as AML
6. RAEB 1 and 2 (Refractory anemia with excess blasts); distinction based on blast percentage in PB/BM has useful prognostic significance	6. RAEB 1 and 2 (Refractory anemia with excess blasts); distinction based on blast percentage in PB/BM has no prognostic significance

Table 2 Morphological differences between refractory cytopenia of childhood (RCC) and aplastic anemia in childhood (AA)

RCC	AA
1. BM biopsy shows patchy distribution of erythropoiesis and increased mitoses with maturation arrest and increased proerythroblasts among at least 20 erythroid precursors	1. BM biopsy may not reveal erythropoiesis or show a single focus with less than 10 cells with maturation to late erythroid stages with no dysplastic changes
2. Decreased granulopoiesis with marked dysplastic changes	2. Decreased granulopoiesis with maturation and no dysplasia
3. Decreased megakaryopoiesis with dysplasia and presence of micromegakaryocytes in BM biopsy	3. Hardly any megakaryocytes in BM biopsy without any dysplasia. No micromegakaryocytes
4. CD34 positive blasts may be seen in the BM biopsy	4. Blasts are not present in the biopsy specimen

BOX 2 Differential diagnosis which may present with morphological features indistinguishable from refractory cytopenia of childhood

Infections: Cytomegalovirus, herpes virus, parvovirus B19, visceral leishmaniasis
Vitamin deficiency: B12, folate, vitamin E
Metabolic disorders: (mevalonate kinase deficiency)
Rheumatic disease
Autoimmune lymphoproliferative disorder
Mitochondrial deletions (Pearson syndrome)
Inherited BM failure syndrome (Fanconi anemia, dyskeratosis congenita, Shwachman-Diamond syndrome, amegakaryocytic thrombocytopenia, thrombocytopenia with absent radii, radioulnar synostosis (Seckel syndrome)
PNH (rare in childhood)
Acquired aplastic anemia during hematological recovery.

myelodysplasia-related changes in peripheral blood and bone marrow, including myelodysplasia-related cytogenetic abnormalities may also have slowly progressive disease. These cases, considered as refractory anemia with excessive blasts in transformation (RAEB-t) by the French-American-British cooperative classification, may lack the clinical features of acute leukemia and behave more like MDS than AML. They also do not respond to AML-like therapy. Hence, RAEB-t has been retained in childhood MDS as compared to adult MDS where it is no longer retained in the present WHO classification. Follow-up is necessary to monitor the disease in such cases. It is important to note that children having recurrent translocation cytogenetic abnormalities like t(8;21)(q22;q22), inv(16)(p13.1q22) or t(16;16)(p13.1;q22) or t(15;17)(q22;q12) should be considered to have AML regardless of the blast count.

Treatment

The most appropriate therapy for children with RAEB or RAEB-T is unknown. Although most investigators agree that HSCT can improve survival, the importance of cytoreductive therapy prior to grafting remains controversial. Data from the European Working Group of MDS in Childhood (EWOG-MDS) indicate that intensive chemotherapy prior to HSCT will not improve survival. In this study of advanced primary MDS, the probability of survival was about 50% and not influenced by marrow blast percentage at the time of transplantation.

MYELOYDYSPLASIA IN GENETIC DISORDERS

Monosomy 7 is the most common cytogenetic abnormality in childhood MDS and is seen in up to one-third of such cases. Trisomy 8 and trisomy 21 are the second most common chromosomal numerical abnormalities. Presence of a complex karyotype (up to or more than three chromosomal abnormalities including at least one structural aberration) is considered the most important prognostic marker as far as outcome of the cases are concerned.

PRIMARY MDS WITH INCREASED BLASTS

(Refractory Cytopenia with Excess Blasts and Excess Blasts in Transformation; RAEB and RAEB-t)

Refractory Anemia with Excess Blasts (RAEB)

Refractory anemia with excess blasts (RAEB) is characterized by the presence of 2–19% blasts in peripheral blood (PB) or 5–19% blasts in bone marrow (BM). It is further classified as RAEB-1 and RAEB-2 based on the presence of 5–19% blasts in BM/2–4% blasts in PB and 10–19% blasts in BM/5–19% blasts in PB, respectively. There are no data at present to distinguish the prognostic significance of RAEB in children. Children with RAEB generally have stable peripheral blood counts for weeks or months.

Refractory Anemia with Excessive Blasts in Transformation (RAEB-t)

Some cases diagnosed in children with AML with 20–29% blasts in the peripheral blood and/or bone marrow that have

Myeloid Leukemia of Down Syndrome (ML-DS)

Children with trisomy 21 or DS have an approximately 10-20-fold increased risk for developing acute leukemia compared with children without DS. More than half of these cases are AML and this trend persists till about the fourth year of age. Among the myeloid leukemia (ML), the incidence of acute megakaryocytic leukemia (AML M7) from birth till the fourth year of age remains the highest. The incidence of AML M7 is up to 500-fold greater in children with DS till the age of 4 years compared to the general pediatric population. Interestingly, the ratio of acute lymphocytic leukemia (ALL) to AML reverts to that of the general pediatric population once the child completes 5 years of age. Majority of these AML often present with features of MDS and almost uniform presence of *GATA1* mutation. Some neonates with DS or trisomy 21 mosaicism may manifest as transient myeloproliferative disorder (TMD). The cure rate of AML in DS is high. This may be due to an increased in vitro sensitivity of myeloblasts to cytarabine as a result of generation of ara-C triphosphate. Blasts are also sensitive to daunorubicin. The myeloid leukemia seen in young children with DS is unique and classified under the unifying term *myeloid leukemia of DS* (ML-DS).

Transient Myeloproliferative Disorder (TMD)/ Transient Abnormal Myelopoiesis (TAM)/DS Transient Leukemia (DS-TL)

This is an intriguing syndrome which is generally diagnosed in up to 10% of neonates with Down syndrome, usually during the first week of life. TAM cannot be readily distinguished from congenital AML. Blasts in TAM have now been proved to be clonal in origin.

Clinical features of TAM include very elevated leukocyte count with circulating blasts which may be megakaryoblasts as well as erythroblasts, hepatosplenomegaly, and an increased percentage of blasts in the bone marrow. Additional manifestations of DS-TL include cutaneous involvement, hyperviscosity, myelofibrosis, cardiopulmonary failure, splenomegaly, and spleen necrosis.

There is complete clinical and hematological recovery in more than 70% of these neonates within weeks to a maximum of three months of life without therapy. Unfortunately there is a small subgroup of infants with TAM who die from liver failure and multiorgan failure due to megakaryoblastic infiltration of the liver and hepatic fibrosis. Early death in 17% is associated with high WBC at diagnosis, increased bilirubin and liver enzymes and failure to normalize WBC. Almost 30% of infants with TMD/TAM eventually develop AML (mostly AML M7) before 4 years of age. There is usually a prodrome of several months in which there is evidence of persistent thrombocytopenia and BM myelofibrosis

with dysplastic megakaryocytic. Mutations in *GATA-1* gene (an erythroid/megakaryocytic transcription factor) are present in the blast in infants with TMD as well as patients with DS with AML. **Table 3** depicts the differences between TAM and congenital leukemia. Majority of infants with TAM never require therapy in the first month of life; these infants should be observed and given supportive therapy. A small group of infants with liver failure warrants a course of low-dose cytarabine.

JUVENILE MYELOMONOCYTIC LEUKEMIA (JMML)

Juvenile myelomonocytic leukemia is a uniquely pediatric clonal disorder of the hematopoietic stem cell and is the most common form of myeloproliferative syndrome in childhood. It was previously referred to as juvenile chronic monocytic leukemia (JCML) or chronic myelomonocytic leukemia (CMML). The incidence is approximately 1.2 per million, comprising 2-3% of all childhood leukemias but 40% of childhood MDS. Mutations in the *RAS* gene is seen in 20%, in *PTPN11* in 35%, *NF1* gene in 15% and clinical *NF1* in another 15%. **Box 3** depicts diagnostic criteria of JMML.

Differential Diagnosis

Making a diagnosis of JMML is not easy as its clinical and laboratory features can also be associated with other myeloproliferative neoplasms, infection (Epstein-Barr virus, cytomegalovirus, human herpes virus 6, histoplasmosis, mycobacterium and toxoplasmosis), Langerhans cell histiocytosis, hemophagocytic lymphohistiocytosis (HLH), Fanconi anemia, Kostmann syndrome and Down syndrome.

Management

Juvenile myelomonocytic leukemia is a rapidly fatal disorder if left untreated. Intensive chemotherapy is mostly unsuccessful in JMML because of an increased risk of treatment related death, a low rate of true remissions and long-term survival of less than 10%. Allogeneic stem cell transplantation (SCT) is the only curative approach for JMML resulting in long-term survival in more than half the patients. Non SCT treatment includes AML-like therapy, low dose chemotherapy, interferon alpha and 13-cis retinoic acid. Tipifarnib, a farnesyltransferase inhibitor has also been tried. The efficacy of chemotherapy, is however, limited. Low platelet count, age above 2 years, high Hemoglobin F and high bone marrow blast count at diagnosis are the main factors predicting a short survival.

This disorder is described in detail in Section 45 on malignant disorders.

Table 3 Differences between transient abnormal myelopoiesis (TAM) and congenital leukemia

Transient abnormal myelopoiesis	Congenital leukemia
1. Usual subtype is acute megakaryoblastic leukemia	1. Usual subtype are acute monoblastic leukemia and acute megakaryoblastic leukemia
2. Prognosis is excellent and majority recover within 3 months of life	2. Prognosis extremely poor and majority succumb to the disease
3. Majority do not require treatment except close follow-up	3. High dose chemotherapy followed by hematopoietic stem cell transplantation is the only option
4. Always presents in the first week of life	4. Presents at birth or within first month of life
5. Nearly all cases have <i>GATA-1</i> mutations	5. Majority display mixed lineage leukemia (MLL) gene translocation at 11q23
6. Blasts are highly sensitive to chemotherapy, particularly to cytarabine and daunorubicin	6. Blasts are generally resistant to chemotherapy due to MLL gene mutations
7. Commonly presents with hepatosplenomegaly and occasionally cutaneous involvement	7. Twenty five to thirty percent of infants have specific cutaneous infiltrates (leukemia cutis) which usually appear as firm blue or red nodules (Blueberry Muffin)

BOX 3 Diagnostic criteria of juvenile myelomonocytic leukemia (JMML)*Required laboratory criteria (all three required)*

- No Philadelphia chromosome/no *bcr/abl* rearrangement
- Peripheral blood monocyte count $> 1 \times 10^9/L$
- Bone marrow blasts $< 20\%$

Suggestive clinical features

- Hepatomegaly
- Splenomegaly
- Pallor
- Fever
- Skin rash

Additional criteria (minimum of two required)

- Increased HbF (age corrected)
- Myeloid precursors in peripheral blood
- White blood cell count $> 10^9/L$
- Clonal abnormalities, including monosomy 7
- GM-CSF hypersensitivity of myeloid progenitors in vitro.

IN A NUTSHELL

1. Myelodysplastic syndrome in childhood is extremely rare and accounts for less than 5% of all hematopoietic neoplasm in children below the age of 14 years.
2. The primary MDS in children also known as de novo MDS differs from secondary MDS which generally follows congenital or acquired bone marrow (BM) failure syndromes as well as from therapy related MDS commonly resulting from cytotoxic therapy.
3. Many of the morphologic, immunophenotypic and genetic features of MDS in adults are also observed in childhood forms of the disease but there are some significant differences reported, particularly in patients who do not have increased blasts in their peripheral blood (PB) or bone marrow.
4. There are no data at present to distinguish the prognostic significance of Refractory anemia with excess blasts (RAEB-1 and RAEB-2) in children as compared to adults.
5. RAEB-t has been retained in Childhood MDS as compared to Adult MDS where it is no longer retained in the present WHO classification.
6. Monosomy 7 is the most common cytogenetic abnormality in childhood MDS and is seen in up to one-third of such cases.
7. MDS associated with Down syndrome which accounts for approximately one-fourth of cases of childhood MDS is now considered a unique biologic entity synonymous with Down syndrome-related myeloid leukemia and is biologically distinct from other cases of childhood MDS.
8. Refractory cytopenia of childhood (RCC) is the most common type of MDS.
9. The most effective and curative treatment is hematopoietic stem cell transplantation and this is particularly effective in children with monosomy 7 genetic defect as well as those displaying complex karyotype abnormalities provided it is instituted early in the course of the disease.

Section 39 RESPIRATORY DISEASES

Section Editors Varinder Singh, GR Sethi

Chapter 39.1

Anatomy and Physiology of Respiration

Pankaj C Vaidya

The process of respiration in the humans is materialized by both external and internal respiration. *External respiration* includes breathing (moving air in and out of respiratory tract) and ventilation (alveolar air absorption of oxygen and release of carbon dioxide); whereas *internal* or *cellular respiration* involves production of energy by oxidizing substrate molecules.

External respiration takes place in the respiratory tract comprising of upper (starting from the external nares, nasal cavities, nasal septum, paranasal sinuses, pharynx to the larynx) and lower (includes conducting and acinar) airways. The conducting airways (trachea, main bronchi, segmental bronchi, subsegmental bronchi (up to 5th generation), smaller bronchi (about 15 generations), bronchioles and terminal bronchioles) are connected by the transitional bronchioles with the acinar airways [respiratory bronchioles (3 generations), alveolar ducts and alveolar sacs] (Fig. 1).

EMBRYOLOGY OF THE LUNGS

The phases of development of the human lungs are shown in **Figure 2**. Postnatally, alveoli continue to develop till 5–8 years and enlarge through adolescence. The number of alveoli and alveolar surface area at birth (in a term neonate) are 20–50 million and 2.8 m² respectively, which increase at 8 years to 300 million and 32 m² respectively. In adulthood the alveolar surface area increases to 75 m².

ANATOMY OF LUNGS

Blood Supply of the Lungs

Bronchial arteries, derived from the thoracic aorta or upper aortic intercostal arteries, supply blood for the nutrition of the lungs. Blood supply to the conducting airways is from the bronchial vessels and to the terminal respiratory units from the pulmonary vessels. Pulmonary veins are formed from the capillary network and join together to form the four main pulmonary veins, which drain oxygenated blood to the right atrium. Pulmonary artery pressure is high at birth and falls over the next days and weeks, in response to the higher oxygen levels. Bronchial arterial circulation is at systemic pressure.

Lymphatics of the Lung

The pulmonary lymphatics comprise of lymph ducts, lymph nodes and thoracic duct and there are two networks: pleural and parenchymal. These are vital for the removal of lung liquid at birth.

Figure 1 Human lung's airway branching

Owing to valves, the flow in the lymph channels moves in one direction and most drainage is toward the hilum. On the left side, veins follow the trachea and empty into the thoracic duct which drains into the veins on the left side of the neck while on the right side the main lymphatic ducts follow the right side of the trachea and join the venous system at the right jugular and subclavian veins junction. Lymphatic drainage of the lung is complex and varies from individual to individual.

Nerve Supply of the Lung

It is from the branches of the thoracic sympathetic ganglia and the vagus nerve. Lungs are supplied by the upper 3–5 sympathetic ganglia branches while the lower supply intercostal nerves. The sensory (afferent) system is mainly in the vagus nerve and the motor (efferent) pathways are shown in **Figure 3**.

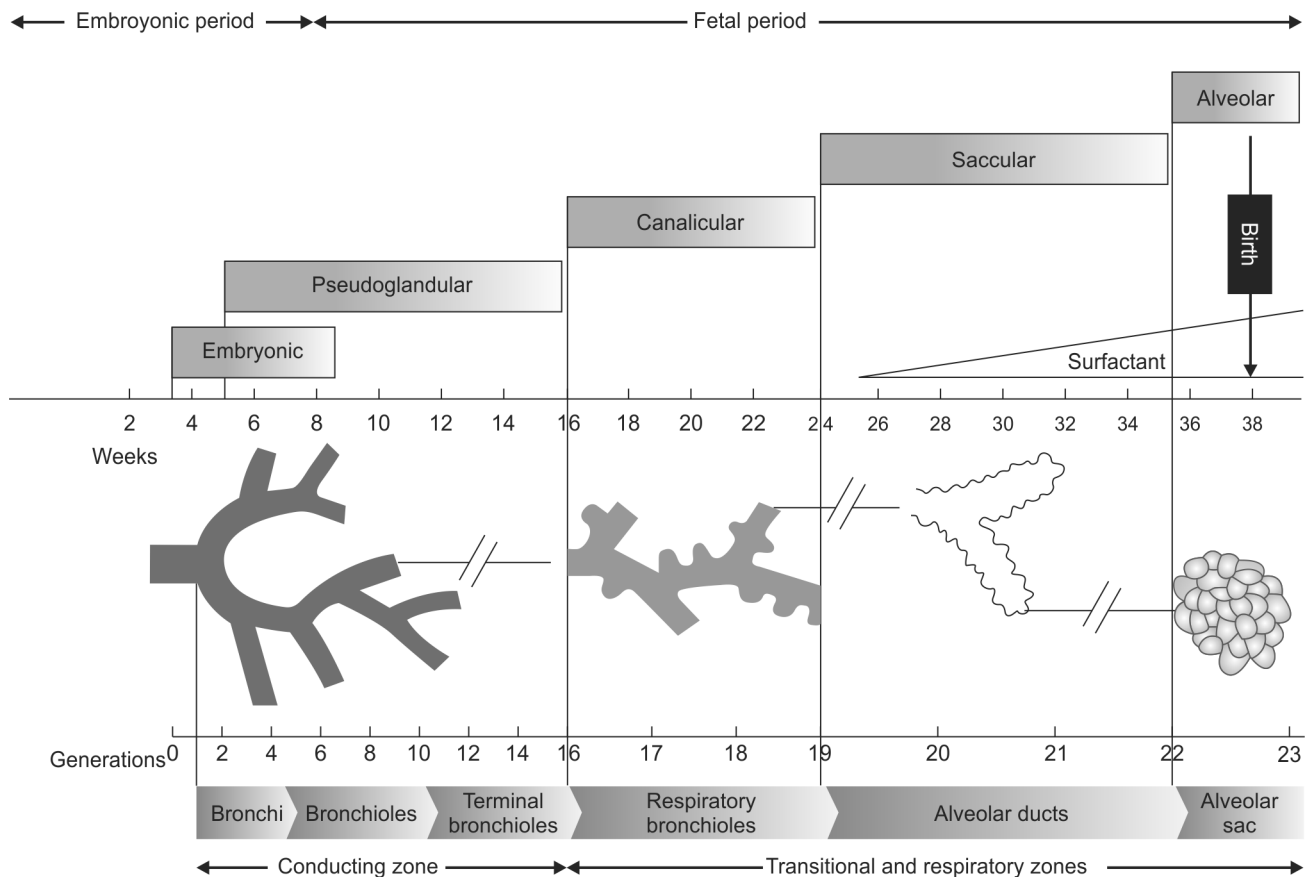

Figure 2 The five phases of embryonic development (approximate and overlapping)

Figure 3 Efferent nervous system of the lung

Figure 4 Lungs and heart in the thorax, front view (retracted anterior borders of the lungs)

The Lungs

Both lungs occupy the thoracic cavity, separated by the heart and mediastinum (**Figs 4 and 5**). They are spongy and pink in early years and with age gradually become grayer. The apex extends into the root of the neck and the base which is concave rests on the convexity of the diaphragm. The right lung has three lobes and two fissures and the left has two lobes and one fissure. Each lung gets divided functionally into 10 subdivisions because of branching

of the bronchial tree known as the bronchopulmonary segments (**Figs 6 and 7**). Each segment has an autonomous blood supply and airflow.

Lungs are covered by both visceral/pulmonary (extends into the fissures) and parietal (lines the inner surface of the thoracic cavity) pleurae, which join at the root of the lung (hilum) with an expandable space between the two layers.

Figure 5 Right lung (mediastinal surface)

Mediastinum

It lies in the thoracic cavity between the plurae of the two lungs bounded anteriorly by the sternum and posteriorly by the vertebral column. The superior mediastinum is above the pericardium (contains thymus, trachea, esophagus, thoracic duct, and the upper great vessels including the arch of the aorta), while below the pericardium there are three parts—anterior mediastinum which lies in front of the pericardium, middle mediastinum which contains the heart and pericardium and posterior mediastinum which is behind the heart (**Fig. 4**). The hila of the lungs are where the structures of the lung enter from the mediastinum, the usual level being anteriorly the third-fourth costal cartilage and posteriorly the fifth-seventh thoracic vertebrae.

Muscles of Respiration

These are the intercostal muscles and diaphragm. The right diaphragm overlying the liver is higher than the left, which overlies the stomach and spleen. There are three major openings—at

Figure 6 The bronchopulmonary segments

Figures 7A to C The nomenclature of bronchopulmonary anatomy. (A) Right lateral view; (B) Anterior view; (C) Left lateral view. Segments: Right upper lobe: (1) apical, (2) posterior, (3) anterior. Right middle lobe: (4) lateral, (5) medial. Right lower lobe: (6) superior (apical), (7) medial basal, (8) anterior basal, (9) lateral basal, (10) posterior basal. Left upper lobe: (1) apical, (2) posterior, (3) anterior, (4) superior lingual, (5) inferior lingual. Left lower lobe: (6) superior (apical), (7) medial basal, (8) anterior basal, (9) lateral basal, (10) posterior basal. Note absence of medial basal segment (7) in the left lung

the thoracic vertebral level (T12) is inferior vena cava, at T10 is esophagus, and at T12 is aorta. The opening of anterior diaphragm is the foramen of Morgagni and of the posterior is the foramen of Bochdalek, which are sites of diaphragmatic hernia (**Fig. 8**).

The diaphragm is attached to the lower costal margins and the leaves are dome shaped. With inspiration, the diaphragm flattens and the lower border of the lung correspondingly descends resulting in a different level of lower lung border.

PULMONARY PHYSIOLOGY

The respiratory system's function is to provide oxygen to arterial blood to nourish the body's tissues and to remove carbon dioxide from the returning venous blood. Gas exchange takes place at the level of the alveoli surrounded by a network of thin capillaries. Oxygen and carbon dioxide move between the air and blood by a process of diffusion. Air is brought to the alveoli by branching bronchi and bronchioles. The muscles of respiration act as pump to move air in and out of the lungs. Elastic properties of the lung and chest wall and airway resistance affect the work and efficiency of the system. Disease processes that alter these relationships can lead to respiratory failure that is defined as failure of the lungs to oxygenate and ventilate adequately.

Gas Exchange

Partial pressure of gases in atmosphere and the lung are shown in **Table 1**. Dry atmospheric air (primarily nitrogen, 20.93% oxygen and minimal carbon dioxide) gets humidified while traveling down the airways into the lungs. The alveolar PO_2 depends on the balance between the amount that flows in and the amount that is removed by the pulmonary capillaries. It decreases in the absence of fresh air supply (atelectasis), elevation of PCO_2 (hypoventilation) or at low barometric pressure (high altitude).

Gas exchange occurs on a large surface area when gas moves in and out of the alveolus and blood flows through the pulmonary capillary vessels. As shown in **Figure 9** the driving force for gas

Figure 8 Diaphragm image from below

Table 1 Partial pressure of gases in atmosphere and the lung

	Air (mm Hg)	Humidified air (mm Hg)	Alveoli (mm Hg)
Oxygen	159	149	104
Carbon dioxide	0.3	0.3	40
Nitrogen	600.6	564	569
Water vapor	0	47	47

exchange is the pressure difference of PO_2 and PCO_2 between the venous blood and alveoli. Normally, the gases equilibrate fully and thus the PO_2 and PCO_2 of pulmonary capillary blood equals that of the alveoli.

O_2 consumption and CO_2 production In 1 minute the total amount of O_2 taken up by the body is O_2 consumption (VO_2) and amount of CO_2 produced is CO_2 production (VCO_2). Both are increased with exercise. The ratio between the two is respiratory quotient and is usually 0.8.

Ventilation

It is the process of bringing air in and out of the lungs. During inspiration, the size of the thoracic cavity increases and air moves into the lungs. It is carried through the conducting airways to the alveoli, which are responsible for gas exchange. Relationship of tidal volume to dead space and alveolar volume is depicted in **Figure 10**. Components of total ventilation are shown in **Figure 11**.

Figure 9 Gas exchange in the alveolus

Figure 10 Relationship of tidal volume to dead space and alveolar volume. With each breath (tidal volume) some air goes into the alveoli and is available for gas exchange (alveolar volume)

Relationship of ventilation to arterial PCO_2 (Fig. 12) Decrease in tidal volume and respiratory rate decrease the total ventilation and increase the arterial carbon dioxide tension. Increase in respiratory rate and tidal volume increase the total ventilation and decrease the arterial carbon dioxide tension. Dead space changes affect carbon dioxide levels and alveolar ventilation but do not affect total ventilation (Table 2).

Regulation of arterial PCO_2 The arterial carbon dioxide concentration reflects a balance between carbon dioxide production and elimination. More carbon dioxide is produced

Figure 11 Components of total ventilation: tidal volume, respiratory rate, alveolar ventilation and dead space ventilation. An example showing number of breaths per minute multiplied by the volume of each breath is total ventilation

Figure 12 Relationship between ventilation and carbon dioxide levels in the lung

when the metabolic rate is increased. Ventilation is controlled by sensors called chemoreceptors (brain and carotid bodies) which sense changes in arterial carbon dioxide concentration and respond by activating effectors that alter ventilation to keep arterial carbon dioxide concentration normal.

Acid-Base Status

In the blood, carbon dioxide gets transported in three forms: dissolved, bicarbonate, and combined with proteins such as carbamino compounds. Ninety percent of it is carried as bicarbonate in arterial blood. In the red blood cell water and carbon dioxide are converted to carbonic acid (in the presence of the enzyme carbonic anhydrase) which spontaneously dissociates into bicarbonate and hydrogen ions (acid).

The blood pH depends on the relationship between carbon dioxide and bicarbonate. As the arterial PCO_2 increases, the pH decreases, known as respiratory acidosis and as the arterial PCO_2 decreases, the pH increases, known as respiratory alkalosis. The concentration of carbon dioxide is regulated by the lungs and that of bicarbonate controlled by the kidneys. In response to a respiratory acidosis, the kidneys compensate over 3–5 days by conserving bicarbonate and create secondary metabolic acidosis. While in response to a respiratory alkalosis the kidneys eliminate excess bicarbonate and create a secondary metabolic acidosis in compensation (Table 3).

The primary acid-base disorders and the compensations can be determined by plotting the values on a nomogram (Fig. 13). For acute respiratory acidosis an increase in PCO_2 of 10 mm Hg will decrease the pH by 0.08 and the bicarbonate by 1 mEq/L. In chronic respiratory acidosis, after renal compensation, the bicarbonate will increase by a total of 4 mEq/L for each 10 mm rise in PCO_2 . In acute and chronic respiratory alkalosis, similar changes occur in the opposite direction. Remembering the relationship between change in PCO_2 and pH can be useful in determining whether a patient has a compensated, partially compensated, or uncompensated respiratory acidosis.

Oxygenation

Oxygen reaches the alveoli through the conducting airways and diffuses across the very thin membrane to the capillary blood. Normally, oxygen composes 21% of air. The amount of oxygen in the alveolus is determined by the presence of other gases, fresh air supply and barometric pressure changes. The PO_2 decreases when the PCO_2 increases. The PO_2 depends on a fresh flow of air, so when the airflow decreases like in apnea, atelectasis or mucous plugging, then the PO_2 in the alveolus decreases. It also depends on the atmospheric pressure, which is low at high altitude resulting into less oxygen availability causing hypoxemia or low arterial oxygen level.

In the red blood cell, oxygen is primarily bound to hemoglobin and a small amount is dissolved in plasma. Normally, a red

**Figure 13** Acid-base abnormalities nomogram

blood cell takes about three-fourths of a second to transverse the pulmonary capillary bed and about one-fourth of a second for the oxygen to be fully transferred to the red blood cell. The transfer may take longer and unable to get completed by the end of its transit time if the capillary membrane gets thickened. It can be aggravated by exercise, as the blood may not have adequate time to get saturated as it moves more quickly through the lungs.

MECHANISMS OF HYPOXEMIA

The primary processes contributing to hypoxemia (abnormally low arterial blood oxygen) are shown in **Figures 14A to E**.

Oxygen Transport

Oxygen is primarily carried in the blood bound to hemoglobin and a small amount is dissolved in the plasma. The total amount carried by the blood is known as *oxygen content* and the maximum amount of oxygen that can be combined with hemoglobin is called *oxygen capacity*. One gram of hemoglobin can combine with 1.34 mL of oxygen.

The *oxygen saturation* is the percentage of binding sites of hemoglobin that have oxygen attached. The normal oxygen saturation is 98% for arterial blood and 75% for venous blood.

Figures 14A to E Causes of hypoxemia. (A) Hypoventilation: ventilation is decreased and there is an increase in PCO_2 resulting in decrease of alveolar PO_2 ; (B) Diffusion impairment: diffusion across the alveolar-capillary membrane to the hemoglobin in the red blood cell is decreased; (C) Shunt: pulmonary venous blood bypasses the lung without being oxygenated example: right-to-left shunt in congenital cardiac disease or arteriovenous malformation; (D) Ventilation/perfusion mismatch: some areas of the lung are nonfunctional and poorly oxygenate the venous blood. There is mixing of blood from functioning alveolar units; (E) Low venous PO_2 : the PO_2 in the venous blood may be abnormally low because of anemia, fever or decreased cardiac output. In the presence of lung disease, shunt or exercise, it may not be fully oxygenated as it completes its course through the lung

In general, oxygen saturation increases as the PO_2 of the blood increases. The dissociation curve for oxygen is "S" shaped (**Fig. 15**). Between an oxygen tension of 20 mm Hg and 75 mm Hg, there is a sharp, linear rise in oxygen saturation.

Factors altering affinity of hemoglobin from oxygen As shown in **Figure 16**, many factors shift the oxygen dissociation curve to the right and cause oxygen to bind less avidly to hemoglobin (increased temperature, acidosis, hypercarbia and increased 2, 3 diphosphoglycerate). Conversely, decreased temperature, alkalosis and low CO_2 levels shift the curve to the left resulting in O_2 binding more avidly to the hemoglobin which leads to lesser delivery to tissues.

Assessment of Oxygenation and Ventilation

It is extremely difficult to assess the adequacy of oxygenation and ventilation by physical examination. The most specific sign of impaired oxygenation, i.e. cyanosis, can be detected usually at an oxyhemoglobin saturation of 80%. Arterial oxygen saturation can

Figure 15 Oxygen dissociation curve (for pH 7.4, PCO_2 40 mm Hg, 37°C and hemoglobin concentration 15 g/100 mL)

Figure 16 Factors that change the oxygen dissociation curve

Table 4 Measures of oxygenation impairment

Oxygen	Normal values (mm Hg)
$PAO_2 - PaO_2$	< 10
PaO_2 / PAO_2	1
PaO_2 / FiO_2	500

be assessed noninvasively using pulse oximetry. Arterial PCO_2 can be assessed noninvasively by end-tidal CO_2 monitoring. Arterial blood gas analysis is the gold standard for assessing PO_2 and PCO_2 . The degree of impairment of oxygenation can be assessed by calculating the A-a gradient (**Table 4**).

Figure 17 Muscles of breathing

MECHANICS OF BREATHING

The muscles of respiration act like a pump to move air in and out of the lungs. The efficiency of the pump is determined by the elastic properties of the chest wall and lungs and the resistance of the airways. Disease processes can alter these relationships and lead to respiratory failure.

Muscles of breathing The inspiratory muscles are the diaphragm, external intercostals and accessory muscles such as the sternocleidomastoid and scalene. Expiration with quiet breathing is passive. Active expiration requires the use of the abdominal and internal intercostal muscles (**Fig. 17**).

Elastic properties of the lung and chest wall The ease with which the lungs can be stretched is compliance; it gets reduced in fibrosis, pulmonary edema or acute respiratory distress syndrome while it increases in emphysema with aging. The resting lung volume (functional residual capacity) represents the balance between the tendency of the lungs to collapse and the chest wall to recoil (**Figs 18A to C**).

Airway resistance It is the force that opposes the forward motion of the airflow. About 25–40% of the total airway resistance is located in the upper airway. In laminar airflow, resistance is directly proportional to the radius of the airways. Therefore, if the radius of an airway is narrowed by half, the resistance increases by 16-fold. In the airways of infants and children which are already narrow relative to an adult, small change in the airway caliber produce large changes in resistance.

Work of breathing It is proportional to the tidal volume and the change in pressure that is required to move the air. It increases when the compliance of chest wall or lung is decreased or airway resistance is increased. Infants and young children are at higher risk of respiratory failure because their chest walls are more compliant and their diaphragms are flatter and more prone to fatigue.

Assessment of lung mechanics Measurements of airflow, lung volumes and airway resistance can be done by pulmonary function testing.

Figures 18A to C Interactions of the chest wall and lung in diseased states. (A) In the normal lung, the outward recoil of the chest wall balances the inward recoil of the lung. The final volume of the lung depends on the equilibrium between the two; (B) If the chest wall becomes less compliant and stiffer; there is less outward force to balance out the inward recoil of the lungs. The result is a smaller lung volume. Examples: obesity, neuromuscular weakness, trauma to or defects in the chest wall; (C) If the lungs become less compliant, they overcome the outward force of the chest wall and have a smaller resting volume. Examples: pulmonary edema, interstitial fibrosis, acute respiratory distress syndrome

IN A NUTSHELL

1. Human respiration is materialized by both external (breathing and ventilation) and internal/cellular respiration.
2. The right lung has three lobes and two fissures and the left has two lobes and one fissure. Each lung has 10 bronchopulmonary segments.
3. Bronchial arteries nourish the lungs while pleural and pulmonary lymphatics drain the lungs. Muscles of respiration are the intercostal muscles and diaphragm.
4. Gas exchange occurs on a large surface area when gas moves in and out of the alveolus and blood flows through the pulmonary capillary vessels. The blood pH depends on the relationship between carbon dioxide and bicarbonate.
5. For acute respiratory acidosis, an increase in PCO_2 of 10 mm Hg will decrease the pH by 0.08 and the bicarbonate by 1 mEq/L. In chronic respiratory acidosis, after renal compensation, the bicarbonate will increase by a total of 4 mEq/L for each 10 mm rise in PCO_2 . In acute and chronic respiratory alkalosis, similar changes occur in the opposite direction.
6. The amount of oxygen in the alveolus is determined by the presence of other gases, fresh air supply and barometric pressure changes. The primary processes contributing to hypoxemia (abnormally low arterial blood oxygen) are hypoventilation, diffusion impairment, shunt, ventilation/perfusion mismatch and low venous PO_2 .
7. Oxygen is primarily carried in the blood bound to hemoglobin and a small amount is dissolved in the plasma.

Chapter 39.2

Approach to Diagnosis of a Respiratory Disorder

Soumya Tiwari, Varinder Singh

Respiratory disorders are the most common causes of morbidity and mortality among children of all ages. The presentation may vary from trivial to life-threatening symptoms. While a carefully conducted history and physical examination are vital for a correct diagnosis, various laboratory and radiological investigations aid in finally clinching the diagnosis. Disorders involving other organ systems may also present with symptoms related to respiratory system.

HISTORY

The evaluation of a child with respiratory disorder should start with the history of present illness, past history, family history as well as antenatal and birth history. The parents should be inquired regarding the chief complaint for presentation at hospital, along with the frequency, total duration, severity and onset of symptom. History of prior treatment and response to it should be recorded. History of past illness will include all previous respiratory and other complaints. These include history suggestive of recurrent lower respiratory tract infections (seen in structural disorders of lower and upper airway, cystic fibrosis, immotile cilia syndrome, primary immunodeficiency disorders, HIV), known allergy and malnutrition. The family/environmental history will provide information about history of contact or that suggestive of asthma in relatives, nutritional and financial status of the family, and history of exposure to allergens. The detailed history-taking of the cardinal respiratory complaints is discussed here:

Cough

A complete evaluation of cough requires detailed history on following points: *Nature of cough*—whether dry or wet and if wet—the *color of the sputum*/whether blood tinged or not; *Diurnal variation*: At what time of the day or night does it occur; *Aggravating or relieving factors*; any *association with feeding* (increase in cough and choking episodes while feeding may indicate gastroesophageal reflux disease or H-type tracheoesophageal fistula or swallowing dysfunction) or exercise (asthma). The *character of the cough* also helps, e.g., cough due to postnasal drip in a child having sinusitis can be dry, throat-clearing type while a loud honking cough occurring only during the day time when the child is conscious of the surroundings in the presence of normal respiratory examination suggests psychogenic cough.

Chest Pain

A *catching* pain on deep inspiration may indicate underlying pleural effusion. Chest pain aggravated by coughing/sneezing may suggest underlying pleural disease or rib fracture. Chest pain too localized or very vaguely placed may not be due to any serious illness particularly if there are no other accompanying symptoms.

Difficulty in Breathing

Difficulty in breathing is usually preceded by a prodrome of fever, cough or coryza, in which case it could be due to underlying lower respiratory tract infection like bronchiolitis, pneumonia or wheeze associated lower respiratory tract infection (WALRI). It is important to ask whether the onset was sudden or gradual and how rapid was the progression. Sudden onset difficulty in breathing

following an episode of choking indicates foreign body aspiration. If breathlessness is sudden and is associated with sharp pain in the chest with very rapid progression it might suggest a pneumothorax or pleural effusion. Gradual onset of dyspnea with previous history of increasing pallor or bleeding diathesis indicates congestive cardiac failure. In a child with previous history of repeated episodes of hospitalization since early infancy in view of pneumonia, and history of suck-rest-suck cycle during feeding, there could be underlying congenital acyanotic heart disease with increased pulmonary blood flow. Hyperventilation in isolation (without other signs and symptoms of respiratory disorder) might be psychogenic especially in adolescent children or it may be provoked by fever. However, if it is associated with history of poor growth or delayed mental development/convulsions, it might suggest metabolic acidosis with respiratory compensation due to an underlying renal problem or inborn error of metabolism. In a patient with history of fever, convulsions and alteration in sensorium, hyperventilation is indicative of raised intracranial tension.

Other Complaints

Following are other important clinical pointers specific to some common conditions, as obtainable in the history:

- Gastroesophageal reflux disease, swallowing disorders, children with history of surgery in upper aerodigestive tract are at increased risk of recurrent pneumonia.
- *Atopy*: History of infantile eczema, hay fever, allergic dermatitis in child or parental history of asthma or skin allergies may be an important feature in children with allergic rhinitis or bronchial asthma.
- Growth failure, recurrent skin and other infections, history of blood transfusion in child or injection drug abuse in parents may provide a valuable clinical clue toward primary immunodeficiency disorders or HIV infection.
- *Environmental injury*: Exposure to dust due to construction in the house/neighborhood, presence of pet animals or birds, exposure to environmental pollutants and smoke from passive smoking, automobiles and household sources.
- History of close contact with a case of tuberculosis.
- *Associated symptoms*: Presence of associated symptoms may help in localization of respiratory disorder. Pedal edema, feeding problems, dyspnea, and exercise intolerance indicates congestive heart failure and may be due to underlying pulmonary artery hypertension because of chronic lung disease or chronic upper airway obstruction or due to a primary cardiac disease. Infections of paranasal sinuses may be associated with headache and frontal tenderness. Snoring is commonly seen in children with chronic adenotonsillar enlargement. Presence of malabsorption should prompt investigation for cystic fibrosis. History of recurrent blepharoconjunctivitis suggests predisposition to allergic airway disease. Development delay or other chronic neurological diseases are associated with aspiration and hence recurrent respiratory infections.

PHYSICAL EXAMINATION

A thorough general physical examination is extremely important in the approach to a child with respiratory disorder. The respiratory rate should be counted for one full minute making sure that the child is not crying. The respiratory rate is an important indicator of respiratory illness and should be examined at rest or in sleeping state. However, high grade fever, psychiatric illness and metabolic acidosis due to other cause may be associated with tachypnea even in absence of respiratory illness.

Nasal flaring and use of accessory muscles of respiration (sternocleidomastoid) are indicators of respiratory distress. Both are adaptive mechanisms with nasal flaring reducing the nasal

resistance to flow of air and use of accessory muscles helps to increase the respiratory effort. Respiratory distress may also be seen in children with neuromuscular disorders. The respiratory pattern and depth may also point toward a particular pathology. Shallow and rapid respiration is seen in children with restrictive lung disease. Deep and rapid respiratory efforts may be indicative of metabolic acidosis and hypoxia rather than true respiratory disease. On contrary, the shallow and slow breaths may be seen in metabolic alkalosis as a result of compensatory retention of CO_2 . Hyperpnea alternating with apnea (Biot respiration) is associated with brain stem lesion involving centers for respiratory control. Cheyne-Stokes respiratory pattern is characterized by gradually increasing and decreasing respirations and is seen in comatose patients.

Recording the anthropometry is as important as is looking for presence of cyanosis, pallor and clubbing. Supraclavicular and cervical lymph nodes should form part of the examination routinely.

Upper Airway

An examination of the upper airway will indicate presence of nasal foreign body or infection, tonsillar enlargement, or presence of stridor. The tracheal position should be confirmed during clinical examination of neck. The deviation of trachea may be seen due to a mass in neck or disorders related to lung. The trachea may shift away from abnormal lung (pneumothorax, pleural effusion, congenital lobar emphysema, inhaled foreign body) or toward the abnormal lung (lung collapse, ipsilateral lung agenesis or hypoplasia).

Chest

Inspection The shape of chest and presence of any chest wall deformity should be carefully inspected. A barrel chest (increased anteroposterior dimension) denotes obstructive lung disease. *Pectus excavatum* also termed as *funnel chest* and *pectus carinatum* also termed as pigeon's chest can be seen as a result of persistently increased work of breathing as seen in chronic asthma, cystic fibrosis or lung fibrosis.

Use of accessory muscles of respiration may indicate severity of respiratory distress and intercostal recession may point toward airway obstruction and a noncompliant lung. The symmetry of chest movement and presence of retractions should be noted.

The relative duration of inspiratory and expiratory phase may also vary with respiratory illness. The expiratory and inspiratory phases of respiration are roughly of equal duration in children. A prolonged expiratory phase may be seen in diseases associated with significant bronchospasm (e.g., bronchial asthma, acute bronchiolitis). Younger children normally may have some abdominal breathing; however, conspicuous abdominal breathing may be a feature of diaphragmatic and other respiratory muscle weakness.

Palpation The chest should be palpated with the palm and fingertips of the palpating hand. The abnormal palpatory findings include friction rubs, which are usually felt in sync with the respiratory pattern. Vibrations in association with voice (tactile fremitus) may also be palpated in the intercostal spaces and is decreased in the presence of major airway obstruction (atelectasis), pleural fluid, or pleural thickening. Chest expansion should be measured by both hands anteroposteriorly holding the child's chest wall and comparing any asymmetry of movement of either hand. Any shift of point of maximum cardiac impulse should be noted; it may shift contralaterally with effusion/pneumothorax and ipsilaterally with volume loss/atelectasis.

Percussion Percussion should be performed with the child sitting straight with the head neutral, and using the indirect method (one finger strikes on the middle finger of the other hand placed on an interspace). A gentle force should be used so as to avoid causing

injury, especially in a young child). Percussion of the chest may elicit the following sounds:

- **Tympany:** Normally heard with percussion of the abdomen, is heard in the chest with a pneumothorax.
- **Resonance:** Resonance is the normal sound heard on percussion of a normal chest.
- **Hyper-resonance:** Accentuation of the normal percussion occurs with states of hyperinflation like emphysema or asthma.
- **Impaired or flat:** A flat sound on percussion comes out on percussing over normal muscles in a chest with consolidation or pleural effusion.
- **Dullness:** A dull, flat sound is produced on percussion if the underlying lung has massive pleural effusion or mass lesion.
- **Coin test:** In a chest having pneumothorax, a resonant metallic sound is heard with a stethoscope when a coin taps on another coin placed on an interspace.

Auscultation Auscultation of the chest should be performed with the age appropriate stethoscope (one should be familiar with various chest pieces available for different age groups). The diaphragm of the chest piece is used for preferentially hearing high pitched sounds and the bell for low pitched sounds on auscultation. Using an adult stethoscope in a small child may lead to false assessment of adventitious sounds due to poor fit and extraneous sounds.

A pattern should be followed so as not to miss auscultating any part of the lung. It is always preferable to auscultate corresponding areas of the chest on either side in order to compare their symmetry. Remember to auscultate all over, particularly the infraclavicular regions for the upper lobes, the infrascapular regions for lower lobes, and the lower parasternal areas for the right middle or the lingular lobes respectively. To be adequately informative, the auscultatory findings should be recorded in terms of timing (early/late/continuous) and character (fine/coarse) of sounds. Both the breath sounds and adventitious should be noted separately.

Breath Sounds

Vesicular breath sounds These are normal breath sounds heard during respiration in a healthy individual/healthy part of the lung. They are low pitched and longer as well as louder on inspiration. They arise from lobar and segmental airways.

Bronchial breath sounds These are high pitched, louder and may be heard as long in expiratory phase as the inspiratory phase unlike vesicular sounds. They can be heard normally when auscultating directly over trachea, but over rest of the lung field they suggest underlying abnormally like consolidation, cavity and/or collapse.

Bronchophony Transmission of syllables spoken by the child and auscultated on the chest wall as a result of better conductance over a large consolidation. If severe enough, an underlying consolidation may result in transmission of whispered voice, called whispering pectoriloquy.

Adventitious Sounds

Fine crackles Sounds made when previously closed alveoli suddenly reopen during inspiration. Seen with bronchitis, resolving asthma, pneumonia and atelectasis.

Coarse crackles Mainly inspiratory sounds made by movement of fluid in bronchi or bronchioles, typically present in pneumonia.

Wheeze Mostly expiratory continuous musical sounds which are monophonic/polyphonic in character and suggest obstruction to the airflow. They can be biphasic in presence of severe obstruction.

Stridor Monophonic musical sound, high-pitched sound, heard in inspiration.

Pleural rub Patients with pleuritis may have a leathery rubbing sound during inspiration.

Other Signs

Clubbing Clubbing is an important sign in the evaluation of respiratory system and is the result of chronic hypoxia leading to hypertrophy and hypervascularity of distal phalangeal connective tissues. A host of chronic respiratory conditions may lead to clubbing including bronchiectasis, lung abscess, empyema, interstitial lung diseases and pulmonary arteriovenous malformations.

Cyanosis Cyanosis may indicate severe underlying respiratory disorder and is an essential component of respiratory system evaluation. It may not be apparent in the presence of severe anemia. Arterial blood gas analysis may be used to confirm clinically apparent cyanosis.

Pulsus paradoxus This refers to a fluctuation in systolic blood pressure of the child with different phases of respiration, and is measured by finding the difference between systolic blood pressure during inspiration and expiration. It is valuable in evaluation of children with severe asthma.

INVESTIGATION

Imaging

Conventional radiology (X-ray) The knack for reading a chest X-ray is important in developing a clinical acumen as far as respiratory system is concerned. It is the most commonly used investigation for initial evaluation and follow-up of these children. A self-developed and all inclusive systematic approach is required to read a chest X-ray so as to avoid missing out on subtle but important signs. Usually a posteroanterior view and sometimes an anteroposterior or lateral views are ordered. The reader should refer to other detailed texts for X-ray reading skills.

Ultrasonography (USG) Absence of ionizing radiation makes ultrasound an attractive investigative tool for pediatric patients but its current use is limited. The USG image is formed when the sound waves emitted by a transducer are reflected back from the tissues and recorded by another transducer. As air is a poor sound conductor, well-aerated tissue such as lung lacks predictable images on ultrasound. However, non-aerated tissues like pleural fluid, diaphragm and other soft tissues are well examined on USG. Ultrasonography is also useful in evaluation of diaphragmatic lesions, e.g., diaphragmatic hernia. Ultrasound imaging with color flow Doppler is used to diagnose the changes in vascularity of the thoracic and mediastinal lesions.

Chest computed tomography In computed tomography, the image is formed when an anode transmitting X-rays rotates around the body and a battery of detectors record those X-rays. A number of images thus formed are combined to form a cross-sectional image of the patient at that position. CT is most useful to study the anatomy of the upper and lower respiratory tracts as well as lung parenchymal and mediastinal anomalies. A high resolution CT (HRCT) is particularly useful to diagnose diffuse disorders such as interstitial lung disease or bronchiectasis. This, however, has high radiation cost and therefore should be used only where necessary and useful.

Fluoroscopy Fluoroscopy uses the X-rays which upon reflection from a patient are converted into an image by an image intensifier and can be viewed live. It is particularly useful in diagnosing extrinsic tracheal compression by a foreign body or lymph node.

Nuclear medicine or radioisotope studies Nuclear medicine imaging, utilizes the principle that the organ of interest takes up the radiation emitted by a patient when a radiation emitting

substance is administered to him and an image of the organ is formed by a scintillation camera. Positron emission tomography (PET) detects foci of infections and tumors when a radioisotope, fluorodeoxyglucose (FDG), having the same utilization rate as glucose, gets accumulated at these sites.

Magnetic resonance imaging (MRI) MRI is one of the less commonly preferred imaging modality for diagnosis of pulmonary pathologies. Radiofrequency waves reflected from a patient lying in a strong magnetic field are collected and processed to form images using tissues as a contrast.

Angiography and interventional radiology Pulmonary vascular malformations can be diagnosed as well as treated by angiography which uses fluoroscopy. Interventional radiology is used to perform percutaneous drainage of complicated empyema, lung or mediastinal abscesses or percutaneous lung biopsy under fluoroscopic guidance.

Pulmonary Diagnostic Procedures

Thoracentesis This is a diagnostic procedure involving percutaneous insertion of a needle into the pleural space to obtain pleural fluid for cytology and biochemical examination. It may be preceded by a chest X-ray or ultrasound of the chest to visualize the location and volume of collection, particularly if there is a suspicion of very little fluid or a loculated empyema.

Pulmonary function testing Pulmonary function testing helps to differentiate between obstructive or restrictive nature of respiratory disorder and to monitor adequacy of treatment.

Most commonly used method for airway obstruction monitoring is measurement of peak expiratory flow rate (PEFR). The diurnal variation and comparison of child's PEFR with expected PEFR can be used to classify and monitor asthma control at home. The expected PEFR can be deduced from age, sex, height and race specific PEFR standards or by using child's own personal best measured in asymptomatic period. PEFR is reduced and diurnal variation is increased in obstructive lung diseases like asthma. Other spirometry measurements require the child to maximally inhale up to total lung capacity and then exhale as far and as fast as possible. Good spirometry examination requires patient cooperation and it may be difficult to perform in very young children. The forced expiratory volume in 1st sec (FEV₁) is important marker and its decrease correlates with severity of obstructive diseases. The ratio of FEV₁/FVC should be > 90% in normal children. Any reduction in this ratio indicates obstructive lung disease. The average flow rate between 25% and 75% of forced vital capacity is a more reliable indicator of smaller airway obstruction. Restrictive lung disease shows normal FEV₁ with reduced FVC. The diffusing capacity of the lung for carbon monoxide (DLCO) can be used to measure gas diffusability across the alveolar-capillary membrane.

Bronchoscopy Bronchoscopy allows for direct visualization of both upper and lower airways. Bronchoscopy has both diagnostic and therapeutic importance in pulmonary medicine. Diagnostic bronchoscopy allows for collection of specimens by bronchoalveolar lavage, bronchial brushings and tissue biopsies. Indications for diagnostic bronchoscopy include—upper airway obstruction, recurrent pneumonia, persistent pneumonia, foreign body inhalation, hemoptysis, congenital anomalies, and for sample collection in suspected tuberculosis. Hemodynamic instability, bleeding disorders, hypoxemic states, severe obstructive disease, and massive hemoptysis are relative contraindications for bronchoscopy.

The bronchoscope can be flexible or rigid. A rigid bronchoscope is passed through the mouth therefore it yields a better view of the posterior aspect of larynx and trachea, whereas

the flexible bronchoscope gives a better view of the anterior part of the larynx and upper trachea because it is introduced through the nose. Flexible bronchoscopy is especially useful in examination of the lower airways in an intubated patient without the need for extubation and a patient in whom there is an unstable cervical fracture, cervical ankylosis, or mandibular hypoplasia. However, rigid bronchoscope can be more advantageous in certain conditions such as extraction of the foreign body and the evaluation of patients with suspected H-type tracheoesophageal fistula, laryngoesophageal cleft, and bilateral abductor paralysis of the vocal cords.

Sputum Examination

Sputum examination is an important component of pulmonary diagnostics. However, the collection of sputum samples poses difficulties especially in younger children. Sputum induction using nebulization with hypertonic saline can be done if the child is unable to produce sputum. Sputum is then examined microscopically for the presence of neutrophils, eosinophils, macrophages (using Giemsa and Wright stain) and bacteria (using Gram and ZN stain) as well as by microbiologic method (using bacterial and mycobacterial culture methods).

IN A NUTSHELL

1. The approach to a child with a respiratory disorder starts not with auscultation but a detailed history. A thorough examination including inspection, palpation and percussion is an essential component of evaluation, as is general examination and evaluation of upper airway.
2. While examining a child with respiratory disorder stabilization of airway and breathing should be the foremost priority.
3. A familiarity with diagnostic procedures is critical to a complete evaluation of the respiratory system, especially when a thorough history and examination fails to provide all necessary information to arrive at a diagnosis and plan appropriate management.
4. Complex pleural effusions are best evaluated with ultrasonography.

Chapter 39.3

Congenital Malformations of the Upper Respiratory Tract

D Vijayasekaran

Respiratory tract can be broadly considered under two anatomic parts namely the extrathoracic airway and intrathoracic airway. Extrathoracic airway can be considered as upper respiratory tract. It extends from the nose to the mid-trachea (thoracic inlet) which includes nose, nasopharynx, larynx and upper trachea. Obstruction of extrathoracic airway results in inspiratory stridor with prolongation of inspiration. From the management point of view, intrathoracic airway can be divided into intrathoracic-extrapulmonary airway (extends from mid-trachea to the main stem bronchi) and intrathoracic-intrapulmonary airway (extends from secondary bronchi including lung parenchyma). The partial obstruction of intrathoracic airway is characterized by wheeze and prolonged expiration.

DIAGNOSTIC EVALUATION

Congenital malformations of nose, nasopharynx, larynx and upper trachea pose a medical emergency as they invariably compromise the respiratory function. Nasal malformations include arhinia (congenital absence of the nose), nasal hypoplasia, congenital defects of the nasal septum, choanal atresia, and congenital midline nasal masses (dermoids, gliomas and encephaloceles). Laryngopharyngeal malformations include hypoplasia of midface, laryngomalacia, congenital vocal cord paralysis, and laryngocele, etc.

The diagnostic evaluation of a child with suspected congenital malformations of the upper respiratory tract should begin with detailed clinical history including perinatal history. Symptoms that arise immediately after birth or within first few months are invariably due to congenital cause. The clinical features of upper respiratory tract compromise include increased inspiratory effort, stridor, and change in voice. Nasopharyngeal malformations are often associated with dysmorphism. Pharyngeal airway pathology (hypopharyngeal hypotonia) worsens during sleep whereas obstruction of the laryngeal lesions worsens when awake, particularly after exertion.

In addition to thorough clinical history and physical examination, imaging studies, CT scan, laryngoscopy, fiberoptic bronchoscopy and barium swallow play an important role in the diagnosis of congenital malformations of the upper respiratory tract. A three-dimensional image reconstructed from the CT is useful in stenotic lesions. Fiberoptic bronchoscopy is considered as gold standard tool in the diagnosis of anomalies with dynamic movements like laryngomalacia or tracheomalacia. Fiberoptic bronchoscopy under local anesthesia with video monitoring has the ability to directly see upper airway anatomy and function and make an accurate diagnosis and also demonstrate the dynamic movements.

The common upper respiratory tract congenital lesions like choanal atresia, laryngomalacia, vocal cord paralysis, laryngeal web and congenital subglottic stenosis are discussed here.

CHOANAL ATRESIA

Choanal atresia is the most common congenital anomaly of the nose that may be *unilateral* or *bilateral*. Unilateral choanal atresia may be missed for a long time. Newborns are obligate nasal

breathers and nasal obstruction can lead to airway compromise. Baby with a unilateral choanal atresia may cry vigorously and develop respiratory distress particularly after viral infection, because of respiratory compromise. Mouth breathing during cry may relieve the distress and the above cycle may continue. High index of suspicion helps in early diagnosis. Difficulty in passing a catheter through the nostril into the nasopharynx may give a clue to the diagnosis.

Bilateral choanal atresia will be diagnosed early as the baby develops respiratory distress and cyanosis soon after the birth. Typically, such babies have intermittent cyanosis which improves on crying. They may also have pursing of the lips as they work hard to breathe through a closed mouth. In majority of cases (90%) the obstruction in bilateral variety is bony and also associated with anomalies. About 10–20% of patients with choanal atresia have the CHARGE association (coloboma, heart disease, atresia choanae, retarded growth and development or CNS anomalies or both, genital anomalies or hypogonadism or both, and ear anomalies or deafness or both). Mutations in the *CHD7* gene have been linked with CHARGE syndrome.

It can easily be suspected at birth if one notices an inability to pass a nasogastric tube (6 French size for a term neonate) through both sides of the nose. Both fiberoptic rhinoscopy and CT scan help in confirming the diagnosis. Transnasal repair is the treatment of choice in unilateral obstruction. Bilateral atresia may present as life-threatening problems warranting an emergency tracheotomy at times. Mitomycin C has been used to help prevent the development of restenosis.

LARYNGOMALACIA

Laryngomalacia (congenital laryngeal stridor) is the most common congenital laryngeal anomaly, which causes stridor in infants. Immaturity of cartilage results in collapse of supraglottic structures (arytenoids, epiglottis, and aryepiglottic folds) inwards during inspiration and results in low-pitched inspiratory stridor which worsens with agitation, crying and feeding. The noisy breathing in infants with laryngomalacia improves with sleep or prone position.

The symptoms usually become apparent by 2 weeks of age, worsen during first few months and then generally resolve by 12–18 months of age. If stridor presents in the first week of life anomalies other than laryngomalacia should be suspected and investigated for. This is important because these mimickers may need definitive interventions unlike laryngomalacia. The diagnosis is confirmed by outpatient flexible laryngoscopy or bronchoscopy. Epiglottis is omega shaped (**Figs 1A and B**) due to shortened aryepiglottic folds or it may bend over the glottis. Children with mild laryngomalacia (majority) will only have stridor without any other serious symptoms. In severe cases, the entire supraglottic structures may sink into the glottic opening with apparent life-threatening events. Supraglottoplasty is the surgical option for severe laryngomalacia.

Since the noisy breathing can be very loud and alarming, it can make the parents of affected child over anxious requiring repeated reassurance to them, explaining the harmless nature of the problem. Since significant proportion of infants with moderate to severe laryngomalacia are associated with synchronous airway anomalies, it is recommended that complete evaluation of lower airway with bronchoscopy be advised especially when they present with frequent attacks of wheeze and respiratory distress.

CONGENITAL LARYNGEAL WEB

Laryngeal webs are rare congenital anomalies of the larynx. Incomplete recanalization of the laryngotracheal tube during the

third month of gestation leads to different degrees of laryngeal webs. Laryngeal webs are located commonly in the glottic area and are anteriorly placed, leaving a concave posterior glottic opening (**Figs 2A and B**). Laryngeal webs may occur in the posterior interarytenoid, in the subglottic or supraglottic area. The extreme of this situation is complete laryngeal atresia.

Symptoms of laryngeal webs vary from mild dysphonia to significant airway obstruction, depending on the size of the web. Stridor is rare except in patients who have a posterior interarytenoids web. One-third of children with laryngeal webs have associated anomalies of the respiratory tract (commonly subglottic stenosis). When respiratory distress is disproportionate to that caused by the web itself, other anomalies should be suspected.

Laryngoscope or fiberoptic bronchoscopy may reveal the presence of a laryngeal web, which may appear as a thin, translucent defect (**Figs 2A and B**) involving the anterior vocal cords which can be released by simple surgery. Laryngeal webs presenting as a thick fibrous structure that extends inferiorly into the subglottic area (associated with subglottic stenosis) are likely to require cartilage augmentation of the cricoid cartilage (laryngotracheal reconstruction).

CONGENITAL VOCAL CORD PARALYSIS

Congenital vocal cord paralysis is one of the laryngeal anomaly, may be bilateral or unilateral. Signs and symptoms of vocal cord paralysis depend on whether the paralysis is unilateral or bilateral.

Congenital bilateral vocal cord paralysis (more common) produces high-pitched inspiratory stridor, and choking with severe respiratory distress. Birth trauma that causes excessive strain to the cervical spine may cause transient bilateral vocal cord paralysis. Bilateral vocal cord paralysis is usually associated with congenital lesions of the central nervous system like hydrocephalus, myelomeningocele, and Arnold-Chiari malformation.

Unilateral vocal cord paralysis may manifest during the first few weeks of life, or it may go unnoticed. Unilateral vocal cord paralysis may occur due to injury of the recurrent laryngeal nerve following surgical management of cardiac anomalies. Unilateral vocal cord paralysis manifests as inspiratory stridor, coughing with frequent aspiration. The diagnosis is made by flexible bronchoscopy or laryngoscopy when the child is awake. Cardiac and neurological evaluation should always be done to rule out the associated congenital anomalies.

Figures 1A and B Bronchoscopic view. (A) Normal larynx; (B) Laryngomalacia

Figures 2A and B Bronchoscopic view. (A) Laryngeal web; (B) Normal vocal cord

Figures 3A and B Bronchoscopic view. (A) Subglottic stenosis; (B) Normal subglottis

Congenital vocal cord paralysis in infants usually resolves spontaneously within 6–12 months. In bilateral vocal cord paralysis, if the obstruction is severe tracheotomy may be indicated.

CONGENITAL SUBGLOTTIC STENOSIS

Congenital subglottic stenosis is the third most common laryngeal anomaly. The subglottis extends from the lower surface of the true vocal cords to the lower surface of the cricoid cartilage. A diameter of (subglottis) 4.0 mm is considered the lower limit of normal in a full term infant and 3.5 mm in a premature infant. Being a fixed obstruction, the stridor produced by congenital subglottic stenosis will be biphasic or primarily inspiratory.

Subglottic stenosis is considered congenital if there is no past history of endotracheal intubation or other forms of laryngeal trauma and approximately 90% of cases manifest in infancy. If the stenosis is severe and congenital, the baby will present with respiratory distress at birth. Viral respiratory tract infections may manifest the congenital subglottic stenosis. One millimeter of edema circumferentially in the subglottis reduces the cross-sectional area by 60%. The edema associated with viral infection is a medical emergency because it may compromise the already narrowed airway. A bronchoscopic view of subglottic stenosis is provided in **Figures 3A and B**.

At times differentiating congenital from acquired subglottic stenosis is difficult if the neonate is subjected for emergency intubation. Majority of subglottic stenosis are acquired and the most common cause is due to endotracheal intubation and the associated inflammatory-type response. The important risk factors are size of the endotracheal tube, the duration of intubation, traumatic intubation, and number of re-intubations.

Since congenital subglottic stenosis is associated with other congenital malformations a thorough search should be done. Cricoid split (anterior laryngotracheal decompression) or laryngotracheal reconstruction with cartilage grafting is usually effective in avoiding tracheostomy. Cricoid split (anterior or multiple cricoid splitting) with cartilage graft interpositioning is usually effective and avoids tracheostomy.

IN A NUTSHELL

1. The important congenital lesions of upper respiratory tract include laryngomalacia, vocal cord paralysis, and laryngeal web subglottic stenosis and choanal atresia.
2. Inspiratory stridor, dysphonia suggests upper respiratory tract pathology.
3. Laryngomalacia is harmless condition presenting with audible stridor in infants.
4. Unilateral choanal atresia may be missed for a long time but the bilateral one presents as a neonatal emergency.
5. Laryngeal web is a rare anomaly with symptoms varies from mild dysphonia to significant airway obstruction.
6. Congenital bilateral vocal cord paralysis is usually associated with congenital lesions of the heart and central nervous system. Subglottic stenosis presents with biphasic stridor.
7. Radiograph of neck, CT scan neck and thorax, fiberoptic endoscopy and barium esophagram are the useful investigations to confirm the diagnosis.

Chapter 39.4

Epistaxis

Jagdish Chinnappa

Epistaxis (bleeding from the nostril), referred to as *Nasagata Raktapitta* in *Charaka Samhita* and other ancient texts, originates from the Greek *epi* meaning upon and *Stazin* meaning to drip. Most children will experience at least one episode of epistaxis, usually after the age of 2 years. Epistaxis is unusual in children younger than 2 years. Most bleeds are without any obvious etiology (primary) while others are secondary to a systemic disease (e.g., hematological) or a local pathology (e.g., nose picking). Children with recurrent attacks of bleeding need to be diagnosed accurately and managed appropriately. Many children who have recurrent idiopathic epistaxis tend to get better in adolescence.

CLASSIFICATION

Anterior bleeds are easily visible and originate from the Little area. This area is copiously supplied by blood vessels (Kiesselbach plexus) and is one of the most common sites of bleeds. Bleeding can also start from the inferior turbinate.

Posterior bleeds originate from the posterior part of the nose from the distribution of the sphenopalatine artery. This site of bleeding is characteristic of angiofibroma, seen in adolescent boys. The Woodruff plexus located in the posterior part of the inferior meatus and can produce venous bleeding.

Recurrent epistaxis Children with bleeding tendencies or nasal pathology present with recurrent bleeding. Causes of recurrent bleeding are summarized in **Figure 1**.

CLINICAL EVALUATION

Initial Evaluation

Initial assessment should aim to rule out signs of serious disease or hemodynamic alteration. Protecting the airway is vital in posterior nasal bleeds. A careful history and examination is essential to distinguish between a primary and secondary bleed. Concomitant presence of skin and/or retinal bleed should raise the suspicion of a serious underlying disease with hematological abnormality due to defects of bleeding (thrombocytopenia) or coagulation. Epistaxis during febrile illness may be a pointer to dengue, malaria, meningococemia or septicemia. Often, the children may

bring up the swallowed blood in the vomitus and this should be differentiated from other sicker children who may be bleeding from several sites due to a generalized disorder. A careful evaluation of the nose will provide invaluable clues to the etiology.

Nasal Examination

Asymmetry, swelling and discoloration of external nares may suggest a hematoma or ethmoidal disease. The anterior nares (Little area) should be looked for active bleeding and crusting. History of a unilateral discharge with blood stain, masquerading as epistaxis may indicate a nasal foreign body. Rarely a telangiectasia may be seen suggesting a systemic disease. Airflow through the nares should be evaluated by compressing alternate nares. Blockage of the nares may be associated with choanal stenosis, deviated nasal septum, a tumor (angiofibroma) and adenoidal hypertrophy.

Most bleeds are single, unilateral and mild and usually have a benign course. Recurrent mild bleeding from the anterior part of the nose is usually due to excessive drying, trauma from nose picking, and allergic rhinitis. History should be sought about exposure to drugs like aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), warfarin and other anticoagulants; improper use of nasal sprays used for the management of allergic rhinitis; or sniffing of illicit drugs as these can predispose to nasal bleed.

Systemic Evaluation

A general physical examination should evaluate for pallor, telangiectasia, purpura, lymph node enlargement, any other cutaneous, mucous or retinal bleed. Systemic examination should focus on hepatosplenomegaly. Disorders of platelets (deficiency or function defects) and coagulopathy (**Table 1**) can often present as nasal bleed; these should be investigated [e.g., platelet count and peripheral smear, prothrombin time and activated partial thromboplastin time (aPTT)], based on available clues from history and examination.

Epistaxis in infancy is most often due to a secondary cause. Congenital syphilis, diphtheria, trauma to nasal passage by tubes, vigorous aspiration of nasal passages and great vein of Galen malformation are some unique causes in this age group.

INVESTIGATIONS

Investigations are indicated in following situations:

- Episode of severe bleed that alters hemodynamic status and is difficult to control
- Recurrent epistaxis
- Posterior epistaxis

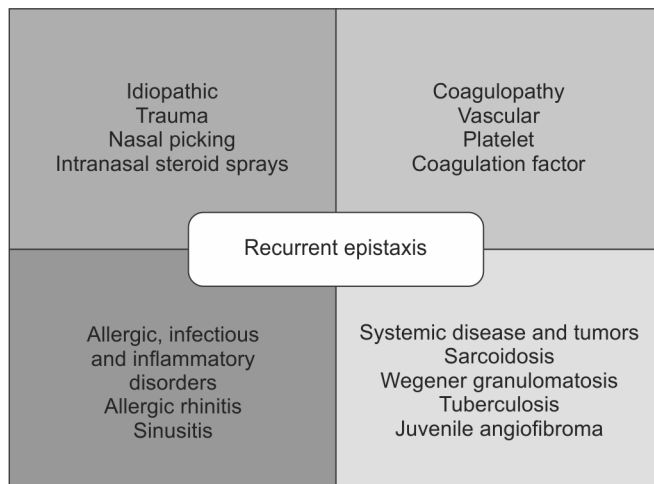

Figure 1 Etiology of recurrent epistaxis

Table 1 Disorders of bleeding and coagulation which may present as epistaxis

Ehler-Danlos syndrome
Hereditary hemorrhagic telangiectasia
Scurvy
von Willebrand disease
Glanzmann thrombasthenia
Bernard-Soulier syndrome
Platelet storage pool diseases
Gray platelet syndrome
Wiskott-Aldrich syndrome
Immune thrombocytopenia
Hemophilia A
Hemophilia B
Factor 5 deficiency
Liver cell failure/renal failure/DIC

- Epistaxis in infants
- Epistaxis part of systemic disease
- Epistaxis that appears for the first time in adolescence.

The most important investigation is visualization of the nasal passages. A flexible rhinoscopy (2.4–3 mm) with adequate suction may reveal the site of bleeding. Sometimes it may be prudent to control the bleeding and do a rhinoscopy in the quiescent stage. Anatomy of the Little area and the Woodruff plexus should be evaluated carefully. In addition, nasal polyp, papillomas, angiofibroma, ulcerated nasal septum as seen in Wegener granulomatosis, and submucosal nodularity seen with sarcoidosis can be identified easily. Radioimaging is valuable in posterior bleeding. It should be done in cases of trauma, suspected neoplasm or if the epistaxis is recurrent and significant.

Coagulation Work-up

Children with recurrent epistaxis without a clear secondary cause should be investigated for a coagulation disorder. Vessel wall anomalies like Ehler-Danlos syndrome, hereditary hemorrhagic telangiectasia and scurvy can be diagnosed clinically. Complete blood count and peripheral smear evaluation will help in the diagnosis of thrombocytopenia and platelet morphology. Platelet function tests should be done when there is a high index of suspicion. Coagulation factor deficiencies are uncommon, when the only manifestation is epistaxis. In select cases, where the bleeding is particularly severe or prolonged, a complete coagulation factor study is indicated. Two of the commonly identified disorders in children with recurrent *idiopathic* epistaxis are von Willebrand disease and hereditary hemorrhagic telangiectasia.

MANAGEMENT

Acute Bleeding

Pressure on the nares in cases of acute bleeding, making the patient bend forward and pinching the nares for about 10 minutes will stop the bleeding in most cases. *Local vasoconstriction* with use of oxymetazoline HCL (0.25, 0.5 or 1%) or phenylephrine drops may help. Excessive use of these should be avoided as it may lead to headaches, dizziness and rarely arrhythmias. Topical anesthesia and nasal packing with or without matrix sealant is useful in most cases with significant bleed, and milder cases not responding to above measures. *Fluid resuscitation* and blood (or its components) replacement may be needed depending upon the severity and cause of bleed. Rarely *endoscopic ligation* of the bleeding artery or *arteriography* with embolization may be needed in extreme cases.

Recurrent Anterior Bleeding

When the patient presents with recurrent epistaxis, identification of the site of bleeding is vital. Simple measures like humidification of the child's bedroom and saline nasal drops 3–4 times a day

will prevent drying and crusting. Application of petrolatum jelly (Vaseline) on the vascular area was advised often but has not been shown to be better than placebo. An antiseptic cream (mupirocin, neomycin) twice a day for 4 weeks will be helpful in many cases. Application should be done with a soft cotton applicator in a gentle manner as rough or forceful application may lead to further bleeding and rarely perforation.

Troublesome recurrent epistaxis may need cauterization of the involved mucosa. An ENT referral may be desirable for thermal or chemical (silver nitrate) cautery. This is an OPD procedure and most children tolerate the procedure well.

Patients with allergic rhinitis on intranasal steroids who develop epistaxis should be asked to discontinue the intranasal steroids till complete cessation of bleeding. They should be instructed on the proper use of the intranasal device.

Recurrent/Severe Posterior Nasal Bleeding

This is a rare situation in children; however an adolescent male with this presentation could have a juvenile angiofibroma. Urgent control of the bleeding by a posterior nasal pack and protection of the airway is vital. An MRI will identify the mass; ENT referral should be done immediately.

IN A NUTSHELL

1. Epistaxis is frequent in children aged 2–14 years.
2. Most cases are benign and local pressure is enough to stop bleeding.
3. Recurrent, severe or posterior bleeding should be investigated.
4. Less severe bleeding disorders like von Willebrand disease and diseases like hereditary hemorrhagic telangiectasia may present as nasal bleed as the predominant symptom.
5. Recurrent, idiopathic anterior bleeding can be managed by local antibiotic creams or cautery.
6. Posterior bleeding in an adolescent male should raise the suspicion of juvenile angiofibroma.

Chapter 39.5

Allergic Rhinitis

Ankit Parakh, Varinder Singh

Rhinitis is an inflammation of the lining of the nasal cavity. It may affect up to 40% of the general population. The most common form of rhinitis is allergic rhinitis, which is thought to affect up to 10–20% of the population. Recent evidence suggests that the prevalence of the disorder might be increasing. Allergic rhinitis may be associated with major impairments in quality of life, sleep and school performance in children.

Earlier allergic rhinitis was thought to be a disease localized to the nasal cavity. However, current understanding suggests that often the whole airway can get involved in the disease process due to physiological, functional and immunological relationships that exist between the upper and lower respiratory tracts. Allergic rhinitis and asthma appear to represent a *unified airway disease* in many children and this needs to be addressed to ensure optimal and management of rhinitis. Since the accompanying sinus epithelia are also usually involved, the term rhinosinusitis is preferred, but is used in context of more severe disease.

PATHOPHYSIOLOGY

A multitude of inflammatory cells, including mast cells, T-cells, B-cells, macrophages, and eosinophils, infiltrate the nasal mucosa when exposed to an inciting allergen. T helper (Th2) cells release cytokines [interleukin (IL)-3, IL-4, IL-5, and IL-13] which increase the production of immunoglobulin E (IgE) antibody by plasma cells that trigger the release of histamine, leukotrienes and other mediators. These factors lead to dilation of arterioles, heightened vascular permeability, itching, rhinorrhea and contraction of smooth muscle. The early phase of the immune response starts a cytokine cascade resulting in a late phase inflammatory response over the next 4–8 hours, which leads to persistence of symptoms.

CLASSIFICATION

Earlier, allergic rhinitis was classified as seasonal, perennial and occupational based on the exposure of the allergen. The implicated allergens in seasonal allergic rhinitis are a wide variety of outdoor allergens such as pollens or molds while indoor allergens such as house dust mites, molds, insects (cockroaches) and animal danders are implicated in perennial allergic rhinitis. However, in certain areas an individual may be allergic to a variety of outdoor pollens and molds and thus may lack seasonality—mimicking perennial allergic rhinitis. On the other hand symptoms of perennial allergy may be present intermittently such as many patients allergic to house dust mites suffer from mild intermittent allergic rhinitis (IAR). Some patients might have baseline symptoms with perennial allergic rhinitis and also experience seasonal superadded exacerbations when exposed to pollens or molds. Given this variety of responses, this classification has been found to be unrealistic.

Allergic Rhinitis and its Impact on Asthma (ARIA) group proposed a new classification (**Table 1**) for allergic rhinitis. It is now reclassified as IAR and persistent allergic rhinitis (PER) and the severity of the disease is classified as mild or moderate/severe. The terms “IAR” and “PER” are not synonymous with *seasonal* and *perennial* as they do not represent the same stratum of the disease.

Table 1 Classification of allergic rhinitis according to ARIA

Intermittent	Symptoms are present < 4 days a week or for < 4 consecutive weeks
Persistent	Symptoms are present > 4 days a week and for > 4 consecutive weeks
Mild	<i>None of the following items are present:</i> Sleep disturbance Impairment of daily activities, leisure and/or sport Impairment of school or work Symptoms present but not troublesome
Moderate to severe	<i>One or more of the following items are present:</i> Sleep disturbance Impairment of daily activities, leisure and/or sport Impairment of school or work Troublesome symptoms

Abbreviation: ARIA, Allergic Rhinitis and its Impact on Asthma.

CLINICAL FEATURES

The symptom complex of allergic rhinitis includes: nasal congestion, nasal itch, rhinorrhea and sneezing. The duration and frequency of symptoms including the effect on the quality of life requires evaluation to classify the severity of rhinitis. Associated ocular symptoms like conjunctival erythema, watering and itching of the eyes suggest an associated allergic conjunctivitis. Symptoms suggestive of associated bronchial asthma like chronic cough, wheezing, breathlessness, etc., should also be elicited. History of persistent mouth breathing, snoring and damp voice would point toward an adenoid enlargement. Hearing should also be evaluated for associated serous otitis media. Personal history of past or ongoing atopic dermatitis should also be evaluated. Family history of any atopic disorder should be elicited. Symptoms of comorbidities as sinusitis, conjunctivitis, asthma should also be asked for. A detailed evaluation of the patient environment is recommended (home, school) to determine potential triggers of the child's rhinitis. The commonly offending allergens include pollens, animal fur and tobacco smoke, mosquito coils and house dust mites.

Physical examination should particularly identify evidence for possible mouth breathing, transverse nasal creases secondary to regular rubbing of the nose, frequent throat clearing suggesting a postnasal drip, and allergic shiners (discoloration and swelling under the eyes). Nasal examination should focus on turbinate hypertrophy, pale mucosa, deviated nasal septum and any polyps. Ears should also be evaluated although usually they are normal. Some children can have a serous otitis media associated with adenoid enlargement, which requires assessment of the tympanic membrane for eustachian tube dysfunction. Sinuses should be palpated for tenderness for sinusitis. Posterior oropharynx should be evaluated for any postnasal drip and tonsillar enlargement. Detailed chest examination for wheezing and skin for atopic disease should also be done in all cases.

DIFFERENTIAL DIAGNOSIS

The important causes of childhood rhinitis can be classified as allergic, nonallergic and infective. Conditions that mimic allergic rhinitis, such as nasal foreign bodies, partial choanal atresia, cerebrospinal fluid (CSF) rhinorrhea, primary ciliary dyskinesia and laryngopharyngeal reflux, should be carefully looked for. Some children suspected to have mimickers of allergic rhinitis might need further investigations including a sweat test, immunological work-up, CT of paranasal sinuses, and nasal endoscopy. Adenoid

hypertrophy and deviated nasal septum are conditions which can coexist with allergic rhinitis.

TREATMENT OF RHINITIS

The goals of treatment in children with allergic rhinitis as in any chronic disease are to achieve good symptom control with least adverse effects secondary to drugs. The cornerstones of therapy to achieve these goals include allergen avoidance measures, intranasal corticosteroids, oral antihistamines, leukotriene receptor antagonists, and immunotherapy. Since many children with allergic rhinitis would have associated asthma, a *unified airway disease* evaluation and treatment of asthma is important.

Allergen Avoidance

Allergen avoidance measures can significantly improve symptoms. Parents and children should be counseled regarding these. The importance of the avoidance of common household allergens like house dust mites, molds, pets, pollens and tobacco smoke should be advised. A combination of these measures lead to optimal results. The patients allergic to house dust mites are often advised to use allergen-impermeable bedding covers but recent studies and meta-analysis have not shown this to be useful. Bed and linen should be washed in hot water and blankets should be kept in sunlight weekly. Exposure to outdoor allergens (pollen and molds) can be decreased by minimizing opening of windows, using an air conditioning, and reducing the time spent outdoors. Removal of the offending pet would be required in children who are allergic to animal fur. Many patients would experience good symptomatic relief with allergen avoidance alone, although some children continue to have persistent symptoms despite avoidance of allergen and trigger. Even in these children allergen avoidance would reduce the drugs required to achieve good control.

Oral H₁ Antihistamines

First-generation antihistamines (chlorpheniramine, diphenhydramine) have sedative properties and can reduce work performance. Oral second-generation antihistamines (detailed in **Table 2**) are better tolerated with fexofenadine having the least sedating potential. These drugs also do not cause significant QT prolongation and have no major drug interactions.

Antihistaminics have found to be more effective than placebo and can reduce the total nasal symptom scores by 7 (5–9)%. Antihistaminics are more effective on neurally-mediated symptoms like itch, sneeze and rhinorrhea with only a modest effect on nasal blockage. Regular therapy with second generation antihistaminics is more effective than *as-needed* use in children with persistent symptoms.

Nasal H₁ Antihistamines

The therapeutic effects of intranasal antihistaminics (azelastine, olopatadine) are superior to oral antihistamines for control of nasal symptoms but being topical they do not improve symptoms at other sites (conjunctivitis, postnasal drip, urticaria). The onset of action is quick (within 15 min) and hence these are useful for acute symptomatic relief. The major drawbacks are the local irritation and the taste disturbance with azelastine. Antihistaminics are the therapy of choice for mild to moderate intermittent and mild PER. They can also be used as add on therapy to intranasal corticosteroids (INCS) for children with

moderate to severe persistent rhinitis which is uncontrolled on INCS alone.

Intranasal Corticosteroids

Intranasal corticosteroids are the most effective available therapy for allergic rhinitis and are shown to be superior to antihistamines in meta-analysis. They suppress inflammation in the inflammatory cascade at multiple points. As compared with placebo, the reduction in the symptom score with INCS is 17% more. INCS are the therapy of choice for (1) moderate to severe PER, (2) in all children presenting with rhinitis associated with nasal polyps, and (3) for those who have inadequate response to oral/intranasal antihistamines alone. Adverse effects are less common (seen in < 10% cases) and include nasal irritation, sore throat and nasal bleeding. Reduction in the local adverse effects can be achieved by the correct use of the intranasal spray. Hypothalamic-pituitary-adrenal (HPA) axis suppression can occur when concomitant inhaled steroids are also used in high doses along with INCS. Fluticasone furoate and mometasone are approved above the age of 2 years, fluticasone propionate above the age of 4 years, and budesonide/ciclesonide above the age of 6 years. Budesonide is now not preferred as its high bioavailability can lead to more systemic side effects. Otherwise all INCS have comparable efficacy at equipotent doses.

Oral Corticosteroids

Oral steroids are rarely required for the treatment of children with allergic rhinitis, except in cases of severe disease for short-term rescue medication. A short course of oral steroids at a dose of 0.5 mg/kg can be used for 5–7 days in combination with INCS.

Leukotriene Receptor Antagonists

Leukotriene receptor antagonists (LTRA) are less effective than INCS and reduce symptoms scores by 5% less than placebo. The response appears to be variable in children. They appear to have a role in children with asthma associated with rhinitis.

The combination of H₁ antihistaminics and LTRA does not show added benefit to either drug when used alone and hence is not recommended. The combination is also less effective than INCS alone.

Other Drugs

Topical anticholinergics like ipratropium bromide are useful for symptomatic relief for rhinorrhea, but do not have effect on any other symptom. They can be used as an add-on therapy to INCS. The drawback is that it requires thrice daily administration. Intranasal decongestants like xylometazoline increase nasal vasoconstriction and are useful for brief use (typically for < 10 days). Prolonged use of decongestants might lead to rhinitis medicamentosa and hence should be avoided. Oral decongestants like pseudoephedrine are less effective in reducing nasal obstruction but have a longer duration of action.

Allergen Immunotherapy

Immunotherapy has been recommended in children with allergic rhinitis (1) where allergen avoidance is difficult, and (2) who have failed to respond to antihistaminics and INCS. The risk to benefit ratio should be considered in the individual case. The quality of allergen used is extremely important and only standardized extracts should be used. Sublingual immunotherapy (SLIT) is an alternative to subcutaneous immunotherapy and might be beneficial in children. It is performed at few centers in India.

Table 2 Overview of pharmacologic treatment options for allergic rhinitis

Drug	Formulations	Recommended dose	Common adverse effects
Intranasal steroids			
Fluticasone propionate	50 µg	< 12 years: 1 spray in each nostril BD; > 12 years: 2 sprays in each nostril BD	Irritation, epistaxis, HPA suppression in high doses. Usually occurs if receiving inhaled steroids at high doses for associated bronchial asthma
Mometasone	50 µg	< 12 years: 1 spray in each nostril BD; > 12 years: 2 sprays in each nostril BD	
Budesonide	32 µg	< 12 years: 1 spray in each nostril BD; >12 years: 2 sprays in each nostril BD	
Ciclesonide	50 µg	< 12 years: 1 spray in each nostril OD; > 12 years: 2 sprays in each nostril OD	
Fluticasone furoate	27.5 µg	< 12 years: 1 spray in each nostril OD; >12 years: 2 sprays in each nostril OD	
Second generation oral antihistaminics			
Cetirizine	Tablet 10, 20 mg; Syrup 5 mg/5 mL	6 months–2 years: 2.5 mg OD; 2–6 years: 5 mg OD; > 6 years: 10 mg OD	Sedation with some salts is the only adverse effect. Can be reduced with bed time dosing. Headache, GI symptoms, dry mouth can also occur
Levocetirizine	Tablet 5, 10 mg, Syrup 2.5 mg/5 mL	6 months–2 years: 2.5 mg OD; 2–6 years: 2.5 mg OD; > 6 years: 5 mg OD	
Fexofenadine	Tablet 120, 180 mg, Syrup	6 months–2 years: 15 mg BD; 2–11 years: 30 mg BD; > 11 years: 60 mg BD	
Loratadine	Tablet 5 mg	2–6 years: 5 mg OD; > 6 years: 10 mg OD	
Olopatadine	Tablet 5 mg	6 months–2 years: 2.5 mg OD; 2–6 years: 2.5 mg OD; > 6 years: 5 mg OD	
Intranasal antihistaminics			
Azelastine	140 µg	< 12 years: 1 spray in each nostril OD; > 12 years: 2 sprays in each nostril OD Available also as a combination with fluticasone propionate and furoate	Irritation, bitter after taste
Leukotriene receptor antagonists			
Montelukast	4 mg, 5 mg, 10 mg	6 months–4 years: 4 mg; 4–14 years: 5 mg; 14 years: 10 mg	Rarely headache, abdominal pain, dyspepsia, fatigue, dizziness, elevated liver enzymes

Abbreviations: HPA, hypothalamic-pituitary-axis; GI, gastrointestinal.

IN A NUTSHELL

1. Allergic rhinitis is a common chronic disorder in children that can significantly impact quality of life but is under diagnosed.
2. The diagnosis is usually made with a thorough history and examination with investigations required in rare cases of mimickers.
3. The concept of unified airway disease should be remembered and coexisting asthma and sinusitis should be evaluated.
4. The therapies available for the management of allergic rhinitis are effective, and safe and well-tolerated.
5. The main stay of therapy remains as second-generation oral antihistamines and intranasal corticosteroids. Sublingual or subcutaneous immunotherapy might be required in select cases.

Chapter 39.6

Otitis Media

Jagdish Chinnappa

Otitis media is an inflammation of the middle ear cleft, in an otherwise sterile environment, from invasion by either a viral or bacterial pathogen. This is followed by production of an exudative fluid which accumulates in the middle ear cleft, and distends the sensitive tympanic membrane producing the clinical symptoms and signs. The severity and rapidity of progress of the inflammation depends on the virulence of the organism and the inflammatory response. Acute otitis media (AOM) can be classified into *Severe* and *Nonsevere* based on symptoms and signs secondary to this response.

TYPES OF OTITIS MEDIA

Most children are able to effectively clear the inflammation over time, with or without antibiotic treatment but the course can be variable. Some children can run an extremely stormy course, with extension of the infection beyond the middle ear [*Complicated (AOM)*]. There could be extensions into the inner ear, external ear [*Acute suppurative otitis media (ASOM)*] surrounding tissue (mastoiditis) or even intracranial (cerebral abscess, etc.). A few children may continue to retain fluid in the middle ear cleft for prolonged periods of time [*Otitis media with effusion (OME)*]. OME needs to be recognized and followed up as it can lead to hearing aberrations and resultant speech abnormalities in small children.

A very small percentage of children tend to form biofilms in the middle ear cleft. These children may present with intermittent episodes of otitis media with asymptomatic intervals. Children with craniofacial anomalies, defects in immune function, adverse environmental conditions and eustachian tube dysfunction can have repeated episodes.

Chronic suppurative otitis media (CSOM) is a syndrome where there is a perforation of the tympanic membrane and persistent or recurrent purulent drainage from the middle ear. It is a distinct entity with a microbial and management perspective that is very different from AOM.

Table 1 describes the complete clinical spectrum of otitis media. The goals of management should be prevention of complications and hearing loss. This can be achieved by accurate diagnosis, with judicious use of antibiotics (restricting use to only select patients to prevent antibiotic resistance).

EPIDEMIOLOGY

Annually, more than 700 million cases of AOM occur worldwide with half of them occurring in under-fives. The global burden of

illness from CSOM involves 300 million individuals with draining ears with 20% in under-five children. More than half of children with CSOM suffer from significant hearing impairment. India, with 7.8% prevalence of CSOM, ranks second only to Tanzania. Prevalence of acute and chronic otitis media in general population of India ranges from 1% to 1.7% and 1.6% to 4.6%, respectively. Prevalence is much higher in rural areas. In some areas, every third child in a rural population has a discharging ear.

Otitis media is most often seen in young children between the ages of 6 and 18 months. Neonates and infants may have a spectrum of disease ranging from septicemia to asymptomatic middle ear effusion. The disease is seen less commonly and with reduced severity in preschool and school going children. It occurs infrequently in children older than 7 years and is rare in adolescents.

ETIOLOGY

Acute otitis media is often triggered by a viral upper respiratory infection with a background of pathogenic bacteria colonizing the upper respiratory tract. Upper airway colonization with pathogenic pneumococci is known to occur as early as 2 months of age in our country. The viruses most often implicated are the respiratory syncytial virus, rhinovirus, coronavirus, influenza and parainfluenza viruses, and adenovirus. BOCA and Metapneumoviruses are less often involved. Severe virus infections like measles can also predispose to AOM.

Bacteriology of AOM and OME is similar; the most common organisms being *Streptococcus pneumoniae* (40%) followed by *Haemophilus influenzae* (25–30%), *Moraxella catarrhalis* (10–15%) and *Streptococcus pyogenes*. In about 50% cases of OME with effusion, bacteria can be cultured from middle ear fluid. *Chlamydia trachomatis* is incriminated in infants below 6 months of age. Serotypes of *S. pneumoniae* producing otitis media vary region wise. Serotypes 19A, 3, 19F, 6b and 14 are implicated globally.

Nontypeable *H. influenzae* (NTHI) frequently colonizes the nasopharynx in young children. It causes a less severe disease than pneumococcus and is often associated with the conjunctivitis otitis media syndrome. NTHI is implicated in otitis media in all age groups, including adolescents. Many strains of NTHI produce β -lactamase. *Moraxella catarrhalis* is a frequent colonizer of the nasopharynx and produces a milder disease and is a significant pathogen in children with recurrent otitis media. Group A and B streptococci, *S. aureus*, *S. epidermidis* and gram-negative bacteria like *Proteus* and *Pseudomonas* may occasionally cause AOM. *Chlamydia* and *Mycoplasma* may occasionally produce AOM as a part of generalized respiratory infection. Both tuberculosis and nontuberculosis mycobacteria can also produce chronic middle ear disease with frequent involvement of the mastoids.

Otitis media with effusion was considered to be immunological and parainfectious in nature. However, recent studies have

Table 1 The spectrum of otitis media

Condition	Definition
Acute otitis media (AOM)	Acute onset of signs and symptoms of middle ear inflammation and presence of fluid in the middle ear
Resistant otitis media	Inadequate response of the AOM to the initial antibiotic after 72 hours of appropriate treatment
Relapse of AOM	Reappearance of signs and symptoms after initial response during therapy or within 4 days of stopping therapy, indicates that the infection has not been eradicated
Recurrence of AOM	Reappearance of signs and symptoms 5–14 days after therapy ends
Recurrent otitis media	Three or more episodes in a 6-month period or four or more episodes in a year
Otitis media with effusion (OME)	Presence of fluid in the middle ear cleft without signs of inflammation following an episode of AOM. Persistent OME indicates presence of this fluid beyond 12 weeks
Chronic suppurative otitis media (CSOM)	Chronic discharge from the ear following an episode of AOM; Minimum duration 2 weeks; acceptable 6–12 weeks despite medical management

reported microbial pathogen isolation in about half the cases. Various organisms like *S. epidermidis*, *S. aureus*, *Moraxella*, *Streptococcus* sp., NTHI, and *S. pneumoniae* have been isolated. The significance of this isolation is unclear.

Data from many studies from India implicate external ear pathogens like *Pseudomonas aeruginosa*, *S. aureus* and anaerobes in CSOM.

Recurrent otitis media is associated with colonization with NTHI more frequently than controls. Formation of biofilms, presence of intracellular organisms and polymicrobial milieu are some of the other features of middle ear pathology in recurrent otitis media.

PATHOGENESIS

The pathogenesis of OM is a complex interplay of anatomical, functional, immunologic, environmental, microbial and genetic factors (**Fig. 1**). The key event is invasion of the middle ear cleft by microorganisms present in the nasopharynx or rarely through a perforated tympanic membrane. The eustachian tube connects the middle ear to the nasopharynx. It (1) equilibrates pressure between the middle ear and the atmospheric pressure, (2) prevents aspiration of nasopharyngeal contents into the middle ear, and (3) facilitates clearance of fluid from the middle ear. Eustachian tube dysfunction plays an important role in pathogenesis of OM. The eustachian tube is shorter and more horizontal in children making it more vulnerable to aspiration.

Anatomical factors predisposing to otitis media include craniofacial anomalies like Pierre Robin sequence, Down syndrome, Turner and other syndromes. Cleft palate, submucous clefts and bifid uvulas may also predispose to otitis media through alteration of eustachian tube function.

Immune mechanisms play a very important role in initiating, resolving and perpetuating inflammation in the middle ear. Allergic rhinosinusitis is an important predisposing factor for OM. The mechanisms are complex and include inflammation of the respiratory mucosa of the eustachian tube, increased secretions in the nasopharynx facilitating aspiration and circulating inflammatory mediators altering the mucosal dynamics of the eustachian tube. Immune deficiencies impair the clearance of microbes in the middle ear fluid leading to persistence or recurrence of the disease. Mucociliary clearance may be affected

in children with ciliary dyskinesia and cystic fibrosis making them more prone for OM. Bottle feeding, pacifier use and exposure to smoke are high-risk factors for susceptibility to OM. Attendance to day-care centers, exposure to passive smoking, and overcrowding are the other high-risk factors.

CLINICAL FEATURES

Acute Otitis Media

Acute otitis media usually follows an attack of common cold. Symptoms are nonspecific in young children. Irritability, poor feeding, nausea, vomiting, diarrhea, disturbances in sleep are common presenting symptoms. Fever is usually moderate but may not be always there. Ear pain in older children and tugging or repeated painful gestures involving the ear may be seen. Ear pain alone is insufficient to diagnose AOM as it may occur in many other conditions like inflammation in the external ear or referred pain from the dental or pharyngeal structures. Discharge from the ears occurs when there is an acute perforation of the tympanic membrane. Purulent conjunctivitis may be seen in conjunction with otalgia in AOM caused by NTHI organisms.

Symptoms in complicated AOM spread of infection within the ear can produce symptoms of instability and clumsiness, facial asymmetry, swelling in the postauricular space and ringing sound in the ear. Intracranial spread produces symptoms characteristic of the site involved.

Examination may reveal the temperature to be as high as 40°C (104°F). Otoscopy demonstrates congested, i.e., red and bulging tympanic membrane. Most children with AOM are irritable and resist evaluation. Administering an oral analgesic (Paracetamol) prior to evaluation could help. In older children, the opportunity to play with a toy otoscope and doll may reduce apprehension. The child may also present with a discharging ear. Evaluation of craniofacial structures should be done prior to eardrum evaluation. ENT examination should include looking for evidence of allergic disease, obstruction, deviation and polyps in the nose, evaluation of the throat to look for tonsillar and adenoidal hypertrophy, submucous clefts and bifid uvulas. A postnasal drip and discharge may be evident.

Otoscopy

Otoscopy is the most important component of evaluation of OM. There are three main components of doing otoscopy in clinical practice, namely (1) proper visualization and performing a pneumatic otoscopy, (2) interpreting the findings, and (3) recording and following up. For proper visualization it is important to have a good otoscope with pneumatic facility (**Figs 2A to C**), a cooperative patient and knowledge about the anatomy and pathology of the ear drum. Many otoscopes are available with varying light sources, magnification and pneumatic capability.

A systematic examination of the ear drum include position of the drum, its color, opacity and mobility (**Fig. 3**). Evaluation of the tympanic membrane in a crying child may show increased vascularity especially around the handle of malleus. This is not a sign of acute otitis media. A combination of intense erythema, bulging and limited mobility is the hallmark of acute otitis media. In addition to this, it may not be easy to identify the landmarks of the normal drum, a feature called opacification of the drum. Perforation is a late event in an acute otitis media. Hearing loss is usually not complained of by the very young and may not even be noted by the parents.

Otitis Media with Effusion

Most children are asymptomatic but the occasional patient with bilateral disease may have hearing loss, behavioral problems like hyperactivity or speech abnormalities. Rarely tinnitus and

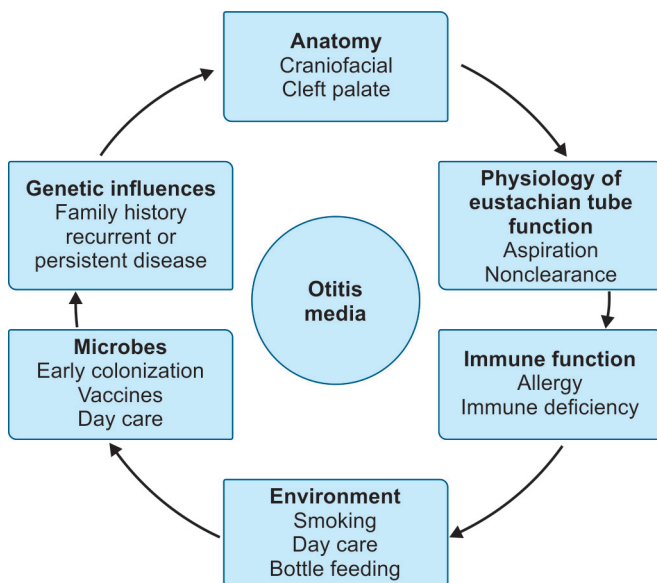

Figure 1 Key issues in pathogenesis of otitis media

Figures 2A to C (A) Otoscope with pneumatic facility; (B) Macro view otoscope; (C) Ear speculum of various sizes and rubber adaptors to facilitate tight seal

vertigo may be the manifestations. Pneumatic otoscopy findings include a full or retracted drum (depending on the type of fluid and chronicity), limited mobility and opacity. Redness and signs of inflammation are not seen.

Chronic Suppurative Otitis Media

There may be discharge, deafness, bleeding, tinnitus, vertigo, and pain. Discharge and deafness are the most common of these, which at times persist for a very long time, even for years. The external ear may have purulent foul smelling discharge. The drum may be opacified, retracted and may reveal a central perforation in pars tensa of the tympanic membrane (*safe type of CSOM*) or a defect in pars flaccida often associated with cholesteatoma (*unsafe type of CSOM*).

COMPLICATIONS

- **Hearing loss:** Most important sequel of otitis media is hearing loss, which usually is of conductive type (because of fluid in the middle ear), but at times can also be of sensorineural type. The initial months of life are important in language acquisition and a child by four years of age produces all the basic syntactic structures that he will ever use. Since so much progress in language acquisition is made during infancy, any problem in receiving or interpreting sound signals will have a significant effect on development of speech and language.
- **Intratemporal complications** include acute and chronic perforation of tympanic membrane, cholesteatoma, mastoiditis, petrositis, labyrinthitis, and facial paralysis.
- **Intracranial extension:** Untreated otitis media, whether acute or chronic, may lead to life-threatening intracranial complications. These include brain abscess, meningitis, extradural abscess, lateral sinus thrombosis, subdural empyema or otitic hydrocephalus.

INVESTIGATIONS

The diagnosis of OM is clinical and most cases do not need any investigations. Severe, complicated, recurrent, persistent or

relapsing cases may need to be evaluated. Careful history and a detailed clinical evaluation will point toward the pattern of investigations needed. Anatomical evaluation of the craniofacies and adenoidal hypertrophy by imaging may be needed in select cases. Nasopharyngoscopy and endoscopy of the eustachian tube may be needed in complex situations. Immune function evaluation may be needed in those with severe nonresponsive disease or with other pointers to immune dysfunction. Functional impairments may have to be evaluated by tympanometry, reflectometry and age appropriate audiometry. These are particularly of value in persistent OME. Tympanometry is an important investigation in OME; persistent OME and recurrent OME.

Figure 3 Examination of tympanic membrane

MANAGEMENT

Acute Otitis Media

All children with AOM should be given adequate analgesia and antipyretics. Oral paracetamol and occasionally nonsteroidal anti-inflammatory drugs (NSAIDs) are the agents of choice. Topical anesthetic agents in ear drops may offer temporary relief. Antibiotic ear drops should not be used. Locally active nasal decongestants may be used for short periods.

Antibiotics

There has been considerable revision in the guidelines for antibiotic administration in AOM. The main issues have been the judicious use of antibiotics since many older children with mild or unilateral disease tend to resolve spontaneously. In clinical settings we need to decide on the following parameters:

- Which group of children should be started on antibiotics at diagnosis? Which group of children can be managed by watchful waiting without antibiotics and can be started on antibiotics if the condition worsens?
- Which is the antibiotic of choice?
- For how long should the antibiotic be given?
- How should we manage refractory and relapsing cases?

It may be useful to consider presence of risk factors in the decision making for antibiotic usage (**Figs 4A and B**). Where the decision has been to withhold antibiotics, the parents must be counseled and asked to return for follow-up. Up to one-third of patients may need starting an antibiotic on follow-up at 72 hours.

Choice of Initial Antibiotic

The initial antibiotic of choice should be oral amoxicillin in a dose of 40–50 mg/kg/day in 2–3 divided doses. In areas where pneumococcal resistance to beta lactam is increasing (currently not the situation in India) the dose could be started at 90 mg/kg/day in 2–3 divided doses. Co-amoxycylav (45 mg of amoxicillin/kg/day in 2 divided doses) should be the initial antibiotic of choice in severe disease; or nonresolution of symptoms after 48–72 hours of starting amoxicillin. It is also the initial antibiotic of choice in conjunctivitis otitis syndrome caused by NTHI, or in children with relapse or recurrence of OM after treatment with amoxicillin in the previous 30 days. First and second generation cephalosporins may also be used but are not as cost-effective as the above. Cefixime has

not been shown to clear pneumococcal infections effectively and is not a drug of choice in most situations. Parenteral ceftriaxone (50 mg/kg) in a single dose may be given initially in children who have intractable vomiting and severe toxicity. In children with penicillin allergy type 1 macrolides (clarithromycin or azithromycin) or clindamycin (not active against NTHI) may be used. In penicillin allergy type 2, cefdinir, cefpodoxime and cefuroxime can be used. Commonly used drugs for AOM in children are summarized in **Table 2**.

Antibiotics in Nonresponsive or Relapsing Cases

In children who do not respond to initial antibiotic choice or who relapse soon after stopping, a careful consideration to the causes of nonresponse should be given. Compliance with instructions is a frequent problem. Prolonged exposure to precipitating factors may be another issue. After due consideration of these issues an alternative antibiotic course could be given. Usually the choice of a third generation oral cephalosporin like cefpodoxime or cefdinir is acceptable. A combination of clindamycin (covers pneumococci effectively) with cefixime (covers NTHI) could also be tried. If there is still no response then parenteral ceftriaxone (50 mg/kg/day) for 3 days may be administered.

Other Considerations

In instances where there is a highly toxic child in severe pain and a red bulging drum, an ENT referral for Myringotomy may be necessary. In children who have frequently relapsing disease, consideration for adenoidectomy and grommet insertion is in order.

Duration of Antibiotics

In children less than 2 years the duration of treatment should be 10 days. In older children between 2 years and 5 years, 7 days of antibiotic usage should be adequate. Above the age of 5 years AOM is uncommon and 5 days of antibiotic should be sufficient.

Management of Persistent OME

Otitis media with effusion is a common sequel of AOM. Most cases resolve spontaneously and need only a careful follow-up. A small percent of children have bilateral fluid collection that persists beyond 12–16 weeks. Some children have intermittent fever, and occasional otalgia. These children may be given a

Figures 4A and B Decision to (A) start antibiotics; or (B) withhold antibiotics in acute otitis media depends on several factors

Table 2 Drugs used for treating otitis media in children

Drug	Dosage Per day	Number of doses	Duration of treatment in < 2 years age	Comments
Amoxicillin	40–90 mg/kg	2–3	10 days	Drug of initial choice
Co-amoxiclav	40–90 mg/kg	2	10	Severe disease, Relapse, Conjunctivitis
Cefaclor	40 mg/kg	3	10	Alternative to amoxicillin
Cefdinir	14 mg/kg	1–2	5/10	Alternative to amoxicillin
Cefpodoxime	10 mg/kg	2	5	Resistant or relapse
Cefuroxime	30 mg/kg	2	10	Resistant or relapse
Azithromycin	10 mg/kg	1	3	Penicillin allergy
Clarithromycin	15 mg/kg	2	10	<i>Mycoplasma</i> or <i>Chlamydia</i> infection
Co-trimoxazole	8 mg/kg of trimethoprim	2	10	High incidence of <i>Pneumococcus</i> resistance
Clindamycin	30–40 mg/kg	3	7–10 days	Useful against resistant <i>Pneumococcus</i>
Ceftriaxone	50 mg/kg	1	3 days resistant or refractory	Parenteral
Levofloxacin	10–20 mg/kg	1–2	5–7	Reserve for drug resistant cases

course of coamoxyclov for 10 days. If hearing loss is significant in these children, there may be a role for myringotomy with grommet insertion. Other forms of medical treatment like antibiotics, decongestants (oral or nasal), steroids (intranasal, oral), and leukotriene antagonists have not been shown to be effective. Careful attention to environmental triggers and optimal management of allergic rhinitis will help a small percentage of children.

Management of CSOM

Chronic suppurative otitis media presents as a chronically discharging ear with hearing loss. Mild cases can be treated with topical quinolone drops and aural toilet. Treatment can be continued till the ear is dry. Closure of perforation by myringoplasty can be considered once the ear is dry. Myringoplasty is usually not undertaken before the age of 10 years due to a high incidence of re-infection and re-perforation in younger children. The only treatment for an unsafe type of CSOM is surgical in the form of mastoid exploration (mastoidectomy).

OUTCOME AND PROGNOSIS

Most children with AOM resolve spontaneously or with appropriate antibiotic treatment. A small percentage may have a

stormy complicated course. Otitis prone children usually have a backdrop of atopy, craniofacial anomalies, immunodeficiency or adverse environmental factors. Persistent OME usually resolves with time, those children who have significant hearing loss, may need ventilating tubes (grommet). Mild cases of CSOM can be managed with topical quinolones; more serious cases need expert ENT consultation (**Table 3**).

PREVENTION

Primary prevention consists of promoting exclusive breastfeeding for at least 6 months; avoid bottle feeding and pacifier use; vaccination with the Hib and conjugate pneumococcal vaccines; environmental control; strict avoidance of smoke exposure; avoiding crowded areas especially day-care units; optimal management of allergic rhinosinusitis; and maintaining good nutrition.

Prevention of recurrent otitis media has been advised in children who have had three or more documented episodes of otitis media in 6 months, or more than 4 episodes in 12 months. Modalities available for prevention of otitis media include immunoprophylaxis and chemoprophylaxis. Prophylactic antibiotics should be discouraged. These children should be evaluated for craniofacial anomalies, and immune disorders (IgA deficiency, ciliary dyskinesia).

Table 3 Indications for referral to an ENT surgeon

Clinical	Reason for referral	Expected procedure
Acute otitis media	Indeterminate diagnosis; inability to visualize drum Toxic severe AOM Complicated AOM	Cerumen clearance, Confirm diagnosis Myringotomy Co-manage
Persistent OME	Confirming fluid Hearing loss	Tympanometry Audiometry Grommet tube placement
	Adenoidal hypertrophy	Adenoidectomy
Recurrent otitis media	Identification of pathogen Cytology	Myringotomy with aspiration
CSOM	Draining ears	Aural toilet, Surgery

IN A NUTSHELL

1. Antibiotics for AOM are indicated in (1) infants less than 6 months of age with presumed or confirmed diagnosis; (2) those 6 months–2 years with confirmed diagnosis or serious disease; and (iii) more than 2 years with confirmed diagnosis and serious disease.
2. Prescribe an antibiotic which is clinically and microbiologically active against both *S. pneumoniae* and *H. influenzae*. Amoxicillin 40–50 mg/kg/day is the first-line agent.
3. Obvious improvement should start in 72 hours. In case of nonresponse, initiate second line agents which include amoxicillin-clavulanic acid, cefuroxime or ceftriaxone.
4. If pain still does not subside within 48–72 hours and the tympanic membrane is still bulging, surgical treatment (myringotomy) is indicated. Myringotomy refers to a therapeutic incision usually given in anterior lower quadrant of the tympanic membrane.
5. Decongestants and antihistaminics do not shorten the overall duration of illness; these may help symptomatically.

Chapter 39.7

Approach to a Child with Cough

NK Subramanya, Vidya K

Cough is a frequent presenting symptom seeking medical attention. Cough is an important protective reflex that allows clearance of secretions and particulates from the airways, so as to keep the airway clean and healthy. Cough is not a disease by itself, but, a symptom of underlying disease ranging from benign self-limiting upper respiratory tract infection to severe life-threatening disease. Cough in children causes significant anxiety to parents. Drugs prescribed for treatment of cough and the available over the counter sales account for huge revenue sales and it is important to note that majority of these medications are unnecessary, irrationally prescribed or administered by parents.

Cough is the symptom of respiratory disease which may be secondary to a non-respiratory illness such as a cardiac disease. When cough presents with other symptoms that gives clue to the causative factors like fever, dyspnea, hemoptysis, etc. the diagnosis depends on the clinical manifestations. Any respiratory disease can manifest with cough, thus discussing all the causes of cough is beyond the scope of this chapter. In this chapter, we will focus more on diseases where cough is the *sole manifestation*.

APPLIED ANATOMY AND PHYSIOLOGY

Cough receptors are present in airways, sinuses, middle ear, pleura, diaphragm, but the distribution of receptors is nonuniform. The intensity of cough is maximum when it is laryngeal (vocal cords). The cough becomes less explosive as we move proximal or distal to vocal cords in the airways. Vagal afferent nerves regulate involuntary coughing. There is higher cortical control that regulates voluntary coughing. The implication of cortical regulation is evident from the fact that the placebos can have profound effect on coughing. The psychological issues can be considered either the cause or effect of coughing. Cough center is situated in the medulla oblongata, which will be suppressed by cough suppressants. The defensive nature of the cough reflex can be suboptimal in neuromuscular weakness of muscles of respiration. Violent bouts of cough can cause syncope, rib fractures, subconjunctival hemorrhage, prolapse, hernia and alterations in intracranial pressures. Cough can be categorized based on duration (i.e., acute or chronic), quality (dry or wet, brassy or staccato) or etiology (specific or nonspecific).

ACUTE COUGH

Acute cough is generally defined as the cough of less than 4 weeks duration. The pediatric definition of acute or chronic cough is based on the natural history of acute upper respiratory tract infections (URTI) in children, wherein usually the cough resolves within 1–3 weeks. Hence, it is logical to define chronic cough as daily cough lasting more than 4 weeks. Published definitions of chronic cough in children have varied duration from 3 weeks to 12 weeks. In contrast, the current definition of duration of chronic cough in adults is 8 weeks. The cough between 4 weeks and 12 weeks in adults is called subacute cough, the relevance of this definition in children is not clear. It may be worth mentioning that these cut-offs can sometimes also vary for the purpose of defining a particular disease suspect, e.g., a child with prolonged cough of more than 2 weeks in our country is considered as a TB suspect.

The cause of acute cough in children is usually obvious by clinical evaluation. The infections of upper and lower respiratory tracts account for majority of cases. Nose block, mouth breathing, postnasal discharge, soreness of pharyngeal mucosa exposing cough receptors to be stimulated believed to be responsible for cough.

Postinfectious Cough

The postinfectious cough can follow an upper or lower airway infection. The child continues to cough while other symptom like fever resolve. It is thought to be due to exhaustive inflammation and disruption of airway mucosal integrity. In lower respiratory tract infection this is often associated with excessive accumulation of mucus and transient airway and cough receptor hyper-responsiveness. This may be clinically identified as acute or subacute cough pattern described in adults.

Management of Acute Cough

The diagnosis of the illness causing acute cough is essentially clinical such as acute rhinosinusitis, acute otitis media, sore throat, acute laryngitis, etc. They are managed as per the standard guidelines. The accompanying cough resolves with recovery of underlying cause in most of the children. There is no need of laboratory investigations in general, unless an individual case demands work-up. Anticold preparations available over the counter and also largely prescribed by clinicians have largely been criticized for lack of scientific evidence. The expectorants have variable response and cough suppressants can be dangerous in children younger than 6 years of age. The clinician should weigh the advantages of such prescription over the benign self-limiting nature of many infections in day to day practice. The herbal remedy, honey, and steam inhalation are popular among parents and pediatricians but lack strong scientific evidence.

Recurrence of Acute Cough

Upper respiratory tract infections are common in early life and on an average 6–8 episodes occur in infancy. The frequency of these episodes decrease with increasing age and reassurance to the anxious parents may avoid unnecessary investigations. However, malnutrition, bottle feeding, day care admissions, exposure to environmental factors like parental smoking, pollution is responsible for *recurrent episodes* of acute cough. Exacerbations of asthma as a cause of recurrent cough is common and associated history should be elicited to make the diagnosis.

CHRONIC COUGH

Chronic cough is defined as cough lasting more than 4 weeks. Chronic cough in children is evaluated and managed differently than in adults. Unlike in adults, the relationship between chronic cough and upper airway disorders, asthma, and gastroesophageal reflux disease (GERD) is less convincing in children. Pediatric cough can be classified in several ways, including those based on the etiology, time frame, characteristics, and specific/nonspecific cough.

Cough is categorized as *expected*, *specific* and *nonspecific*. In *expected cough*, the presence of cough is expected (e.g., after an acute respiratory tract infection). In *specific cough*, the etiology and necessity for further investigations is usually evident from the presence of coexisting symptoms or signs (e.g., suppurative lung disease, immunodeficiency, etc.). The presence of any of these symptoms or signs suggests that the cough is likely to be associated with an underlying specific etiology. The clinical evaluation and investigation depend upon the suspected specific diagnosis. The standard guidelines for the diagnosis should be followed,

e.g., work-up of a child with suspicion of tuberculosis. Specific pointers of cough are listed in **Table 1**. The diagnosis can be based on the characteristics of cough such as age at the onset of cough (**Table 2**), nature of cough (**Table 3**), and the timing of the cough in the day (**Table 4**). A detailed history, repeated questions and clinical examination (**Table 5**) are needed to find out etiology.

Some Special Situations with Chronic Cough

Upper Airway Cough Syndrome

Upper airway cough syndrome (UACS), also referred to as post-nasal drip, is characterized by dry cough with throat clearing associated with upper airway problems such as rhinosinusitis of

Table 1 Specific pointers of cough

Asthma	Seasonal, trigger induced, atopic, nocturnal, responding to salbutamol/steroids
Bronchiectasis or recurrent pneumonia	Cystic fibrosis, primary ciliary dyskinesia (PCD), immunodeficiency, congenital airway lesions, foreign body, tracheoesophageal fistula (TEF)
Aspiration	Neurologically abnormal, TEF, GERD, cleft palate
Chronic infections	TB, nontubercular mycobacteria, fungal diseases, parasites
Interstitial lung disease	Drugs, radiation, autoimmune diseases
Airway abnormality	Tracheomalacia, airway compressions
Cardiac diseases	Murmurs, pulmonary hypertension
Miscellaneous pulmonary conditions	Tumors

Table 2 Age and onset of cough

Age	Acute	Recurrent	Persistent
Infancy	Viral infection	GERD	PCD, Congenital anomalies
Early childhood	Foreign body	Asthma	Retained foreign body Tuberculosis
Older children	Asthma	Rhinosinusitis psychogenic	Bronchiectasis (CF/Non-CF/immunodeficiency), ILD

Abbreviations: CF, cystic fibrosis; GERD, gastroesophageal reflux disease; ILD, interstitial lung disease; PCD, primary ciliary dyskinesia.

Table 3 The nature of cough

Nature of cough	Probable cause
Throat clearing	Postnasal drip
Dry, irritating	Postviral
Barking cough	Laryngitis
Brassy	Tracheitis/mediastinal mass or nodes
Paroxysmal	Pertussis, asthma
Staccato cough	Chlamydial infection
Nocturnal	Asthma
Wet, rattling	Suppurative lung diseases

Table 4 Timing of cough

Time of cough	Probable cause
Early morning	Dry cough: Asthma Wet cough: Bronchitis
Worsen in evening	Pollution
Worse in night	Asthma, postnasal drip
After feeds, lying down	GERD
Soon after exercise	Asthma
Loud, bizarre, absent during sleep	Psychogenic

Abbreviation: GERD, gastroesophageal reflux disease.

Table 5 Cough and clinical features

Clinical finding	Cause
Wheeze, atopy, rhinitis	Asthma
Cold, fever, rashes	Viral infections
Excessive regurgitation	GERD
Multiple multifocal infections	Immunodeficiency
Clubbing	Suppurative lung diseases, ILD
Malabsorption, failure to thrive	Cystic fibrosis

Abbreviations: GERD, gastroesophageal reflux disease; ILD, interstitial lung disease.

infective or allergic origin. Some of the children also have GERD as the comorbid condition aggravating the cough.

Aspiration Syndrome

Micro- or macroaspiration of contents of upper gastrointestinal tract (GIT) can occur from lower esophagus (GERD), mid esophagus (tracheoesophageal fistula) or at higher level (palate-pharyngeal in coordination, cleft palate, etc.). The relationship of the cough aggravated by supine posture or after feeds makes the diagnosis clinically possible. Barium studies clinch the diagnosis in tracheoesophageal fistula (TEF) and diaphragmatic hernia. Gastroesophageal reflux disease requires 24-hour pH monitoring of esophagus, and responds to thickening of feeds with antireflux therapy (proton pump inhibitor).

Asthma

Asthma is a clinical diagnosis. Cough in asthma is recurrent, episodic, seasonal, trigger-induced, nocturnal and occasionally paroxysmal resulting in vomiting. The accompanying breathlessness and wheeze help in the diagnosis. Cough responds typically to bronchodilators and steroids. Isolated cough in the absence of wheezing, responding to bronchodilators is called cough variant asthma.

Pertussis

Pertussis is often underdiagnosed. The typical paroxysmal cough with or without whoop, with laboratory evidence of lymphocytosis is hallmark of the disease. The diagnosis should be considered even in immunized children. Cough does not respond to bronchodilators or cough suppressants. Cough is very distressing and macrolides (azithromycin) given early in the first week of illness reduces morbidity.

Tuberculosis

Cough of more than 2 weeks with history of contact in developing country should be evaluated for tuberculosis. Parenchymal

involvement, extrinsic compression of airways by lymph nodes, endobronchial spread, cavitation, and bronchiectasis can cause chronic cough. The attempt should always be made to isolate acid fast bacilli (AFB).

Foreign Body in Airway

In acute cases, history of sudden onset of cough with choking in a toddler should raise the suspicion of foreign body (FB). In chronic cases the ingestion of FB may be *forgotten* and high index of suspicion is needed. When in doubt, rigid bronchoscopy should be done even in the *absence* of history. X-ray chest can show air trapping, localized emphysema, and mediastinal shift depending on the sight of FB in airways. Normal X-ray does not exclude the presence of FB.

Psychogenic Cough

It is also referred to as habit cough typically seen young adolescents and cough is explosive, attention-seeking and disappears in sleep. Counseling and referral to psychiatrist, multidisciplinary approach is required.

Protracted Bacterial Bronchitis

Prolonged *wet* cough of more than 2 weeks duration is usually due to the formation of *biofilms* due to microbial colonization in the airway mucosa making it difficult to treat. Prolonged antibiotics for 4 weeks are needed.

Evaluation and Approach to Chronic Cough

Every effort should be made to arrive at specific diagnosis of cough. If specific diagnosis is not possible at the point of evaluation, a diagnosis of nonspecific cough is made. Nonspecific cough has been defined as usually dry cough in the absence of identifiable respiratory disease or known etiology. The categorization is overlapping and is not very well demarcated. Cough is subjected to period effect (i.e., spontaneous resolution of cough). The therapeutic benefit of placebo treatment for cough has been reported to be as high as 85%. This forms the basis for *wait and watch*, and *review* approach in many children with nonspecific cough. It can also be noted that in some children the specific pointers to diagnosis evolves over a period of time.

Chest X-ray should be done in all cases of chronic cough except in asthma, as asthma is essentially clinical diagnosis. Radiological findings in chronic cough are summarized in **Table 6**. Other investigations are listed in **Table 7**.

A Simplified Approach to Chronic Cough

1. If specific pointers are present, evaluate as per standard guidelines.
2. If not, do chest X-ray and spirometry (if above 6 years, based on the availability).
3. Is cough characteristic? If yes, refer to **Tables 2 to 4**.
4. If not it is nonspecific cough, follow *wait, watch and review*.
5. Evaluate for environment, child's activity and review in 1–2 weeks.
6. If not resolving, discuss with parents for further evaluation.
7. Treatment after evaluation and specific diagnosis is ideal approach. However, few clinicians may try a trial of therapy (antimicrobial therapy for *wet cough* and bronchodilators for *dry cough*).

Table 6 Chest X-ray in chronic cough

Radiological findings	Probable causes
Normal	Asthma, postnasal drip, aspiration syndromes, habit cough, FB, drugs, vascular compression
Persistent shadow	FB, TB, congenital anomalies
Multifocal lesions	Aspiration, asthma, cystic fibrosis, immunodeficiency, congenital heart disease
Focal shadows	Nodes, tumors, cysts
Interstitial pattern	Infections, ILD

Abbreviations: FB, foreign body; ILD, interstitial lung disease; TB, tuberculosis.

Table 7 Investigations in chronic cough

X-ray chest	All cases
Sputum examination	AFB, fungal studies
Barium study	Aspiration syndromes
2D-Echo	CHD, Pulmonary hypertension
Pulmonary function tests	Asthma
HRCT	Suppurative lung disease, interstitial lung disease

Abbreviations: AFB, acid fast bacilli; CHD, congenital heart disease.

IN A NUTSHELL

1. *Acute cough* is commonly due to URTI, self-limiting, and unnecessary investigations and indiscriminate use of drugs should be avoided.
2. *Chronic specific cough* should be evaluated based on clinical clues/pointers, individualized in approach, and treated.
3. *Chronic nonspecific cough* should be evaluated over the period of time; wait and watch. Re-evaluate for appearance of specific pointers; consider trial of antibiotics (infective) or inhaled corticosteroids (allergic). Parents should be involved in decision making.

Chapter 39.8

Common Cold and Acute Pharyngitis

Satnam Kaur, GR Sethi

Acute respiratory infections (ARIs) are common causes of morbidity and mortality in children and one of the main reasons for visit to pediatric practitioners. A significant chunk of ARIs (80–90%) is contributed by upper respiratory tract infections (URTIs) including common cold (rhinitis), pharyngitis, tonsillitis, sinusitis, and acute otitis media. Majority of URTIs are caused by viruses; bacterial infections are responsible for only a minor fraction. Irrational prescribing of antibiotics is a common practice in URTIs, thus a thorough knowledge of these disorders is essential to avoid unnecessary use of antibiotics and prevent emergence of drug resistance.

COMMON COLD (RHINITIS)

Common cold is a mild, self-limiting viral illness with prominent nasal symptoms (nasal stuffiness, coryza, sneezing). Though, referred to as rhinitis, paranasal sinuses are frequently affected and therefore, viral rhinosinusitis may be a more appropriate terminology.

Etiology

As discussed earlier, common cold is a viral illness. More than 100 different viruses have been described to cause common cold, the most common being rhinovirus responsible for about 40–60% of cases. The major etiological agents are listed in **Box 1**.

BOX 1 Etiological agents of common cold

Most common: Rhinovirus

Common: Coronavirus, metapneumovirus*, respiratory syncytial virus*, influenza virus; and parainfluenza virus*

Occasional: Adenovirus; enterovirus; and bocavirus*^.

*Agents causing symptoms in addition to those of common cold
^ often found as coinfection with other agents.

Epidemiology

Common cold occurs more frequently in rainy season and winters in tropical climate. Usual incubation period is 1–5 days. Young children have more frequent colds (average 6–8 episodes/year), have greater concentration of virus in their secretions and shed virus for longer periods of time. They are also a common source for spreading infection to others, particularly adults. Not surprisingly, therefore, attendance in day care centers and presence of young siblings at home are risk factors for the illness.

Pathophysiology

Transmission of infection occurs by hand contact with infected secretions, small particle aerosol or large particle aerosol. Mode of transmission varies with different agents. Rhinovirus is primarily spread by direct contact with infected secretions. After direct inoculation of nasal mucosa or from conjunctiva via lacrimal duct, virus reaches the nasopharynx and enters the epithelial cells via cell surface receptors and starts replicating leading to acute inflammatory response. Degree of epithelial destruction and cytopathology vary with different viral agents. Little or no epithelial damage occurs in rhinoviral infection. Increased vascular

permeability and vasodilatation cause symptoms of rhinorrhea and nasal obstruction. Sneezing and increased mucus secretion occurs due to cholinergic stimulation. Nasal discharge may become mucopurulent between day 2 and 7 of illness because of desquamated epithelial cells and polymorphonuclear leukocytes. Eustachian tube dysfunction and involvement of paranasal sinuses occur frequently because of spread of inflammation to eustachian tube and sinus ostium, predisposing to development of otitis media and bacterial sinusitis. Viremia usually does not occur during typical common cold, infection being restricted to epithelia of upper respiratory tract. Impairment of mucociliary clearance may persist for 3–4 weeks.

Clinical Features

Symptoms of common cold are not specific for any etiological agent. The illness usually starts with dryness and irritation in nose and a scratchy throat. Nasal stuffiness, sneezing, watery nasal discharge, watering eyes and cough follow. There may be low-grade fever, muscle aches and malaise. Nasal secretions may become thick and mucopurulent during the course of illness. However, that does not signify bacterial superinfection. Examination may reveal congested, erythematous nasal turbinates, rhinorrhea and nasal excoriation. Infants are more likely to have fever and nasal obstruction which may cause faster respiration and feeding difficulty. Usual duration of symptoms is 7 days but symptoms may persist for up to 2 weeks in few.

Differential Diagnosis

Allergic Rhinitis

Allergic rhinitis should be distinguished from infectious rhinitis in a child with recurrent colds. Nasal discharge is clear and watery in allergic rhinitis with a pale and boggy appearing nasal mucosa. Presence of nasal/ocular pruritis, positive family and/or personal history of allergic disorders, possible allergic triggers, nasal eosinophilia and serum IgE help in diagnosing allergic rhinitis.

Sinusitis

Headache/facial pain, anosmia, persistence of nasal discharge and cough for more than 2 weeks in an illness which started as usual common cold should lead to the suspicion of sinusitis.

Initial symptoms of some illnesses, e.g., pertussis, diphtheria, measles, epiglottitis are similar to common cold but over the course of illness other features become apparent.

Management

Common cold is a mild, self-limiting illness and no therapy is indicated in majority of cases. Antibacterial and antiviral agents are of no benefit. Antibiotic use is potentially harmful as it increases emergence of resistant organisms. Use of symptomatic treatment in children is not proven. Few of these options are discussed here:

Antipyretic and Analgesics

Acetaminophen can be given for symptomatic relief of fever and aches.

Cough and Cold Medications

Various over the counter (OTC) cough and cold medications containing varying combination of antihistaminics, antitussives, decongestants, mucolytics and expectorants are available in the market. First generation antihistaminics have been shown to reduce rhinorrhea in adults with colds due to their anticholinergic action. However, no studies are reported in children. Similarly, no robust studies or meta-analysis support any role of cough suppressants, expectorants, or decongestants in the management

of common cold for symptomatic relief. Systemic decongestants (pseudoephedrine, phenylephrine) may cause serious side effects (CNS stimulation, tachycardia, and hypertension). Mucolytics are also not effective in children.

Relief of Nasal Obstruction

Efficacy of nasal decongestants (xylometazoline, oxymetazoline) in children with common cold is unproved and potential side effects are a concern especially in young children. Excessive use of nasal vasoconstrictors may cause rebound nasal obstruction. They are not approved for children less than 2 years of age. Use of isotonic saline nasal drops and gentle aspiration may provide temporary relief of nasal obstruction in young children. General humidification of room air may dilute tenacious secretions and facilitate their elimination. However, a Cochrane review concluded that steam inhalation does not offer consistent benefit.

Micronutrients

A major controversy relates to efficacy of vitamin C in prophylaxis and treatment of common cold. A Cochrane review concluded that prophylactic vitamin C does not reduce the incidence of cold but there is a small benefit on duration and severity of cold. Given at the onset of cold, it does not have any benefit. Another recent Cochrane review concluded that zinc, administered within 24 hours of onset of symptoms, shortened the duration and severity of cold in healthy people and prophylactic use reduced the incidence of colds and decreased school absenteeism in children. However, in view of differences in study population, dosages, formulations and duration of treatment used in different studies and potential side effects of zinc lozenges, no firm recommendations about the dose, duration and formulations could be made.

Prognosis and Complications

Common cold is a self-resolving condition with complete recovery in 7–10 days. Complications occur in a minority of children and include otitis media, sinusitis, adenoiditis, lower respiratory tract infections and exacerbations of bronchial asthma.

PHARYNGITIS

Pharyngitis is inflammation of the mucous membrane and underlying structures of pharynx causing sore throat and accompanied by objective evidence of inflammation (erythma, exudates or ulceration). It is subdivided into (a) *nasopharyngitis*—sore throat accompanied by nasal symptoms and almost always viral in origin; and (b) *tonsillopharyngitis*—sore throat without nasal symptoms and can be caused by wide variety of agents including bacterial, viral and fungal. Majority of pharyngitis cases are self-limiting viral illnesses. Group A β hemolytic *Streptococcus* (GAS) or *Streptococcus pyogenes* is the most important bacterial cause of pharyngitis because of its potential to cause acute rheumatic fever. Prevention of acute rheumatic fever by adequate and timely treatment of GAS pharyngitis defines the management of pharyngitis.

Epidemiology

Children of any age can develop pharyngitis. However, pharyngitis due to *S. pyogenes* occurs primarily in children between 5 years and 15 years of age and is unusual in children below 3 years of age. Pharyngitis occurs more frequently during colder months of the year. Incubation period varies between 2 days and 5 days. Children are major reservoir of infection. In India, prevalence of GAS pharyngitis ranges from 4.2% to 13.7% with incidence rates varying between 0.12 and 0.95 episodes per child per year. Various studies have shown asymptomatic streptococcal throat carriage rate between 2.3% and 20%.

Etiology

Most cases of pharyngitis in children are viral. *S. pyogenes* is the most important bacterial cause and accounts for 15–30% cases. Adenovirus is the most common cause of nasopharyngitis, other common viral agents being influenza and parainfluenza. Although rhinovirus, respiratory syncytial virus, corona virus, human metapneumovirus and bocavirus infection are common in children, objective evidence of pharyngeal inflammation is less common. In enteroviral infection, pharyngeal involvement is often overshadowed by systemic complaints (fever, exanthema, meningitis). Epstein-Barr (EBV) virus can cause pharyngitis as part of infectious mononucleosis. Primary and recurrent herpes simplex virus (HSV) infection, occasionally, have pharyngeal involvement. Bacteria other than GAS are rare causes of pharyngitis and include group C and G *Streptococcus*, *Haemophilus influenzae* and *Neisseria meningitidis* (along with systemic illness), *Arcanobacterium haemolyticum* and *Corynebacterium*. *Chlamydia pneumoniae* and *Mycoplasma* have also been implicated as cause of acute pharyngitis. Exudative pharyngeal involvement with *Candida* can occur in children who are immunocompromised and whose normal throat flora have been disrupted. **Table 1** enlists etiological agents of pharyngitis.

Clinical Features

The onset of pharyngitis is usually with fever, sore throat and anorexia. Examination shows objective evidence of pharyngeal inflammation in the form of pharyngeal erythma, exudates or ulceration. Clinical distinction between GAS pharyngitis and viral pharyngitis cannot be absolute as there is considerable overlap in clinical features. However, presence of rhinorrhea, cough, hoarseness, conjunctivitis, diarrhea, exanthema suggest viral etiology. On the other hand, GAS pharyngitis classically presents with sudden onset of sore throat, dysphagia and fever while examination findings include tonsillopharyngeal erythema with or without exudates, tender anterior cervical lymphadenopathy, palatal petechiae, and red swollen uvula, but none of these signs is specific as they can be present in adenovirus and EBV infection too. Also many patients with GAS pharyngitis present with milder

Table 1 Etiological agents of pharyngitis

Common viral causes	Less common viral causes
Adenovirus	Cytomegalovirus
Coronavirus	Herpes simplex virus
Enteroviruses	Reovirus
Epstein-Barr virus	Rhinovirus
Influenza virus A and B	Rotavirus
Parainfluenza virus	Rubella virus
Respiratory syncytial virus	
Common bacterial causes	Uncommon bacterial causes
<i>Streptococcus pyogenes</i>	<i>Actinomyces</i>
	Mixed anaerobes
	<i>Arcanobacterium haemolyticum</i>
	<i>Corynebacterium</i>
	<i>Francisella tularensis</i>
	<i>Haemophilus influenzae</i>
	<i>Legionella</i>
	<i>Leptospira</i>
	<i>Neisseria gonorrhoeae</i>
	<i>Neisseria meningitidis</i>
	Streptococci C and G
	<i>Streptococcus pneumoniae</i>

<i>Chlamydia pneumoniae</i>	<i>Mycoplasma pneumoniae</i>

and less classical presentation. Absence of pharyngeal exudates, tender lymphadenopathy, and throat pain have a high negative predictive value for GAS pharyngitis. **Box 2** enumerates features suggestive of viral and GAS pharyngitis.

BOX 2 Clinical features differentiating Group A streptococcal from viral etiology of pharyngitis

Features suggesting group A streptococcal etiology

Sudden onset, absence of cough, tender cervical lymph nodes, palatal petechiae, fever > 38°C, and tonsillar or pharyngeal exudates

Features suggesting viral etiology

Coryza, conjunctivitis, hoarseness, viral exanthema, viral enanthem, diarrhea.

Adenoviral pharyngitis typically presents with fever, pharyngeal congestion, tonsillar enlargement with exudates and enlarged cervical lymph nodes. There may be associated conjunctivitis (pharyngoconjunctival fever). Pharyngeal involvement is overshadowed by other respiratory symptoms (cough, coryza) in influenza and parainfluenza infection. In enteroviral pharyngitis (coxsackie virus, and newer enteroviruses), pharyngeal congestion is present but tonsillar exudates and cervical lymphadenopathy is uncommon. Systemic signs (fever, exanthema, meningitis) are prominent. Herpangina, caused by coxsackie virus A/B and echovirus, presents with fever and painful, discrete gray-white papulovesicular lesions on an erythematous base (which may ulcerate) in posterior oropharynx. In hand-foot-mouth disease, caused by coxsackie virus A 16, painful vesicles and ulcers throughout the oropharynx are associated with vesicles on palms and soles.

Primary and recurrent HSV infection, occasionally have pharyngeal involvement, but the hallmark herpetic lesions are present around the mouth and at mucocutaneous border. EBV pharyngitis can cause a clinical picture of exudative pharyngitis, almost identical to GAS pharyngitis.

Pharyngitis caused by group C and G streptococci and *A. haemolyticum* closely resembles GAS pharyngitis. Pharyngeal diphtheria presents with grayish-white membrane over one or both tonsils which may extend to involve uvula, soft palate and other surrounding areas.

Diagnosis

As bacteria other than *S. pyogenes* are rare cause of pharyngitis and sequelae of acute rheumatic fever do not occur, diagnostic armamentarium is directed towards diagnosis of GAS pharyngitis.

Throat Swab

Culture of throat swab specimen on sheep blood agar is gold standard for diagnosis of GAS pharyngitis. Cultures that are negative at 24 hours should be re-examined at 48 hours after incubation. Performed adequately (swabbing surfaces of both tonsils and posterior pharyngeal wall without touching other oropharyngeal areas), it has sensitivity of 90–95% for diagnosis of GAS pharyngitis. However, the culture isolates have to be seen in the clinical context as many a time the isolate may just be colonizing the throat rather than be a true pathogen.

Rapid Antigen Detection Test

To obviate the problem of delayed diagnosis by throat swab cultures, rapid antigen detection tests (RADTs) have been developed which enable identification of GAS pharyngitis from throat swab specimen within minutes. Older RADT employed latex agglutination and had lower sensitivity of about 70%. Newer tests employ enzyme immunoassay, optical immunoassay and DNA

probes and have sensitivity between 80% and 90%. Specificity of all RADTs is about 95%.

Neither culture nor RADTs differentiate asymptomatic streptococcal throat carriage from bonafide GAS pharyngitis. There is no role for serological test for diagnosis of acute GAS pharyngitis as they indicate past infection.

These diagnostic tests need not be performed in patients with pharyngitis whose clinical and epidemiological features do not suggest GAS pharyngitis, e.g., those with prominent nasal symptoms, herpangina or pharyngoconjunctival fever. Doing so, increases the yield of positive test results and helps in identification of truly infected cases rather than mere GAS carriers. Various clinical scoring systems have been developed to predict the probability of GAS pharyngitis and selectively use throat culture/RADT in those with high-risk of GAS infection. Clinical sign and symptoms used in these scoring systems include absence of cough, enlarged tender cervical lymph nodes, tonsillar exudates/swelling, age, fever above 38°C. Indian Academy of Pediatrics (IAP) has also endorsed the use of throat culture/RADT in the management algorithm of pharyngitis. **Flow chart 1** shows the IAP management algorithm for pharyngitis.

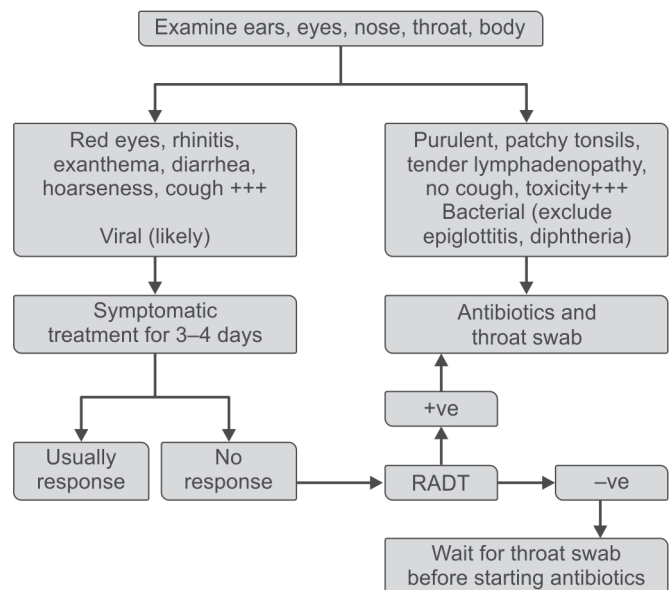

Treatment

As majority of pharyngitis cases are viral, symptomatic treatment is all that is required. Acetaminophen can be given for fever and pain relief. Aspirin should be avoided because of risk of Reye's syndrome in children. Warm saline gargles can be advised in older children. Simple lemon/ginger/honey based lozenges may be soothing, but those containing potentially harmful substances should be avoided.

Antibiotics should not be given to a child with pharyngitis in the absence of diagnosed GAS infection. The main goal of antibiotic treatment is prevention of complications of streptococcal disease as otherwise GAS pharyngitis is a self-limiting condition. Acute rheumatic fever can be prevented if antibiotics are started up to 9 days after onset of illness.

Penicillin is the treatment of choice in view of narrow spectrum of activity, low cost and high efficacy. Amoxicillin is usually preferred over penicillin V in children because of better acceptability and availability of pediatric formulations.

Flow chart 1 IAP management algorithm for pharyngitis

Abbreviation: RADT, rapid antigen detection tests.

For penicillin allergic individuals, macrolides (erythromycin/clarithromycin/azithromycin) are effective but they should not be used as first line antibiotics in nonallergic individuals. No strain of GAS has shown resistance to penicillin till date; however widespread macrolide resistance has been reported. First generation cephalosporins can also be used in penicillin allergic individuals who do not exhibit immediate hypersensitivity. Many studies have suggested that cephalosporins are more effective than penicillin in GAS eradication. However, they are expensive and because of wide spectrum of activity can encourage the development of resistance over a broad range of bacterial pathogens.

Most antibiotics need to be given for 10 days to achieve pharyngeal eradication of GAS, however 5 day course of azithromycin has been shown to be effective. Some preliminary studies have shown that once daily amoxicillin therapy is effective in treatment of pharyngitis.

Table 2 summarizes the antibiotic options and dosage for GAS pharyngitis.

Prognosis and Complications

Pharyngitis is a self-limiting condition that resolves spontaneously in 4–10 days. However complications, both suppurative and nonsuppurative, can occur in GAS infection (**Table 3**).

IN A NUTSHELL

1. Common cold is a viral illness, and antibiotics are not required.
2. Nasal discharge can become mucopurulent during course of common cold and is not an indicator of secondary bacterial infection.
3. Common cough and cold medications are not effective in children.
4. Clinical distinction between viral and bacterial etiologies of pharyngitis is difficult.
5. Throat swab culture and RADT are recommended if there is clinical suspicion of GAS pharyngitis.
6. Penicillin is first line treatment of GAS pharyngitis.
7. Antibiotics given within 9 days of onset of symptoms can prevent acute rheumatic fever.

Table 3 Complications of group A β hemolytic *Streptococcus pharyngitis*

Suppurative complications	Nonsuppurative complications
<ul style="list-style-type: none"> • Bacteremia • Peritonsillar/retropharyngeal abscess • Pneumonia • Otitis media • Sinusitis • Mastoiditis • Cervical lymphadenitis 	<ul style="list-style-type: none"> • Rheumatic fever • Poststreptococcal glomerulonephritis • Reactive arthritis • Pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection (PANDAS)

Table 2 Therapeutic options for group A streptococcal pharyngitis

Drug	Dose	Duration
<i>Penicillins</i>		
Penicillin V	Children < 27 kg: 250 mg BD/TDS Children > 27 kg: 500 mg BD/TDS	10 days
Amoxicillin	40 mg/kg/day TDS	10 days
Benzathine penicillin	Children < 27 kg: 600,000 U Children > 27 kg: 1200,000 U	Once
<i>For Penicillin allergic individuals</i>		
First generation cephalosporin		
Cephalexin	25–50 mg/kg/day BD-QID	10 days
Cefadroxil	30 mg/kg/day BD	
Erythromycin ethylsuccinate	40–50 mg/kg/day BD/TDS	10 days
Erythromycin estolate	20–40 mg/kg/day BD/TDS	10 days
Clarithromycin	15 mg/kg divided BD (max 250 mg BD)	10 days
Azithromycin	12 mg/kg OD (max 500 mg)	5 days

Chapter 39.9

Sinusitis

SD Subba Rao

Sinusitis in most children coexists with rhinitis; hence the term *rhinosinusitis* was coined by 1997 Task Force of Rhinology and Paranasal Sinus Committee. Acute rhinosinusitis (ARS) results from infection of one or more of the paranasal sinuses. Rhinosinusitis is a widely prevalent disease affecting more than 14% of adults and children. A viral infection associated with the common cold is the most frequent etiology of ARS (**Box 1**). A small percentage of post-viral ARS get transformed into acute bacterial rhinosinusitis (ABRS) (**Fig. 1**). It has high propensity to become chronic. Though the acute form of rhinosinusitis is unimicrobial, multiple microorganisms characterize the chronic form. In the chronic form, microbes usually demonstrate antimicrobial resistance and pose a therapeutic challenge for the clinician. Early detection and prompt and appropriate treatment of rhinosinusitis could possibly avert chronic rhinosinusitis.

DEVELOPMENT AND ANATOMY OF PARANASAL SINUSES

The paranasal sinuses develop as outpouching of the nasal cavity. The onset and duration of development of the paranasal sinuses vary depending upon the location. Development of the paranasal sinuses may not be fully complete until 20 years of age; however, by 12 years of age, the nasal cavity and paranasal sinuses in most individuals have nearly reached adult proportions.

- The maxillary sinuses are present at birth and expand rapidly by 4 years of age.
- The ethmoid sinuses are comprised of a collection of tiny air cells and are present at birth; each of these tiny air cells have their own opening into the nose.
- The sphenoid sinuses begin to develop by 2 years of life. They get pneumatized by 5 years of life and attain the adult size by 12 years.
- Frontal sinus development is variable:
 - Radiographic differentiation of frontal sinus from ethmoid sinus happens by 6–8 years of age.
 - Frontal sinuses complete their development by 8–10 years of age.
 - Majority of individuals (80%) have bilateral frontal sinuses and about 20% have unilateral hypoplasia of the frontal sinus.

DEFINITIONS

Sinusitis is defined as inflammation of the mucosal lining of one or more of the paranasal sinuses. Two or more of the following findings clinically define sinusitis:

- Nasal blockage/obstruction/congestion or nasal discharge (anterior/posterior nasal drip); \pm facial pain/pressure; and \pm cough *and either*
- Rhinoscopic signs suggestive of nasal polyps/mucopurulent discharge from middle meatus/edema or mucosal obstruction; *and/or*
- *CT changes*: Findings suggestive of mucosal changes in the ostiomeatal complexes or sinuses.

This definition, however, is not pragmatic as routine use of CT is not advised. Sinusitis is ultimately a clinical diagnosis (**Box 2**).

BOX 1 Common organisms causing acute rhinosinusitis

Viruses

- Rhinoviruses, coronavirus, influenza viruses, parainfluenza viruses, adenovirus, respiratory syncytial virus (RSV), and enterovirus

Bacteria

- *Streptococcus pneumoniae*
- *Haemophilus influenzae*
- *Moraxella catarrhalis*
- Beta-hemolytic *Streptococcus pyogenes*
- *Mycoplasma* and chlamydial species.

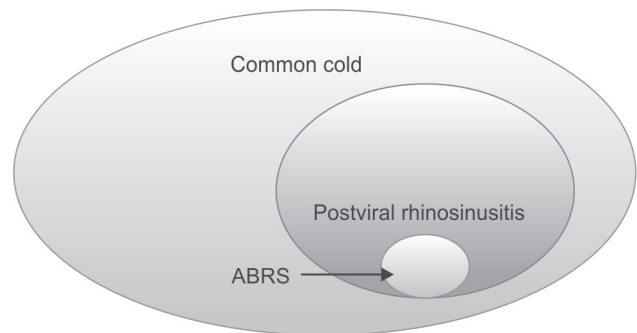

Figure 1 Relation of common cold, acute rhinosinusitis (ARS) and acute bacterial rhinosinusitis (ABRS)

BOX 2 Definitions of sinusitis

- When the duration of symptoms is less than 10 days then it is referred to as *acute viral rhinosinusitis*.
- When the symptoms increase after 5 days or persist beyond 10 days then it is referred to as *acute postviral rhinosinusitis*.
- When there is secondary bacterial infection of the sinuses then the term *acute bacterial rhinosinusitis* is used.

Acute Bacterial Rhinosinusitis

It is characterized by the presence of at least 3 of the following signs/symptoms:

- Pain locally which again could be unilateral
- Purulent secretion in cavum nasi, which may be unilateral
- Fever above 38°C
- Increased erythrocyte sedimentation rate/C-reactive protein (ESR/CRP)
- Deterioration after an initial milder phase of illness.

Acute bacterial rhinosinusitis has been classified as *acute*, *subacute*—symptoms completely resolve within or more than 30 and less than 90 days; and *recurrent acute*—at least three episodes of less than 30 days duration separated by intervals of more than or equal to 10 days without symptoms in a 6-month period, or at least four such episodes in a 12-month period.

Chronic Rhinosinusitis

Chronic sinusitis is defined by episodes of inflammation of the paranasal sinuses that last for above 90 days, during which patients have persistent symptoms.

PREDISPOSING FACTORS

- *Environmental exposures*: Seasonal variations, dust, dampness, exposure to other children with acute respiratory infections, air

pollution with exposure to air pollution, mucosal irritants (e.g., dry air, chlorinated water) have all been associated with an increase in the prevalence of symptoms of ARS.

- **Anatomical factors:** This could include—septal deviation, choanal atresia, nasal polyps and hypoplasia of sinuses.
- **Allergy:** Literature is not clear about the role of allergy in predisposing to ARS.
- **Ciliary impairment:** Loss of cilia and ciliated cells leading to impaired mucociliary clearance in allergic rhinitis predisposes to ARS. This has been seen in both viral and bacterial rhinosinusitis. Ciliary function is also disrupted in smokers and individuals with allergy thus making them prone to acute sinusitis.
- **Smoking:** Smokers with allergic inflammation have an increased susceptibility to ARS.
- **Concomitant chronic disease:** Some chronic diseases like bronchitis, asthma, diabetes mellitus, cardiac disease, and malignancy increase predisposition to ARS.
- **Sudden changes in atmospheric pressure** (e.g., descent in an airplane).

PATHOGENESIS

The paranasal sinuses are usually sterile, but the membranes that line the nose are continuous with the membranes that line the sinus cavities. Therefore, the paranasal sinuses may be contaminated with bacteria that colonize the nasal mucosa and nasopharynx. The contaminating bacteria are typically removed by mucociliary clearance. When mucociliary clearance is altered (e.g., by conditions that damage the ciliary epithelium or affect the number or function of cilia, the production or viscosity of mucous, or the patency of the Ostia), the sinuses may be inoculated with large numbers of microorganisms, and infection may develop.

The integrity of the ostiomeatal complex is most crucial for sinus health. Ostial obstruction is usually the start point for sinusitis. It generates a negative pressure in the sinus, which leads to fluid seepage into the sinus. This fluid being a good culture media gets easily infected. This damages the lining cilia, and mucus production is increased. Mucociliary clearance thus gets compromised. A self-perpetuating cycle is established, which needs to be interrupted for optimal outcome. One or more sinuses may be involved with infection.

CLINICAL FEATURES

Acute Bacterial Rhinosinusitis

The clinical and radiographic manifestations of ABRS in children are similar to those of viral upper respiratory infection (URI). The clinical course, particularly the persistence and severity of symptoms, helps to differentiate between uncomplicated viral URI and ABRS.

Typically two types of settings or clinical presentations are seen. Commonly it presents as an illness starting as a viral URI that lasts for 5–6 days and persists beyond or was initially improving but develops worsening symptoms or signs characterized by the new onset of fever, headache, or increase in nasal discharge. It can also present as an acute illness with severe symptoms or signs of high fever 39°C (102°F), purulent nasal discharge or facial pain lasting for at least 3–4 consecutive days right at the beginning of illness.

Cough (wet or dry) is an important symptom in ABRS. The cough must be present during the day, but is often described as worse at night. Nocturnal cough as a single persistent symptom is nonspecific, and more suggestive of postnasal drip or reactive airways disease. The cough becomes more prominent with increasing duration of illness. Nasal symptoms of ABRS include anterior or postnasal discharge, obstruction, and/or congestion.

The nasal discharge may be of any quality: watery, serous, or purulent. Postnasal discharge may cause vomiting.

On examination, there may be mild erythema and swelling of the nasal turbinates with mucopurulent anterior nasal discharge. Drainage from the posterior ethmoids may lead to purulent material in the posterior pharynx. Temperature above or equal to 39°C for at least 3 consecutive days is a component of the severe presentation of ABRS. Sinus tenderness (rare in young children) may be elicited with percussion of the upper molars or percussion or application of direct pressure over the body of the frontal or maxillary sinuses.

Acute bacterial rhinosinusitis needs to be differentiated from allergic rhinitis, infected nasal foreign body, structural abnormalities, and pertussis, particularly in the catarrhal stage.

Complications

These include preseptal (periorbital) and orbital cellulitis, septic cavernous sinus thrombosis, meningitis, osteomyelitis of the frontal bone, and epidural, subdural, or brain abscess.

Chronic Rhinosinusitis (CRS)

Chronic rhinosinusitis is usually a consequence of untreated, improperly treated, or nonresponding ARS. With chronicity, polymicrobes supercede. These include staphylococci, alpha-hemolytic streptococci, anaerobes such as peptostreptococci, *Bacteroides* and *Fusobacterium* species, *Pseudomonas*, other gram-negative enteric bacteria, and fungi.

Chronic rhinosinusitis is predominantly a heterogeneous inflammatory disease. It is multifactorial with environmental and host general and anatomic factors all playing a role in its development. Persistence of infection (biofilms and osteitis), allergy, immunologic disorders, upper airway intrinsic factors, superantigens-induced polyclonal immune response, fungi with eosinophilic inflammation, remodeling, and metabolic problems such as aspirin sensitivity all contribute to the varied picture of chronic rhinosinusitis. It is a tough disease to manage and is characterized by multiple recurrences.

DIAGNOSIS

Diagnosis of rhinosinusitis in children should be suspected when cold does not improve beyond 10 days or nasal stuffiness is present with purulent discharge, facial pain, headache, fever, and diminution/loss of sense of smell. Sneezing and nasal itching are common with allergic rhinitis. In these children with isolated allergic rhinitis, purulent nasal discharge is usually not seen. In those children of allergic rhinitis with superadded sinusitis, the picture is altered, and along with nasal itching and sneezing, purulent nasal secretions and loss of olfaction sense may also be associated.

The diagnosis of uncomplicated ABRS in children is usually made clinically. *Transillumination of sinuses* is useful in hands of experienced person. A flashlight is placed against the patient's cheek and the doctor looks into the patient's open mouth. A lit-up reddened area is seen in the palatal area with normal sinuses. When sinuses are fluid-filled, this reddened area will not be visualized.

Imaging studies are recommended for children suspected to have orbital and intracranial complications of ABRS. Plain radiography of paranasal sinuses has a limited diagnostic role. It is recommended that children with potential orbital or intracranial complications of ABRS undergo contrast-enhanced computed tomography (CT) imaging of the orbits, sinuses, and brain. MRI is indicated for detection of intracranial complications without exposure to radiation.

Microbiologic Studies

Microbiologic studies usually are not necessary for children with uncomplicated ABRS who improve as expected with antimicrobial therapy. However, attempts should be made to identify the pathogen in children who are toxic-appearing, and those with orbital or intracranial complications, immunocompromised children, children with recurrent ABRS, and children who fail to respond to antimicrobial therapy.

MANAGEMENT

Conservative Therapy

Since majority of ARS is viral in origin, they resolve without the need for antibiotics. They need symptomatic treatment in the form of steam inhalation, adequate hydration, instillation of topical decongestants, warm facial packs application, and saline nasal drops and reassurance.

Antibiotics

Antibiotic therapy should be reserved for patients with severe or persistent ARS. Benefits and adverse effects of antibiotics should be carefully weighed before prescribing them. A *wait-and-watch* policy for 7–10 days is fruitful and cost-effective. About 90% recover without antibiotics in a week. Choice of antibiotics should be guided by local susceptibility studies, safety profile, and child's age. Usual preferred are amoxicillin, co-amoxyclov, oral cephalosporins, and macrolide group of antibiotics. A 2 weeks course is usually required.

Other Treatment Modalities

Intranasal corticosteroids either as monotherapy or in conjunction with antibiotics have been shown to be beneficial in treatment of ARS, in a few studies. Nasal saline irrigations and topical cromolyn have also been found to be useful. Ipratropium bromide may be effective in ameliorating rhinorrhea.

The saline irrigations assist to mechanically clear secretions, minimize bacterial and allergen burden, and improve mucociliary function. Antihistamines are useful only when there is coexisting allergic rhinitis. Nasal decongestants are useful to decrease congestion and in the hope of improving better sinus ventilation and drainage. They also provide symptomatic relief of nasal congestion. Nasal decongestants decrease mucus production and can be safely used for 5–7 days. Even though it is routine practice to use steam inhalation for ARS it has not shown any consistent benefits in the treatment of common cold symptoms.

IN A NUTSHELL

1. A viral infection associated with the common cold is the most frequent etiology of ARS. A small percentage of postviral ARS gets transformed into ABRS.
2. Viral URI and allergic rhinitis are the most frequent predisposing factors for ABRS in children.
3. The clinical features of ABRS include cough, nasal symptoms, fever, headache, facial pain and swelling, sore throat, and halitosis.
4. The clinical course, particularly the persistence and severity of symptoms, helps to differentiate between the ABRS and viral URI.
5. The diagnosis of uncomplicated ABRS can be made clinically. There is no role for X-ray, CT or MRI in uncomplicated cases.
6. Treatment is symptomatic. Antibiotics are needed in a small proportion of children with severe or persistent ABRS.

Chapter 39.10

Tonsils and Adenoids

Pallab Chatterjee

The past decade has seen a major change in the management of adenotonsillar diseases in children. Adenotonsillectomy is now one of the most common surgical procedures in children under 15 years. In recent years, sleep-disordered breathing/obstructive sleep apnea (SDB/OSA) in children (Chapter 39.11) has emerged as the primary indication for removal of the tonsils and adenoids.

ANATOMY

The ring of lymphoid tissue surrounding the opening of the oral and nasal cavities into the pharynx is known as the Waldeyer ring. It is the body's first line of defense against pathogens that are ingested or inhaled. It consists of the palatine tonsils, the adenoids, the lymphoid tissue around the opening of the eustachian tube in the nasopharynx, the lingual tonsil at the base of the tongue, and some scattered lymphoid tissue in the pharynx, especially behind the posterior pharyngeal pillars and along the posterior pharyngeal wall.

The palatine tonsil is situated at the junction of the oral cavity and the oropharynx. The arterial supply is by the tonsillar branches of the dorsal lingual artery and the facial artery, and the venous drainage is into the internal jugular vein. The lymphatic drainage is to the upper deep cervical nodes (tonsillar or jugulodigastric nodes) situated behind the angle of the mandible.

The nasopharyngeal tonsil, or adenoid, is a mass of lymphoid tissue located with the base toward the roof and posterior wall of the nasopharynx and the apex directed towards the nasal septum. Adenoids are fully developed during the seventh month of gestation and continue to grow till the fifth year of life. It is lined by respiratory epithelium (stratified and pseudostratified ciliated columnar), with no surrounding capsule, and simple crypts. The lymphatic drainage is to the lymph nodes situated in the retropharyngeal and pharyngomaxillary space.

IMMUNOLOGY

The adenoids and tonsils serve as secondary lymphoid organs initiating an immune response against antigens entering the body through the nose and the mouth. Both contain B-cell lymphocytes (50–65%), T-cell lymphocytes (40%) and mature plasma cells (3%). They are involved in inducing secretory immunity and regulating secretory immunoglobulin production. The lymphoid follicles thus stimulated result in expansion of B-cell clones and differentiation of B-cells into memory cells and plasma cells. The adenoids and tonsils are thus a source of B-cells for effector sites in the upper respiratory tract mucosa and an important source of secretory immunoglobulin (IgA). The tonsils are immunologically most active between 3 years and 10 years of age, and then decrease after puberty. There are conflicting studies regarding the effects of adenotonsillectomy on immunity, and no studies indicate a demonstrable clinical impact on the immune system.

CLINICAL PRESENTATION

Diseases of the adenoids and tonsils can be broadly classified as those caused by infections or hypertrophy resulting in obstruction of the airways. These disease processes can affect the nasopharyngeal tonsils (or adenoids) or the palatine tonsils, or both. A generalized inflammation of the pharyngeal structures, including tonsils, is known as pharyngotonsillitis. It may be classified according

to the duration of symptoms into acute, chronic and subacute, an acute presentation being the most common. Adenoiditis, an inflammation of the adenoids, is difficult to diagnose in the primary care setting as the tissue is not directly visualized.

ACUTE TONSILLITIS

The most common presentation of acute inflammation of the tonsils is sore throat and fever. It may be associated with enlarged and tender cervical lymph nodes. On examination, the tonsils appear erythematous and swollen with purulent exudates either on the surface or within the tonsillar crypts. There may also be petechiae on the palate, more commonly with Group A beta-hemolytic streptococci (GABHS). There is considerable overlap between the presenting features of a bacterial and a viral tonsillar infection, thus making a definite diagnosis based on clinical examination alone difficult.

The causative organisms for acute pharyngotonsillitis (**Box 1**) are varied with Group A beta-hemolytic *Streptococcus*, adenovirus, Epstein-Barr virus, and *Mycoplasma* accounting for more than 90%. This has been discussed in detail in Chapter 39.8.

Viral Tonsillitis

Adenovirus infection of the tonsils is the most common cause of sore throat in infants and children. It may be associated with high fever, leukocytosis and elevated CRP, creating difficult differential diagnostic problems from bacterial tonsillitis. Coxsackie A viruses cause sporadic outbreaks of herpangina, commonly affecting children between 3 years and 10 years of age. This is a contagious disease that is characterized by small painful vesicular lesions in the oropharynx and on the surface of the tonsils after a 3–4 day incubation period and runs a self-limiting course for 4–5 days. Viral tonsillitis is commonly self-limiting and there are no sensitive rapid diagnostic tests for confirmation of an adenovirus or a coxsackievirus infection. Treatment is symptomatic with avoidance of use of antibiotics.

BOX 1 Causes of pharyngotonsillitis

- A. Common bacterial pathogens
 1. Group A streptococci
 2. Group C streptococci
 3. Group G streptococci
- B. Less common bacterial pathogens
 1. *Chlamydia pneumoniae*
 2. *Mycoplasma pneumoniae*
 3. *Arcanobacterium haemolyticum*
 4. *Corynebacterium diphtheriae*
 5. *Fusobacterium necrophorum*
 6. *Neisseria gonorrhoeae*
 7. *Treponema pallidum*
 8. *Francisella tularensis*
- C. Viruses
 1. Rhinovirus
 2. Adenovirus
 3. Influenza A and B
 4. Parainfluenza
 5. Coxsackievirus
 6. Echovirus
 7. Epstein-Barr virus
 8. Human immunodeficiency virus
 9. Cytomegalovirus
 10. Respiratory syncytial virus
 11. Metapneumovirus
- D. Fungi
 - Candida* species
- E. Parasites
 - Toxoplasma gondii*

Infectious mononucleosis, caused by infection by Epstein-Barr virus (EBV), is an acute self-limiting disease that may present with tonsillitis. Cytomegalovirus infection is also known to produce a syndrome similar to infectious mononucleosis. It may present with hypertrophied tonsils with exudates as those in Group A beta-hemolytic streptococcal infection. The presence of palatal petechiae, splenomegaly and posterior cervical adenopathy are highly suggestive of infectious mononucleosis, while the absence of cervical lymphadenopathy and malaise make the diagnosis much less likely.

Other Organisms

The role of anaerobic bacteria causing tonsillitis in children has been underestimated, and is more common in recurrent or chronic tonsillitis, examples being Vincent's angina and infection with *Fusobacterium necrophorum*. These are best treated with a penicillin and metronidazole or clindamycin. The drug of choice for infection due to *Arcanobacterium haemolyticum* are macrolides (erythromycin or azithromycin); other drugs like clindamycin, doxycycline, ciprofloxacin and vancomycin are also effective.

Diphtheria is caused by toxin-producing strains of *Corynebacterium diphtheriae* and rarely by toxigenic strains of other *Corynebacterium* species (*C. ulcerans*, *C. haemolyticum* or *C. pseudotuberculosis*). It is rather rare now in the developed countries but is endemic in many parts of Africa, Asia (Afghanistan, Bangladesh, Bhutan, Cambodia, China, India, Indonesia, Laos, Mongolia, Myanmar, Nepal, Pakistan, Papua New Guinea, Philippines, Thailand and Vietnam), the Middle East (Iran, Iraq, Syria and Yemen) and Europe (Turkey, Albania and all countries of the former Soviet Union).

CHRONIC AND RECURRENT TONSILLITIS

This entity in children is not very well-defined, but may be described as a sore throat for 3 months or more, associated with inflammation of the tonsils. The etiology of recurrent tonsillitis is polymicrobial in origin (**Box 2**), with mixed anaerobic and aerobic infection or penicillin-resistant GABHS. Persistence of streptococcal carriage in the setting of a viral infection, nonadherence with the prescribed regimen, new infection acquired from close contacts and, rarely, treatment failure of the original infection may be the cause. Bacteria, lymphocytes, desquamated epithelial cells and other debris accumulate in the crypts of the tonsils resulting in cryptic tonsillitis. These cryptic plugs can then calcify into concretions or tonsilloliths. The presenting features are chronic sore throat, halitosis, a foreign body sensation in the throat, or a history of expelling smelly foul-tasting cheesy lumps. Examination reveals tonsils of varying sizes with the crypts having large quantities of debris. The drug of choice in these patients is clindamycin. New guidelines recommend watchful waiting for a 12-month period for recurrent tonsillitis in children not meeting the Paradise criteria (**Box 3**). However, patients with a history of recurrent

severe infections requiring hospitalization, or those who have had sequelae, such as peritonsillar abscess or Lemierre syndrome, may be considered for tonsillectomy before the end of the 12-month period even if they do not meet the frequency criteria.

COMPLICATIONS

The complications are divided into suppurative, local (peritonsillar, retropharyngeal and parapharyngeal cellulitis and/or abscesses, cervical lymphadenitis and mastoiditis) and nonsuppurative, systemic (acute rheumatic fever, scarlet fever, post-streptococcal glomerulonephritis and pediatric autoimmune neuropsychiatric disorder associated with group A streptococci (PANDAS)) complications. The nonsuppurative complications are beyond the scope of this chapter, and are discussed in their respective sections.

Peritonsillar Abscess (Quinsy)

This is a collection of pus between the superior constrictor muscle of the pharynx and the fibrous capsule of the tonsil. The origin is usually believed to be from the tonsillar crypts into the peritonsillar space through the tonsillar capsule, though another theory postulates its origin from supratonsillar fossa from an abscess in the salivary glands.

The symptoms are unilateral throat pain, odynophagia, trismus, otalgia, drooling and fever. There is a deviation of the uvula with an asymmetric peritonsillar swelling. The swelling of the anterior faucial pillar and palate displaces the tonsil downwards and medially. The confirmation of the diagnosis is by radioimaging or needle aspiration, the latter also being therapeutic. However, incision and drainage under general anesthesia with simultaneous tonsillectomy (quinsy tonsillectomy), makes most sense in small children. Anaerobes are commonly implicated, the drugs of choice being penicillin plus metronidazole or clindamycin.

Parapharyngeal Abscess

Infection of the tonsils can spread into the parapharyngeal space, resulting in high-grade fever with pain and stiffness of the neck along with swelling of the lateral pharyngeal wall. Diagnosis is by contrast-enhanced computed tomography (CECT) of the neck and treatment is by external incision and drainage and IV antibiotics.

BOX 2 Common causes of recurrent tonsillitis

Viral

- Adenovirus
- Rhinovirus
- Coronavirus
- Influenza virus
- Epstein-Barr virus

Bacterial

- Group-A beta-hemolytic streptococci
- *Moraxella catarrhalis*
- *Haemophilus influenzae*

BOX 3 Paradise criteria for tonsillectomy

Criterion definition

- Minimum frequency of sore throat episodes 7 or more episodes in the preceding year, (OR)
- 5 or more episodes in each of the preceding 2 years, (OR)
- 3 or more episodes in each of the preceding 3 years

Clinical features (sore throat plus the presence of 1 or more qualifies as a counting episode)

- Temperature more than 38°C, (OR)
- Cervical lymphadenopathy (tender lymph nodes or > 2 cm), (OR)
- Tonsillar exudates, (OR)
- Positive culture for group A beta-hemolytic *Streptococcus*

Treatment

- Antibiotics administered in conventional dosage for proved or suspected streptococcal episodes

Documentation

- Each episode and its qualifying features substantiated by contemporaneous notation in a clinical record, (OR)
- If not fully documented, subsequent observance by the clinician of 2 episodes of throat infection with patterns of frequency and clinical features consistent with the initial history
- Sleep apnea due to (adeno) tonsillar hypertrophy is now considered also a valid indication.

Lemierre' Syndrome

This is a septic thrombophlebitis of the jugular vein. Patients, usually adolescents, are very toxic with sudden onset high-grade fever with chills, neck pain and stiffness. There is associated respiratory distress as a result of multiple septic pulmonary emboli. This is usually a complication of a parapharyngeal space or odontogenic infection from *Fusobacterium necrophorum*. Treatment is by high-dose intravenous antibiotics (ampicillin-sulbactam, clindamycin or ciprofloxacin) and heparinization.

ADENOIDITIS

Acute Adenoiditis

The sudden onset of symptoms of acute adenoiditis is difficult to distinguish from those of a general upper respiratory tract infection and rhinosinusitis. Patients present with nasal obstruction, nasal discharge that may be clear or purulent, high-grade fever, cough, postnasal drip, mouth breathing, and often associated otitis media. Chronic adenoiditis is defined as symptoms lasting for more than 3 months, and results in the adenoid harboring bacteria and acting as a reservoir of infection for the paranasal sinuses. The adenoids play an important role in the development of otitis media. It was initially thought that the proximity of the adenoids in the nasopharynx with the middle ear and the eustachian tube predisposes the child to otitis media as a result of mechanical obstruction. It is now thought that the effect is likely one of local inflammation and mucosal edema as a result of regional spread of a bacterial biofilm leading to eustachian tube dysfunction and development of otitis media, rather than one of direct compression. If a child presents with the classic complaints of otitis media, with or without effusion, with acute or chronic nasal obstruction, mouth breathing, and a postnasal drip, an evaluation of the nasopharynx is warranted in addition to the middle ears.

Recurrent or Chronic Adenoiditis

This diagnosis is based on clinical features more than examination findings as the adenoid tissue is situated at a place where visualization and direct culture is difficult. Most children present with a blocked nose, mucopurulent posterior nasal drip, chronic cough, halitosis. They tend to continuously *snort* or *gag* on the mucus and develop a nasal intonation of speech. This results from the hyperplastic adenoids encroaching on the posterior nasal choanae resulting in collection of secretions in the nose. Common organisms implicated are *Haemophilus influenzae*, *Moraxella catarrhalis*, *Staphylococcus aureus*, and streptococci including GABHS and *Streptococcus pneumoniae*.

Common antibiotics intended for treating upper respiratory pathogens are useful for patients with chronic adenoiditis (see *Chronic tonsillitis* above). Many organisms, particularly *Haemophilus influenzae*, form biofilms inside the adenoid tissue resulting in resistance to therapy. Inflammation of the adenoids can also result from allergic rhinitis and gastroesophageal reflux disease.

Airway Obstruction

Hypertrophied tonsils and adenoids are a major common cause of upper airway obstruction in children. This manifests as (SDB/OSA) syndrome, and upper airway resistance syndrome (See Chapter 39.11). The children present with a history of daytime symptoms (like nasal obstruction, hyposmia, chronic mouth breathing, rhinolalia clausa, poor appetite, poor school performance, and occasionally symptoms of right heart failure) and night-time symptoms (like snoring, choking, gasping, apnea, abnormal sleep postures, restless sleep, somnambulism, night terrors, excessive sweating and enuresis). As a result of chronic mouth breathing there is a change in facial development, leading to an increase in

the total anterior facial height and a tendency towards retrognathia of the mandible, resulting in the typical adenoid facies (**Figs 1A and B**). The size of the tonsils as seen on direct examination of the oropharynx, may not be indicative of the degree of airway obstruction. The oropharyngeal airway is designated by the linear distance between the two anterior tonsillar pillars (**Box 4**). Tonsillar hypertrophy is defined as 3+ or 4+. Tonsils need not be kissing to be graded 4+. Although this grading system is easy to follow and understand, many studies have shown that the volume of the adenoids and tonsils relative to the oropharynx is a better determinant of the severity of the sleep-disordered breathing and obstructive sleep apnea.

Evaluation of the size of the adenoids is done by a radiograph of the neck or fiber-optic nasopharyngoscopy. The simple plain lateral X-ray of the neck is still an excellent tool for screening and identification of the adenoids (**Fig. 2**) and based on the percentage of air column available in front of the adenoids, a 25%, 50% or 75% reduction is classified as mild, moderate or severe adenoid hypertrophy respectively. Another technique is by comparing the air column with the thickness of the soft palate. The air column is normal if it is more than the thickness of the soft palate. When the thickness is similar, it is mild enlargement. When it is narrower than the soft palate but wider than half the soft palate, it is moderate hypertrophy and if further narrowed and less than half thickness of soft palate, it is severe hypertrophy. However, X-rays can underestimate hypertrophy compared with nasopharyngoscopy. The palatine tonsils in the oropharynx cannot be assessed with X-ray.

Nasopharyngoscopic examination of the adenoids gives a better estimation of the degree of adenoid hypertrophy. It is graded from adenoids not in contact with adjacent structures (Grade 1) to the most severe where the adenoid tissue is in direct contact with the palate at rest (Grade 4).

Figures 1A and B A child with typical adenoid facies: (A) Anteroposterior; (B) Lateral views. Note: The allergic shiners, open mouth, increase in anterior facial height and a tendency towards retrognathia of the mandible

BOX 4 Mallampati scoring (or Brodsky grading scale) of tonsillar size

Tonsil 0:	Tonsils fit within the tonsillar fossa
Tonsil 1+:	Tonsils < 25% of space between the pillars/oropharyngeal width
Tonsil 2+:	Tonsils < 50% of space between the pillars/oropharyngeal width
Tonsil 3+:	Tonsils < 75% of space between the pillars/oropharyngeal width
Tonsil 4+:	Tonsils > 75% of space between the pillars/oropharyngeal width

Figure 2 X-ray of the neck showing severe adenoid hypertrophy

TONSILLOADENOIDECTOMY

Tonsillectomy, with or without adenoidectomy, is the second most common surgical procedure performed in children. Complete removal of the tonsil, including its capsule, by dissecting the peritonsillar space between the tonsil capsule and the muscular wall is called tonsillectomy. Tonsillotomy is subtotal removal of the tonsils without violating the tonsillar capsule.

The indications for tonsillectomy are enumerated in **Box 3**. Indications for adenoidectomy include along with tonsillectomy for SDB/OSA, chronic otitis media with effusion and eustachian tube dysfunction, and recurrent acute sinusitis with failure of medical treatment.

The various techniques used are cold dissection (traditional method using scalpel, guillotine and snare), electrocautery (using electric energy to generate temperatures of 400°C–600°C directly to the tonsillar area), Coblation (using bipolar radiofrequency energy to generate a high-energy ionized plasma field at a much lower temperature of 40°C–70°C), and microdebrider (using a rapidly rotating blade that suctions out excised tonsillar tissue while preserving the capsule). Because of the much lower temperatures used, there is reduced thermal damage to surrounding tissue and muscle, resulting in much less pain particularly in the immediate postoperative day with coblation.

Complications of tonsilloadenoidectomy are rare, and include postoperative hemorrhage (immediate postoperative period or delayed after separation of the eschar), anesthetic and airway risks, aspiration, airway obstruction (due to edema of tongue, palate or pharynx, or retropharyngeal hematoma), cardiac arrhythmia, vocal cord trauma, pulmonary edema, subluxation of the atlanto-axial joint (Grisel syndrome), dislocation of the mandible, injury to the eustachian tube, nasopharyngeal stenosis, palatopharyngeal insufficiency, central apnea, refractory torticollis and psychological trauma. Hypernasal speech immediately after surgery is common secondary to pain and restricted movement of the tonsillar pillars and soft palate, and subsides with conservative management. Velopharyngeal insufficiency is an uncommon complication where patients present with hypernasal speech and reflux of fluids through the nose. Children with history of cleft palate or submucosal cleft should not undergo adenoidectomy to prevent this complication. Estimated mortality rates range from 1 in 16,000 to 1 in 35,000 and are due to bleeding, aspiration, electrolyte imbalance or anesthetic

complications (like malignant hyperthermia, cardiac arrhythmia, vocal cord trauma, aspiration with resulting bronchopulmonary obstruction or infection, etc.). Postoperative respiratory complications following adenotonsillectomy are more common in obese children with OSA, hypotonia or craniofacial anomalies (e.g., Treacher Collins syndrome, Crouzon syndrome, Apert syndrome, etc.) in whom the procedure may not be curative for SDB. The potential benefits include reduction in frequency of ear, nose and throat illness, reduction in nasal obstruction with improvement in respiratory function, sleep, craniofacial growth and development, improvement in hearing impairment and improved growth and overall well-being.

Grisel syndrome or atlantoaxial subluxation is an uncommon complication of adenotonsillectomy resulting from decalcification of the anterior arch of the atlas and laxity of the anterior transverse ligament between the atlas and axis in the cervical spine. Patients present with a stiff neck, spasms of the sternomastoid or deep cervical muscle. Patients typically hold their head to one side with slight rotation toward the opposite side. Patients with Down syndrome are more susceptible to traumatic atlantoaxial subluxation after AT and thus great care is taken with cervical spine manipulation during surgery in patients with Down syndrome. Treatment consists of intravenous antibiotics and possible cervical traction as most cases are secondary to infection or trauma.

IN A NUTSHELL

1. Adenoids and tonsils are part of the Waldeyer ring that serve as a defense against inhaled and ingested pathogens and is an important source of precursors of B-cells.
2. The common disturbances are infections and hyperplasia. Self-limiting viral infections are the most common, followed by GABHS. Infectious mononucleosis caused by Epstein-Barr virus usually affects older children and adolescents.
3. Neoplasm is very rare in children, of which lymphomas are the primary cause.
4. Sleep-disordered breathing/obstructive sleep apnea is currently the most common indication for adenotonsillectomy in pediatrics.
5. Children with even moderately severe recurrent tonsillitis (except those meeting the Paradise criteria) may benefit from watchful waiting for a period of 1 year.
6. Adenotonsillectomy may not be curative in obese children with OSA, neuromuscular disorders, Down syndrome and craniofacial abnormalities; it may even be associated with an increased risk of postoperative respiratory complications.
7. Surgical techniques are safe and risk of complications are low in properly selected patients.

Chapter 39.11

Obstructive Sleep Apnea

Zeynep Seda Uyan, Refika Ersu

Obstructive sleep apnea (OSA) is now widely recognized as a cause of significant morbidity among children, especially in the last few decades. It is characterized by episodes of complete or partial upper airway obstruction during sleep, often resulting in gas exchange abnormalities and disruption of sleep patterns. Childhood OSA is frequently diagnosed in association with adenotonsillar hypertrophy and obesity. It is also common in children with craniofacial abnormalities and neurologic disorders affecting upper airway patency. Untreated OSA can be associated with cardiovascular complications, impaired growth, learning problems, and behavioral problems. Therefore, early diagnosis and treatment of OSA may decrease morbidity. However, its diagnosis is frequently delayed.

EPIDEMIOLOGY

Obstructive sleep apnea exists in 1–4% of children and can occur in children of all ages, from neonates to adolescents, with a peak prevalence around 2–8 years. Habitual snoring during sleep which is the hallmark indicator of increased upper airway resistance can be seen in 7–8% of children. The ratio between habitual snoring and OSA is between 4:1 and 6:1 and accurate identification of habitually snoring children who have OSA is particularly challenging. The American Academy of Pediatrics (AAP) recommends that caregivers of children be asked about snoring during routine health-care visits and when the possibility of OSA is raised by suggestive symptoms.

ETIOLOGY

Adenotonsillar hypertrophy and obesity are the major risk factors for OSA in otherwise healthy children (**Box 1**). OSA also occurs in children with upper airway narrowing caused by craniofacial anomalies or in those with neuromuscular abnormalities such as hypotonia or muscular lack of coordination. Infection of the airways, allergy, supraglottic edema, mucopolysaccharide storage disease, laryngomalacia, subglottic stenosis, hypothyroidism may also result in altered soft tissue size leading to OSA. Genetic factors and ethnicity may also play a part. OSA is more common in African-Americans.

BOX 1 Risk factors associated with obstructive sleep apnea

- Adenotonsillar hypertrophy
- Obesity
- Allergic rhinitis
- Craniofacial anomalies (retrognathia, micrognathia, midface hypoplasia, etc.)
- Cerebral palsy
- Down syndrome
- Neuromuscular disorders
- Myelomeningocele
- Mucopolysaccharidoses
- Prader-Willi syndrome
- Achondroplasia
- Orthodontic problems (high narrow hard palate, overlapping incisors, cross bite, etc.)
- History of low birthweight
- Foreign body
- Family history of OSA

Abbreviation: OSA, obstructive sleep apnea.

PATHOPHYSIOLOGY

Childhood OSA results from a combination of structural and neuromuscular abnormalities. It occurs when the upper airway collapses during inspiration. The patency of the upper airway during sleep is controlled by complex interactions between upper airway resistance, pharyngeal collapsibility, tone of pharyngeal dilator muscles, and negative intraluminal pressure generated by the muscles of inspiration. In some children, this balance of mechanical forces can be disrupted. For instance, enlarged adenotonsillar tissue and obesity may increase resistance to airflow and pharyngeal collapsibility. The tendency of the airway walls to collapse under the influence of negative intraluminal pressure is counterbalanced by increased neuromuscular activation of the pharyngeal dilator muscles. Abrupt, intermittent reductions in activation of the pharyngeal dilator muscles during sleep in susceptible individuals leads to episodic airway collapse and hypopneic or apneic events.

CLINICAL FEATURES

Almost all children with OSA snore, although caregivers frequently do not give this information voluntarily at medical visits. Therefore, asking about snoring at each visit is a kind of screening method for OSA but it is important not to forget that OSA is less common than snoring. Thus, a positive answer should be followed by a detailed history and examination to determine whether further evaluation for OSA is needed. Both night-time and daytime symptoms should be evaluated together with physical examination findings (**Box 2**). It is important to note tonsil size during physical examination or to describe oropharyngeal crowding preferably according to objective classifications, e.g., Brodsky classification and Mallampati classification, respectively. Although there is generally no correlation between size of the adenotonsillar tissue and the presence or severity of upper airway obstruction during sleep, the amount of adenotonsillar tissue may be important in guiding management. Further information regarding obstruction can be obtained during direct laryngoscopy performed by an otolaryngologist.

BOX 2 Symptoms and signs of obstructive sleep apnea*Night-time symptoms*

- Habitual snoring (≥ 3 nights/week)
- Restless sleep and frequent awakenings
- Excessive sweating
- Night terrors
- Nocturnal enuresis
- Sleeping in a seated position or with the neck hyperextended
- Observed episodes of apnea

Daytime symptoms

- Mouth breathing and limited nasal airflow
- Chronic rhinorrhea
- Headache on awakening
- Daytime sleepiness
- Recurrent ear infections
- Attention deficit hyperactivity disorder
- Learning problems

Physical examination findings

- Underweight or overweight
- Adenoidal facies
- Tonsillar hypertrophy
- Retrognathia/micrognathia
- Pectus excavatum
- Enlarged neck circumference
- Hypertension

APPROACH TO DIAGNOSIS

A complete diagnostic evaluation for OSA consists of a focused sleep history, physical examination, and polysomnography (PSG). Additional testing is sometimes indicated. The diagnostic process may be modified depending on the clinical level of suspicion for OSA and local resources. Children who snore on most or all nights (equal to or more than 4 days a week) should undergo diagnostic evaluation, which includes a careful history and physical examination. Although history and physical examination are useful to screen patients and determine which patients need further investigation for OSA, the sensitivity and specificity of the history and physical examination are poor. Physical examination when the child is awake may be normal. The size of the tonsils cannot be used to predict the presence of OSA in an individual child. Thus, objective testing is required. The gold standard test is overnight PSG which is, at least presently, the only definitive diagnostic approach for OSA.

Polysomnography

Polysomnography should be performed and interpreted by clinicians with training in sleep medicine. It is a noninvasive test involving the measurement of a number of physiologic functions overnight including electroencephalography, pulse oximetry, oronasal airflow, abdominal and chest wall movements, partial pressure of carbon dioxide and video recording. Specific pediatric measuring and scoring criteria should be used while evaluating the results of children. PSG will demonstrate not only the presence or absence of OSA but also the severity of OSA, which is helpful in planning treatment and in postoperative short- and long-term management.

Indices Used to Characterize Obstructive Sleep Apnea

Apnea is a above 90% decrease in airflow that lasts equal to or above 90% of the duration of two normal breaths, as determined from the baseline breathing pattern. Apnea is considered *obstructive* if there is continued or increased inspiratory effort during the entire period of decreased airflow (**Fig. 1**). It is considered *central* if inspiratory effort is absent during the entire period of airflow cessation (**Fig. 2**). It is considered *mixed* if the inspiratory effort is absent during one portion of the event and the inspiratory effort is present in another

portion (**Fig. 3**). Hypopnea is a more than or equal to 30% decrease in airflow that lasts more than or equal to 90% of the duration of two normal breaths AND the decreased airflow is associated with an arousal or at least 3% oxyhemoglobin desaturation (**Fig. 4**).

The *apnea-hypopnea index* (AHI) is the number of apneas plus hypopneas that occur per hour of sleep. *Respiratory effort-related arousal* (RERA) is a respiratory event associated with an arousal lasting the duration of two breaths, with increasing respiratory effort, flattening of the inspiratory portion of the nasal pressure waveform, snoring, or an elevation in the end-tidal PCO₂ leading to an arousal from sleep, when the sequence of breaths does not meet criteria for an apnea or hypopnea. The *respiratory disturbance index* (RDI) is the number of apneas, hypopneas, and RERAs per hour of sleep. *Obstructive hypoventilation* exists when the end-tidal or transcutaneous CO₂ exceeds 50 mm Hg for more than 25% of the total sleep time. *Hypoxemia* is defined as an oxyhemoglobin saturation (SpO₂) of less than 92%. Additional events reported during PSG include arousals, snoring, changes in body position, and limb movements. Indices other than AHI that can be calculated from the PSG data include sleep efficiency, sleep stage percentage, sleep stage latency, sleep stage distribution, the apnea index and the arousal index.

If overnight PSG is not available, sleep questionnaires, in-home overnight audiotaping, videotaping, pulse oximetry, daytime nap PSG or ambulatory PSG can be used for the diagnosis of OSA keeping in mind that these alternative tests have a low negative predictive value.

MANAGEMENT

Indications for Treatment

Treatment is considered if the child is at increased risk for having OSA and fits at least one of the following criteria:

1. AHI more than 5 episodes/hour in any child, irrespective of the presence of OSA-related morbidity.
2. AHI 1–5 episodes/hour and systolic or diastolic blood pressure consistently above 95th percentile for gender, age, and height, or documented pulmonary hypertension.
3. AHI 1–5 episodes/hour and morbidity from the central nervous system (excessive daytime sleepiness, hyperactivity, inattention, and academic difficulties).

Figure 1 Episodes of obstructive sleep apnea (marked with red) accompanied by desaturations during 120 seconds of sleep

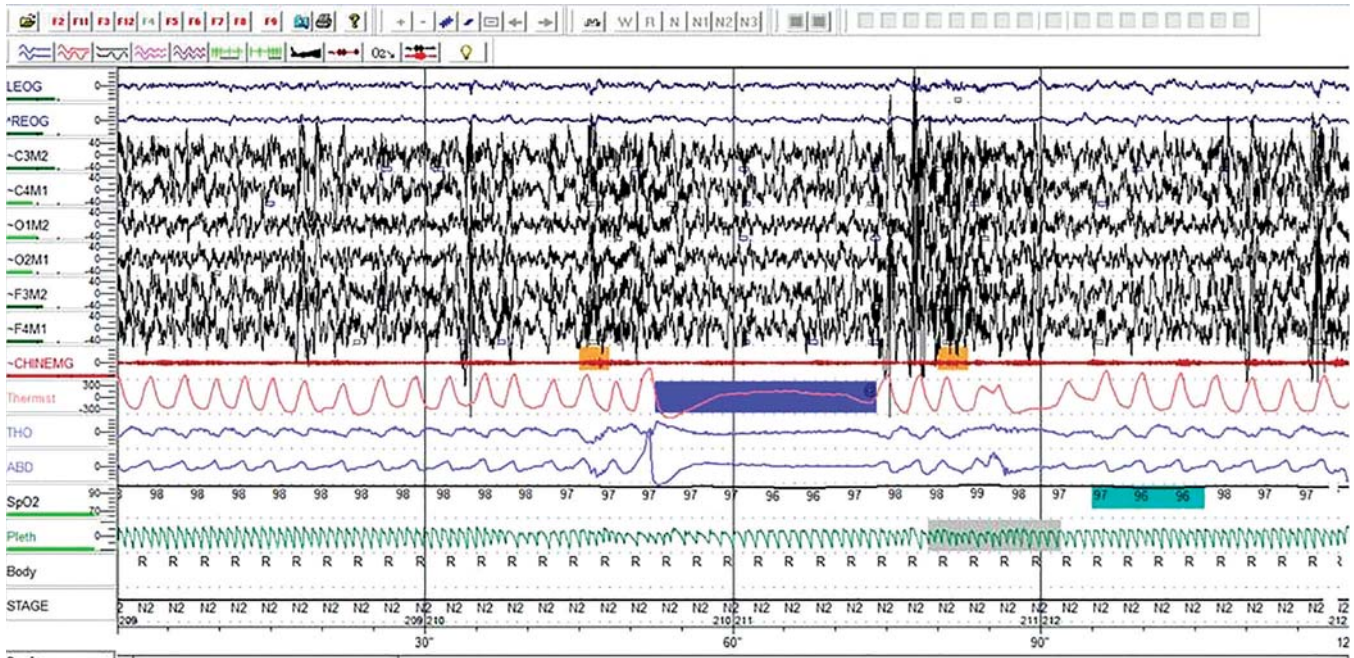

Figure 2 An episode of central apnea (marked with blue) during 120 seconds of sleep

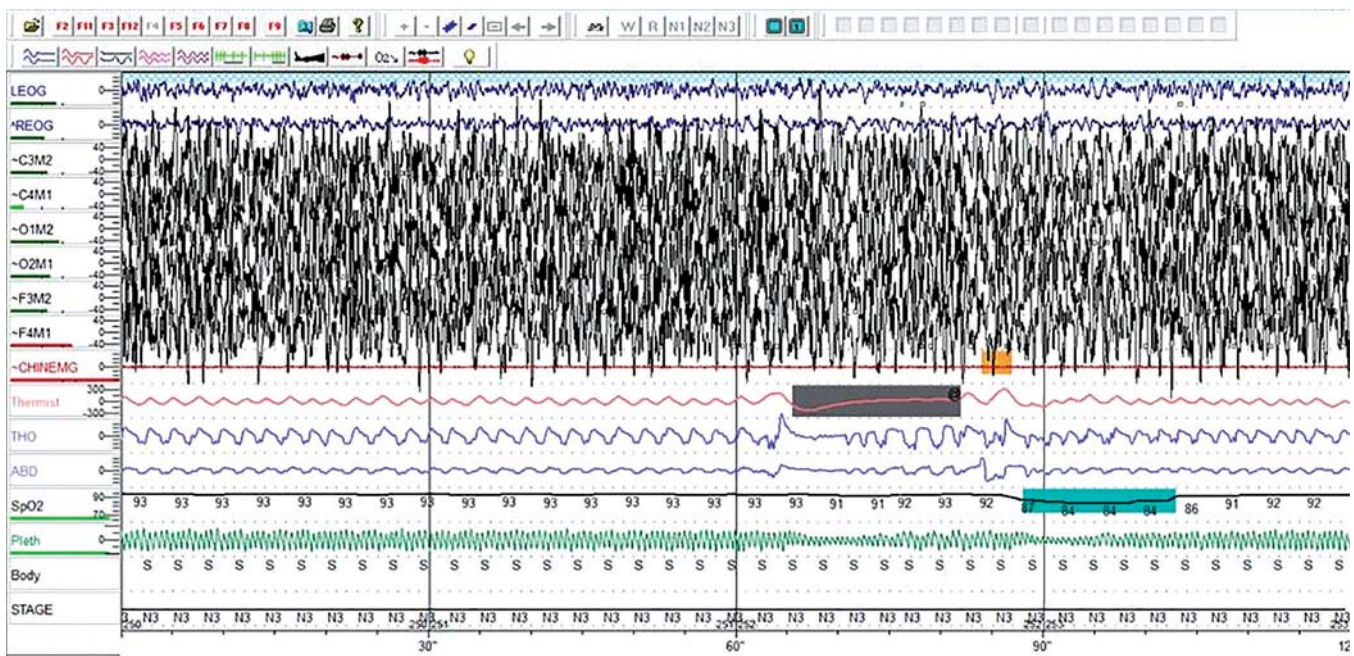

Figure 3 An episode of mixed apnea during 120 seconds of sleep

4. AHI 1–5 episodes/hour and inadequate somatic growth.
5. AHI 1–5 episodes/hour and nocturnal enuresis.
6. AHI 1–5 episodes/hour and presence of risk factor(s) for persistence of OSA in adolescence.
7. AHI 1–5 episodes/hour and diagnosis of muscular or neuromuscular disorder or major craniofacial abnormality or combination of pathogenetic mechanisms.
8. Nocturnal pulse oximetry with three or more SpO₂ drops below 90% and three or more clusters of desaturation events.

Chest radiography, electrocardiography and echocardiography can also be performed while evaluating the children with suspected OSA and evidence of underlying cardiopulmonary disease since children with lower airway disease may have

episodes of hypoxemia during sleep, independent of upper airway obstruction. These tests should also be considered for children with confirmed severe OSA.

Adenotonsillectomy

If a child is diagnosed to have OSA, has a physical examination consistent with adenotonsillar hypertrophy and does not have a contraindication to surgery, adenotonsillectomy is the first line of treatment. Both tonsils and adenoids should be removed, even when one or the other seems to be the primary problem because OSA is the conglomerate result of the relative size and structure of the upper airway components, rather than the absolute size of the adenotonsillar tissue. Adenotonsillectomy improves OSA in

Figure 4 An episode of hypopnea during 120 seconds of sleep

most children by increasing the patency of the upper airway. Risk factors for ongoing OSA after adenotonsillectomy include severe OSA on preoperative PSG or the presence of complicating factors such as abnormal upper airway tone, craniofacial anomalies, and obesity. Postoperative polysomnographic evaluation 10–12 weeks after surgery is probably needed in these patients. Children with OSA are at risk for respiratory compromise postoperatively as a result of upper airway edema, increased secretions, respiratory depression secondary to analgesic and anesthetic agents and postobstructive pulmonary edema. Children younger than 3 years of age, those with more severe OSA on PSG (AHI equal to or more than 24 events per hour, oxygen saturation nadir of less than 80%, or peak PCO_2 of equal to or more than 60 mm Hg), with cardiac complications due to OSA and those with additional medical conditions such as craniofacial syndromes or neuromuscular disease are at high-risk for such complications. Therefore, careful cardiorespiratory monitoring should be performed for at least 24 hours postoperatively in these patients.

Other Treatment Modalities

If a child has OSA but does not have adenotonsillar hypertrophy or if symptoms and signs of OSA persist after adenotonsillectomy, other treatment options should be considered.

Noninvasive positive pressure ventilation which is a long-term therapy, is the most common nonsurgical therapy for OSA in children. It involves administering airway pressure through a nasal mask, which prevents upper airway obstruction and reduces both sleep disruption and the work of breathing. Continuous positive airway pressure (CPAP) and bilevel positive airway pressure (BPAP) are the usual types of positive airway pressure. The pressure required to treat OSA is initially determined by titration during PSG in the sleep laboratory. The pressure level should be periodically controlled with repeat PSG.

Supplemental oxygen can result in improved arterial oxygen saturation in children with OSA without worsening the degree of obstruction. However, it should be reserved as a temporary palliative measure before adenotonsillectomy and should not be used as a first line treatment because it does not address many of the pathophysiologic features associated with OSA. It should not be used without monitoring the potential changes in PCO_2 because

some patients with OSA can develop unpredictable and potentially life-threatening hypercapnia while breathing supplemental oxygen.

Craniofacial reconstructive procedures are reserved for some children with craniofacial anomalies. Tracheotomy is an option for children with severe OSA who have failed to respond to other treatment approaches. It bypasses areas where upper airway obstruction occurs during sleep. It is most often necessary in children with complex anatomic or neuromuscular problems.

Weight loss is recommended as an adjunctive therapy for obese children with OSA since obesity contributes to the increased upper airway resistance which characterizes OSA.

Intranasal corticosteroids or *leukotriene modifier therapy* may be useful to treat mild OSA, and can be considered when adenotonsillectomy was not curative or adenotonsillectomy or noninvasive positive pressure ventilation are not treatment options for the child.

OUTCOME AND COMPLICATIONS

Obstructive sleep apnea can have adverse effects on somatic growth, and can lead to cardiovascular and metabolic alterations including pulmonary hypertension, systemic hypertension, insulin resistance, and hyperlipidemia. Increased energy expenditure during sleep and disruption of the growth hormone and insulin-like growth factor and binding proteins may lead to reduction in growth velocity. Elevation of pulmonary arterial pressure caused by hypoxia-induced pulmonary vasoconstriction is a serious consequence of OSA in children and may lead to cor pulmonale. Intermittent hypoxia may affect left ventricular function through both direct and indirect effects on myocardial contractility. It may also have long-term effects on neuronal and intellectual functions of children leading to school problems, restlessness, aggressive behavior and poor test performances. An association between OSA and attention deficit-hyperactivity disorder has been proposed. Although the mechanism by which OSA may contribute to hyperactivity is not clear, it is possible that both sleep fragmentation and episodic hypoxia that characterize OSA lead to alterations within the neurochemical substrate of the prefrontal cortex with resultant executive dysfunction.

IN A NUTSHELL

1. Adenotonsillar hypertrophy and obesity are the major risk factors for OSA in otherwise healthy children.
2. Asking about snoring at each visit is a kind of screening method for OSA without forgetting that OSA is less common than snoring.
3. Overnight PSG is the gold standard test for the diagnosis of OSA.
4. If a child is diagnosed to have OSA, has a physical examination consistent with adenotonsillar hypertrophy and does not have a contraindication to surgery, adenotonsillectomy is the first line of treatment.
5. Noninvasive positive pressure ventilation is the most common nonsurgical therapy for OSA in children.
6. Intranasal corticosteroids or leukotriene modifier therapy may be useful to treat mild OSA, and can be considered when adenotonsillectomy is not curative or adenotonsillectomy or CPAP/BPAP are not treatment options for the child.
7. Untreated OSA can be associated with cardiovascular complications, impaired growth, learning problems, and behavioral problems.

Chapter 39.12

Congenital Malformations of the Lower Respiratory Tract

D Vijayasekaran

When a common respiratory problem in a child is not responding to usual line of management, the possible association of underlying congenital respiratory lesion should be considered. Majority of congenital malformations of the lower respiratory tract may present as a respiratory infection or a pneumonia mimicker during any time in childhood, usually in the early months of life. The congenital malformations of the lower respiratory tract include those related to airway and that of lung. The common congenital lung lesions include congenital pulmonary airway malformation (CPAM), pulmonary sequestration, bronchogenic cysts, congenital lobar emphysema (CLE), hypoplasia of the lung and the common airway lesions include tracheoesophageal fistula, tracheomalacia, laryngeal web and tracheal stenosis.

DEVELOPMENT OF RESPIRATORY SYSTEM

A brief revision of the embryogenesis of respiratory system may increase our understanding about this subject. Respiratory primordium is derived from primitive foregut and its morphogenesis can be divided into five stages:

1. **Embryonic stage (3–6 weeks):** A ventral outpouching from the endodermal epithelium of primitive foregut (bronchial bud) interacts with the tissue of mesodermal origin.
2. **Pseudoglandular stage (6–16 weeks):** The conducting airways continue to branch and the bronchial bud resembles a gland. Trachea and primitive foregut are separated by progressive fusion of epithelial ridges and similar process occurs between central tendon and pleuroperitoneal folds.
3. **Canalicular stage (16–26 weeks):** Tubules of bronchial bud expand to form sacculles. The airspaces increasingly come into close opposition to capillary network.
4. **Saccular stage (26–36 weeks):** The acinar tubules continue to proliferate and the surface area of the gas exchange region increases.
5. **Alveolar period (36 weeks to maturity):** The alveolar septation continue to occur even after the birth and continue up to 6 years.

The timing and severity of various insults to the developing lung may determine the lesions. Stages of lung development and the common lesions associated with maldevelopment are depicted in **Table 1**.

DIAGNOSTIC EVALUATION

The diagnostic evaluation of a child with suspected congenital malformations of the lower respiratory tract should begin with detailed clinical history including antenatal history. Recurrent respiratory tract infection is the common mode of presentation. In small group of patients, these malformations remain unrecognized for a long time. Pulmonary hypoplasia is associated with oligohydramnios.

The physical examination should focus on symmetry of chest, retractions and change in the resonance and air entry. Scaphoid abdomen may suggest diaphragmatic hernia. Frothing at the mouth of the neonate should alert the possibility of esophageal atresia. Since congenital malformations of respiratory tract are associated with other system disorders, a detailed examination should be done to identify any other associated defect.

Table 1 Stages of lung development and congenital lung lesion

Stage of lung development	Congenital lung lesion
Embryonic (3–6 weeks)	<ul style="list-style-type: none"> • <i>Atresia:</i> Tracheal, laryngeal, esophageal • Pulmonary agenesis/tracheal stenosis • Tracheoesophageal fistula • Bronchogenic cyst • Pulmonary sequestration (extralobar)
Pseudoglandular (6–16 weeks)	<ul style="list-style-type: none"> • Congenital pulmonary airway malformation • Tracheobronchomalacia • Diaphragmatic hernia • Pulmonary sequestration (intralobar)
Canalicular (16–26 weeks)	Pulmonary hypoplasia
Saccular (26–36 weeks)	Respiratory distress syndrome
Alveolar (up to 6 years)	<ul style="list-style-type: none"> • Congenital lobar emphysema • Bronchopulmonary dysplasia

Plain chest radiographs may give a clue about congenital lesion of the lung. Chest radiographic findings such as opacification, mass lesion, cystic lesions, shift of the mediastinum, unusual air collection should be carefully seen. Pulmonary sequestration and CPAM commonly occur in lower lobes and CLE in left upper lobe.

Other diagnostic imaging studies such as barium esophagography, computed tomography (CT) and magnetic resonance imaging (MRI) confirm the diagnosis. Three-dimensional reformatting of the CT scan and virtual bronchoscopy are used to reconstruct the images. Fiberoptic bronchoscopy plays a significant role in the evaluation of luminal pathology (**Figs 1A and B**) and in dynamic lesions such as airway malacias. The antenatal ultrasound scan plays an important role in the prenatal diagnosis.

CONGENITAL PULMONARY AIRWAY MALFORMATION

Congenital pulmonary airway malformation, previously known as congenital cystic adenomatoid malformation (CCAM), is a rare pulmonary disorder. The pathogenesis of CPAM is uncertain; it may result due to abnormality of the branching morphogenesis of the lung. The abnormal hamartomatous CPAM proliferation usually retains its communication with the normal bronchiolar tree but does not participate in normal gas exchange. CPAM is almost always unilateral (85–95%) but occasionally bilateral (2%). Three types of cystic adenomatoid malformation were identified initially (type 1–3), later two additional types were added (type 0 and 4). The current classification of CPAM of the lung is depicted in **Table 2**.

The most common presentation of CPAM in postnatal period is progressive respiratory distress with grunting, retractions and cyanosis. At times, differentiating CPAM from complicated staphylococcal pneumonia is difficult when a newborn presents with respiratory distress. Over a period, pneumatoceles due to a necrotic pneumonia (e.g., staphylococcal) may resolve but CPAM will persist on chest radiograph. The chest radiograph of CPAM of lung often shows shift of the mediastinum to the contralateral side (**Fig. 2**).

Surgical resection of CPAM lesions is necessary even for asymptomatic patients to prevent infection and avoid potential malignant transformation of the lesion. A limited resection of affected CPAM segment is done with due attention to preserve maximal normal lung tissue.

Figures 1A and B Bronchoscopic views of tracheoesophageal fistula (see Section 18 for details)

Table 2 Classification of congenital pulmonary airway malformation (CPAM) of the lung

CPAM type	Features and prognosis
Type 0	Involvement of all lung lobes, incompatible with life
Type 1	<i>Macrocytic:</i> Single/multiple cysts, 2 cm and above; lined by pseudostratified columnar; constitutes approximately 50% of postnatal cases with favorable prognosis
Type 2	<i>Microcystic:</i> Single or multiple cysts, 2 cm and less; cuboidal or columnar epithelial lining associated with higher congenital anomalies (approximately 40%)
Type 3	Predominantly solid lesions with small (< 0.5 cm) cysts, lined by cuboidal epithelium (10%), associated with pulmonary hypoplasia with poor prognosis, grossly elevated amniotic fluid α -fetoprotein
Type 4	Large air-filled cysts, lined by flattened epithelial cells

Figure 2 Chest radiograph of congenital pulmonary airway malformation of left lung showing shift of the mediastinum to right with cystic lesions in left lung

PULMONARY HYPOPLASIA AND AGENESIS

Pulmonary Hypoplasia

It denotes incomplete development of the lungs resulting in an abnormally low number of alveoli. It may be secondary to other fetal abnormalities that interfere with normal development of the lungs which include diaphragmatic hernia, CPAM, fetal hydronephrosis and developmental mediastinal masses. Chest radiograph shows ipsilateral shift of the mediastinum due to volume loss of lung. The orifice of involved main bronchus is narrow and small due to underdevelopment which may be demonstrated by fiberoptic bronchoscopy (**Figs 3A to C**). On CT of the chest, the pulmonary artery is hypoplastic on the affected side.

Agenesis of Lung

It is a primary defect in organogenesis where the affected side demonstrates complete absence of the bronchial system and lung. The trachea continues to normal bronchial system without carina. *Pulmonary aplasia* is category in between hypoplasia and agenesis where bronchial stump and carina are visualized without bronchial system on the affected side. Pulmonary hypertension complicates lung agenesis. Right lung agenesis has a higher morbidity and mortality.

PULMONARY SEQUESTRATION

Pulmonary sequestration is a rare congenital malformation of the lower respiratory tract. It consists of a nonfunctioning mass of lung tissue that lacks normal communication with the tracheobronchial tree but demonstrates blood supply originating from the systemic artery system. When the lesion is located within a normal lung, it is designated intralobar sequestration (ILS) and when outside the lung, it is called the extralobar sequestration (ELS) (**Figs 4A and B**).

The majority of sequestrations occur in the lower lobes. The vascular supply for both generally arises from the lower thoracic or upper abdominal aorta. The knowledge about the major differences between ILS and ELS is helpful for both diagnosis and management (**Table 3**).

Computed tomography scan chest with CT angiography is fairly accurate for the diagnosis of pulmonary sequestration. Contrast-enhanced magnetic resonance angiography (MRA) may help in the diagnosis of pulmonary sequestration by demonstrating a systemic blood supply, particularly from the aorta.

Figures 3A to C Pulmonary hypoplasia. (A) Chest radiograph; (B) CT chest; (C) Bronchoscopy

Figures 4A and B (A) Intralobar pulmonary sequestration; (B) Extralobar pulmonary sequestration

Table 3 Differences between intralobar sequestration and extralobar sequestration

Features	Intralobar sequestration	Extralobar sequestration
Age at diagnosis	Child to adult	Neonate
Sex distribution	Equal	80% male
Frequency	More frequent	Less frequent
Visceral pleura	Lacks pleura	Has its own pleura
Location	Left lung (posterior basal segment)	Left side at costophrenic groove/below the diaphragm
Associated anomalies	Uncommon	Common
Venous drainage	Pulmonary	Systemic
Bronchial communications	Present	None
Surgery	Lobectomy	Sequestrectomy

CONGENITAL LOBAR EMPHYSEMA

The lesion occurs due to intrinsic or extrinsic narrowing of the affected bronchi. Intrinsic narrowing is due to the weakness or absence of bronchial cartilage. The upper left lobe is the most frequently affected (42%) followed by right middle (35%) and right upper lobe (21%). The overdistended portion of the affected lobe compresses the adjacent lobes and thus compromises the ventilation. Males are affected three times as often as females. The most frequently documented cause of CLE is ball-valve type obstruction which results in air-trapping of the developing airway. 50% of the patients become symptomatic in the neonatal period with progressive respiratory distress.

X-ray chest shows a hyperlucent overexpanded area, mediastinal shift and compression of the adjacent lobes (**Figs 5A and B**). CT chest plays a major role in the confirmation of typical CLE. The symptomatic neonate needs to be operated immediately. Asymptomatic CLE or one who has mild symptoms should be evaluated before surgery.

Severe bronchomalacia of the left main bronchus or the left upper lobe proper masquerades as CLE of left upper lobe. In our observation, few children with atypical features of CLE demonstrated either bronchomalacia of the left main bronchus or the left upper lobe or both. In such situations due to dynamic nature of the lesion, the bronchoscope could be negotiated distally (which is not possible with typical CLE) and the distal airway anatomy is found to be normal. Thus, fiberoptic bronchoscopy

plays an important role in identifying children with clinical features of CLE who perhaps can be saved from an unnecessary lobectomy and instead offered more specific intervention such as airway stenting.

BRONCHOGENIC CYST

Bronchogenic cyst results due to abnormal growth of the aerial conducts, occurs at embryonic stage. Bronchogenic cyst usually has no communication with the bronchial tree. At times, bronchial communication develops tension cyst and infection. Bronchogenic cysts are closely attached to major airways and the esophagus by dense fibrous tissue and usually (65%) located in the mediastinum. Intrapulmonary cysts are usually rare, located in the lower lobes. Cyst infection is more frequently seen in intrapulmonary cysts. Chest X-ray may give a diagnostic clue, but confirmation can be made more accurately using CT chest. Not all bronchogenic cysts need intervention. The decision for surgery is predicated by the presence of compression symptoms due to large size cysts or in cases of infection.

AIRWAY MALACIAS

Airway malacias are increasingly recognized due to the availability of smaller size fiberoptic bronchoscopes (**Figs 6A to C**). The

Figures 5A and B Congenital lobar emphysema left upper lobe as seen in (A) X-ray chest and (B) diagrammatic illustration

Figures 6A to C Bronchoscopic views of (A) tracheomalacia, (B) bronchomalacia (bilateral) and (C) laryngomalacia

incidence reported in western literature is between 1:1,500 and 1:2,500, but the actual incidence is believed to be still higher. A recent study done in infants with moderate and severe laryngomalacia reported a high incidence of associated lower airway malacias (48%) of which tracheomalacia was the most common associated lower airway anomaly (29%).

Tracheomalacia is characterized by flaccidity of the tracheal support cartilage. If the condition extends further to the main bronchi, it is termed *tracheobronchomalacia* while those localized to one main bronchus without involving trachea are termed as *bronchomalacia*. Airway malacias may occur in various combinations. These disorders should be considered when unexplained symptoms of wheezing or coughing are present in young infants.

Tracheomalacia

Primary tracheomalacia is thought to be caused by congenital immaturity of the tracheal cartilage. In *secondary tracheomalacia*, previously normal cartilage undergoes degeneration. The intrathoracic trachea normally dilates slightly during inspiration and narrows slightly during expiration. These processes are exaggerated in tracheomalacia leading to airway collapse on expiration. Dynamic compression of the anterior wall of the trachea is a typical finding observed by fiberoptic bronchoscopy (gold standard) done under local anesthesia.

The diagnosis of airway malacias presents a clinical challenge because of the frequent overlap of symptoms with more common childhood respiratory illnesses such as wheezy disorders. The distinction may be of clinical relevance because bronchodilators like β -agonists can worsen the wheeze caused by airway malacias by reducing the muscle tone, thus making the bronchi more compliant. Ipratropium bromide appears to be beneficial in such conditions.

In airway malacias, impaired drainage of secretions resulting in backlog of secretions is an added problem. Understanding the basic pathology is important. A triad including avoidance of β -agonists, airway clearance and semisynthetic anticholinergics may form effective management surgery in airway malacias. In cases with severe malacia, these children may need airway stenting or airway distension by bilevel pressure support.

Tracheal Stenosis

Tracheal stenosis comprises a wide range of tracheal abnormalities, but the common denominator is congenital narrowing of the trachea. Based on the features such as the narrowness of the trachea, the extent of tracheal involvement, the involvement of the bronchi and the presence or absence of complete tracheal rings, many distinct types are described. Congenital subglottic stenosis, a variant of tracheal stenosis,

usually presents immediately after birth. Other forms of tracheal stenosis include funnel-shaped trachea, stenosis with complete cartilage rings and tracheal webs.

In our experience, most common presentation is the one with more circular tracheal cartilage rings with less pars trachealis muscle (membranous part of the trachea). Infants with tracheal stenosis present with biphasic stridor. The affected ones frequently get hospitalized for want of diagnosis. Multidisciplinary approach along with proper communication with the intensive care team may avoid repeated hospitalizations.

Though various surgical techniques are reported, conservative management is preferred especially in minor variants of tracheal stenosis as the tracheal lumen may widen along with the age.

IN A NUTSHELL

1. Tracheoesophageal fistulas, lobar emphysema, diaphragmatic hernia, agenesis of lung and laryngotracheal stenosis may present as neonatal emergency.
2. Lesions such as pulmonary airway malformation, pulmonary sequestration, bronchogenic cysts present as recurrent respiratory tract infection.
3. Airway malacias can present as nonresponsive infantile wheeze.
4. Commonly, a useful diagnostic clue is provided by the chest radiograph. Subsequent confirmatory investigations include barium esophagography, CT, MRI and fiberoptic bronchoscopy.
5. Surgery is indicated in majority of congenital lung masses due to the inherent risk of malignant transformation.

Chapter 39.13

Stridor and Croup

Shalu Gupta

STRIDOR

The origin of word *stridor* is from a Latin word *stridulus*, which means creaking. Stridor is a high-pitched sound produced by abnormal air passage during breathing. Essentially, it is a loud inspiratory sound originating from the extrathoracic airways. A lesion in glottic or subglottic region usually produces a biphasic stridor.

Pathogenesis

Infants and children are particularly prone to develop early airway obstruction. The anatomy of larynx is different in children as compared with adults, which makes them susceptible to airway narrowing. The larynx in infants is situated high in neck, and the epiglottis is narrow, omega-shaped, and vertically placed. In children, the narrowest part of the airway is the subglottic area unlike adults where it is glottis. Further, it is supported by loose, nonfibrous mucosa which gets easily obstructed in subglottic edema. The cartilaginous support of infant airways is soft and compliant. In addition to these factors, children have a large head, relatively lax neck support, large tongue and poor cell-mediated immunity which further predispose them to airway obstruction. The resistance to airflow is inversely proportional to the radius of the airway to the fourth power ($R \propto 1/r^4$). So a small decrease in airway caliber will cause profound increase in airway resistance.

Etiology

The usual lesions causing stridor can be situated in the extrathoracic airways, i.e., nasopharynx, larynx and trachea; or in the intrathoracic part. Stridor is a clinical sign and not a diagnosis. The causes of stridor can range from relatively benign to some very serious and even life-threatening causes (**Table 1**).

Approach to Stridor

The important issues when a child or infant presents with stridor are: (a) to evaluate the severity of airway obstruction, and if required immediate intervention to prevent it from further

worsening and progressing to respiratory fatigue and finally to failure and (b) timely referral when a significant airway lesion is suspected. A detailed history and examination can give a clue to a possible etiology (**Flow chart 1**).

Causes of stridor presenting at birth are usually congenital lesions such as choanal atresia, laryngeal web, laryngomalacia, tracheal stenosis, anomalous vascular rings or congenital vocal cord paralysis. In laryngomalacia and subglottic hemangioma, stridor becomes worse on straining or crying. Stridor also worsens in supine posture in laryngomalacia, tracheomalacia, micrognathia and macroglossia. Feeding increases the stridor in tracheoesophageal fistula, neurologic disorders, gastroesophageal reflux disease and vascular compression.

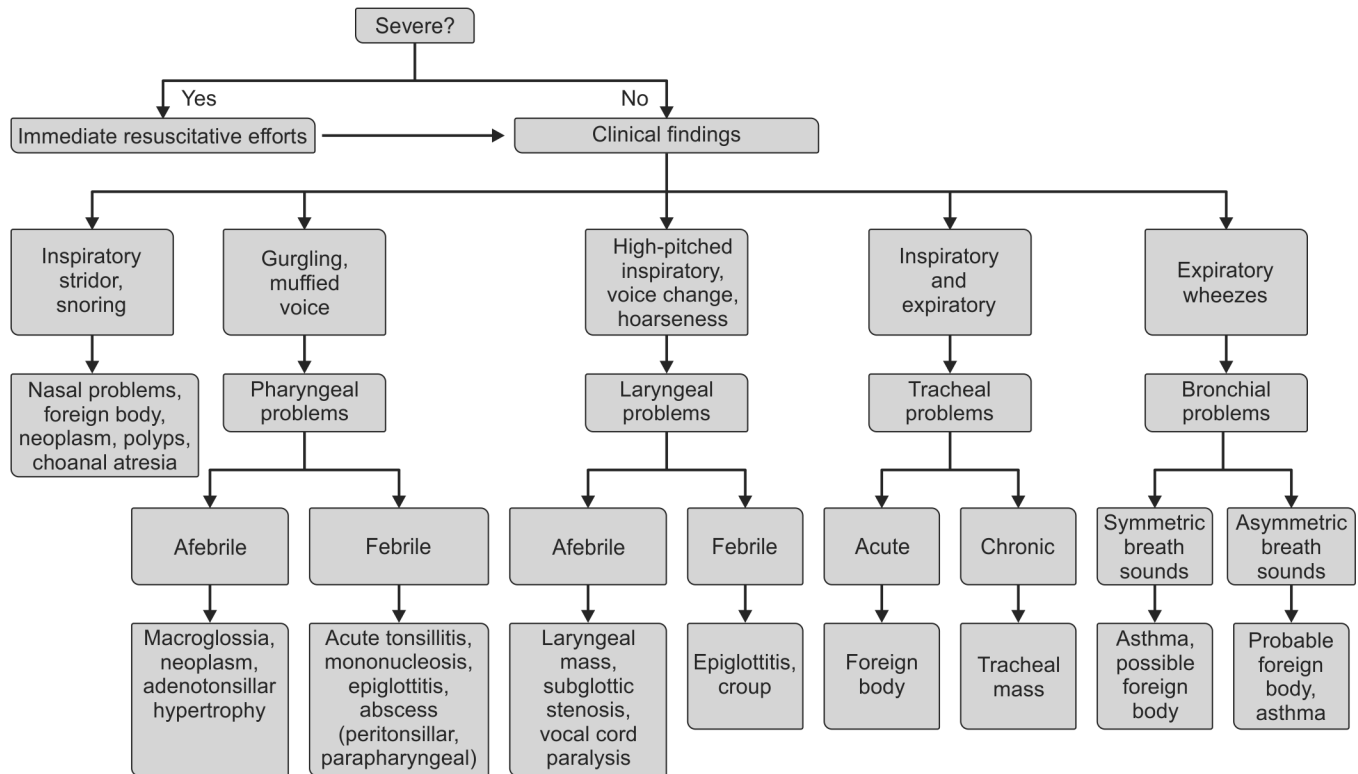

Common causes of stridor in children are croup, epiglottitis or foreign body. In foreign body aspiration, a preceding history of aspiration or choking can be obtained in majority of cases. If there is antecedent history of upper respiratory infection, croup, epiglottitis or tracheitis is a possibility. Drooling of saliva suggests epiglottitis or retropharyngeal and peritonsillar abscess. Barking cough is reported in croup, brassy cough in tracheitis; weak cry in neuromuscular disorder and laryngeal defects, hoarseness of voice in croup and vocal cord paralysis, and muffled cry and dysphagia in supraglottic lesions. If there is a history of endotracheal intubation, then suspect subglottic stenosis or vocal cord injury.

Investigations

Initial investigations include complete blood count and arterial blood gas (ABG) analysis to look for oxygenation and ventilation status. X-rays evaluation of the neck is useful in the initial assessment of airways. Look for adenoids, tonsils and epiglottic size and shape, retropharyngeal space and tracheal delineation. The lateral X-ray neck should be taken with neck extension to differentiate between retropharyngeal and pharyngeal masses. Contrast studies using barium or gastrografin should be used, if either vascular compression or gastroesophageal reflux disease or tracheoesophageal fistula is suspected. Direct visualization and evaluation of the airway using flexible fiberoptic bronchoscopy is often required in children with persistent stridor. CT or MRI is required to clarify the airway anatomy and the surrounding soft tissue structures, including vascular anomalies. If any vascular or structural heart lesion is suspected, an echocardiogram with Doppler may be done.

Table 1 Causes of stridor in newborn and children

Nose and pharynx	Larynx	Trachea
Choanal atresia	Laryngomalacia	Tracheomalacia
Lingual thyroid or thyroglossal cyst	Laryngeal web, cleft, cyst or laryngocele	Bacterial tracheitis
Macroglossia (e.g., Pierre-Robin sequence, Beckwith-Wiedemann syndrome)	Laryngotracheobronchitis (viral croup)	Congenital tracheal stenosis
Retrognathia (e.g., Treacher-Collins syndrome)	Acute spasmodic laryngitis (spasmodic croup)	External compression
Micrognathia (Treacher-Collins syndrome, Hallermann-Streiff syndrome)	Epiglottitis	
Hypertrophic tonsils/adenoids	Vocal cord paralysis	
Retropharyngeal or peritonsillar abscess	Laryngeal stenosis	
	Intubation	
Extrinsic compression	Foreign body	
Lymphatic malformations (cystic hygroma)	Cystic hygroma	
Vascular malformation (AV malformations)	Subglottic hemangioma	
Vascular tumors (hemangiomas)	Laryngeal papilloma	
Encephaloceles	Angioneurotic edema	
	Laryngospasm (hypocalcemic tetany)	
	Psychogenic stridor	

Flow chart 1 Approach to stridor in children

Adapted from Handler SD. Stridor. In: Fleisher GR, Ludwig S. Textbook of Pediatric Emergency Medicine. Baltimore: Williams and Wilkins; 1993. pp. 474-8.

Treatment

Treat the underlying cause. The establishment of airway patency is an emergency in children with severe respiratory distress or impending respiratory failure. Supportive management with oxygen, humidified air, intravenous fluids, steroids and β -adrenergic drugs may be required.

CROUP

Croup or laryngotracheobronchitis (LTB) is characterized by inspiratory stridor, barking cough and hoarseness of voice due to laryngeal and/or tracheal obstruction. The causative agent is most often a viral agent. In infants and children, viral croup is the most common cause of infective upper airway. In most of the cases, the disease has a mild and self-limited course.

Epidemiology

It usually affects in preschool age group with the peak incidence around 18-24 months. Infection is mainly airborne via droplet spread or direct inoculation through fomites. Epidemic can occur with parainfluenza viruses during winter months. In younger children, there is slight male preponderance (1.4:1), while in older age groups both sexes are equally affected.

Etiology

The most common etiologic agents are the parainfluenza viruses. Out of the three strains of parainfluenza viruses, type 1 is the most common causative agent and leads to epidemics. Other etiologic agents which can cause LTB include respiratory syncytial virus, coronavirus, influenza virus, metapneumovirus, adenovirus, rhinovirus and enterovirus. When croup is caused by herpes viruses, the clinical picture is usually more severe and protracted. However, the severity of symptom does not correlate with any particular infectious agent.

Pathogenesis

The incubation period of viral croup varies from 2 days to 6 days. Viral infection results in inflammation, edema of the airways and mucus production, which leads to narrowing of airways. Parainfluenza viruses are trophic for the respiratory epithelium, binding with the ciliated epithelium. Since the subglottic area is the narrowest part of a child's upper airway, with abundant mucous glands, it has a great propensity to become obstructed early. Also the negative intrathoracic pressure generated during inspiration tends to narrow the already inflamed and edematous airway; this further increases the airway obstruction. With the disease progression and production of fibrous exudates, the airways are further compromised. Vocal cord swelling produces hoarseness of voice. The barking cough is produced by the inflammation of the larynx and trachea.

Clinical Features

The initial phase is the prodromal phase which consists of rhinorrhea, pharyngitis, mild cough, and low-grade fever for 1-3 days. This is followed by characteristic *barking* cough, hoarseness of voice and inspiratory stridor. These symptoms are characteristically worse at night and are aggravated by agitation and crying; they often recur over several days with decreasing intensity.

Almost two-thirds children have mild symptoms which resolve within 2-5 days. With increasing severity of croup, the child will have signs and symptoms of respiratory distress, e.g., tachycardia, tachypnea, nasal flaring and use of accessory muscles of respiration (supraclavicular, infraclavicular, intercostal, subcostal and sternal retraction), persistent stridor and finally cyanosis (**Table 2**). Oxygen saturation may be well preserved until the late stages of severe croup, underestimating the respiratory compromise in a sick child who is receiving supplemental oxygen. Conversely, desaturation may be present with mild airway obstruction (lower

Table 2 Severity of croup

Signs/symptoms	Mild croup	Moderate croup	Severe croup
Stridor	Absent at rest	Present at rest	Continuous stridor
Respiratory distress	Nil	Chest wall retraction, tachypnea, use of accessory muscles of respiration	Marked distress, drooling, cyanosis
Sensorium	Playful, eats and drinks well	Less playful, interactive, take liquids orally	Anxious, tired, refuses liquids. Later becomes restless and agitated

airway involvement and ventilation perfusion mismatch). Late signs of airway obstruction are restlessness, agitation, cyanosis, pallor or decreased level of consciousness.

The most familiar scoring used for assessing severity of croup is the *Westley Croup Score*. Points are given according to the severity of symptoms. Mild croup has a score of less than or equal to 2, moderate disease has scores 3–7 and severe disease has scores of greater than or equal to 8. Scores above 12 are considered life-threatening and indicated impending respiratory failure (**Table 3**).

Investigations

Croup is a clinical diagnosis and does not require any laboratory tests. There is no role for radiography in assessment of acute airway obstruction. On the contrary, any unnecessary test will cause apprehension and increased agitation and crying, which might further increase the airway obstruction. The child should be kept calm and comfortable. Radiograph of the neck shows a typical subglottic narrowing *steeple sign* seen in croup (**Fig. 1**). However, this sign may be absent in some cases of croup and may

be seen as a normal variant also. Further evaluation is warranted when foreign body aspiration is suspected, doubtful diagnosis and unsatisfactory response to standard treatment. Additional studies, which might be required after the acute episode has resolved, include airway endoscopy, contrast assessment of upper airway, pH studies and polysomnography.

Differential Diagnosis

Viral croup needs to be differentiated from other infectious and noninfectious causes of stridor (**Table 4**). If a foreign body aspiration is suspected, history of recent aspiration or choking is usually present. A laryngotracheal *foreign body* presents with sudden onset cough, stridor and dyspnea, whereas bronchial foreign bodies present with cough, decreased breathe sounds and monophonic wheeze. *Epiglottitis* is a medical emergency in which the child appears toxic and presents with acute onset of high-grade fever, stridor, difficulty in swallowing and labored breathing. These children will drool and sit or lean forward with a hyperextended neck assuming a tripod position. There is no barking cough. In *bacterial tracheitis*, the initial clinical presentation is like viral croup, but the patient deteriorates with high fever, increasing respiratory distress and airway obstruction. Children have a toxic appearance and do not respond to the conventional treatment for viral croup. In *spasmodic croup*, the initial presentation is like LTB, but without any viral prodrome and fever. Spasmodic croup occurs commonly at night with sudden onset of barking cough, hoarseness, noisy respiration and respiratory distress, which usually diminishes in the morning. As part of anaphylaxis and allergic reactions, *angioneurotic edema* presents with sudden swelling of the face, tongue, laryngopharynx, stridor and respiratory difficulty. Rarely, *hypocalcemia* can present with tetany, irritability and stridor due to laryngospasm.

Table 3 Westley Croup Scoring System

Symptom	Score
<i>Level of consciousness</i>	
Normal (including sleep)	0
Disoriented	5
<i>Cyanosis</i>	
None	0
Cyanosis with agitation	4
Cyanosis at rest	5
<i>Stridor</i>	
None	0
When agitated	1
At rest	2
<i>Air entry</i>	
Normal	0
Decreased	1
Markedly decreased	2
<i>Retractions</i>	
None	0
Mild	1
Moderate	2
Severe	3

**Figure 1** Subglottic narrowing of trachea (arrow) *steeple sign*

Table 4 Differential diagnosis of croup

Infectious	Noninfectious
Croup (laryngotracheobronchitis)	Foreign body
Epiglottitis	Spasmodic croup
Bacterial tracheitis	Angioneurotic edema
Retropharyngeal abscess	Burns or thermal injuries
Peritonsillar abscess	Hypocalcemia
Diphtheria	Smoke inhalation
Infectious mononucleosis	

Management

Treatment of croup is based on clinical severity of the disease (**Tables 2 and 3**). Mild cases may resolve spontaneously without any medical intervention. If left untreated, moderate and severe cases can deteriorate and lead to respiratory failure. Utmost attention should be given to airway management and treatment of hypoxia.

Supportive Care

Mild cases can be managed at home, with plenty of fluids and antipyretics. Parents should be counseled about exacerbation of symptoms during night.

Humidity

Cochrane systematic review has concluded that humidification of air has no evidence and it is no longer recommended. Equipment that increases humidity can cause burn from boiling water and facial scald injuries.

Corticosteroids

Corticosteroids form the cornerstone of treatment for croup. The current evidence strongly supports their role in moderate and severe symptoms. The exact mechanism of action is unclear, although its anti-inflammatory property is thought to decrease the degree of inflammation and swelling in the airway. According to a recent Cochrane review (2012) which included 38 studies ($n = 4,299$), use of steroids was associated with an improved Westley score at 6 hours. At 24 hours, this improvement was no longer significant. The use of corticosteroids was associated with fewer return visits, readmissions, decreased hospital stay and decreased use of epinephrine. However, there are some issues including the optimal route of giving corticosteroids, dosing regimen and the best oral agent. Studies conclude that nebulized, oral and intramuscular routes are roughly equivalent. Nebulized route could possibly increase distress and increase airway obstruction, although it may be used in a child who is vomiting or having difficulty in swallowing. With oral administration, the fear and the discomfort of an injection are gone. The intramuscular route is preferable for children who are suffering from gastrointestinal symptoms.

Studies have used oral dexamethasone, prednisolone and nebulized budesonide. Dexamethasone has a potent anti-inflammatory activity compared to prednisolone and a longer half-life. Because of its long half-life (36–72 hours), one dose of dexamethasone suffices to cover the initial 72 hours period of the illness. The most widely used dosage of dexamethasone is 0.6 mg/kg administered as a single oral dose for the management of croup. Several studies have demonstrated that a dosage of 0.15 mg/kg is as effective (equivalent dose of prednisolone is 1 mg/kg). Oral dexamethasone is as effective as intramuscular dose. Nebulized budesonide has also equal efficacy as

dexamethasone. An improvement in croup symptoms is usually seen within 3–6 hours following corticosteroid administration. Prolonged use of dexamethasone is associated with development of *Candida albicans* laryngotracheitis.

Nebulized Epinephrine

It causes rapid reduction in airway edema and bronchodilation. It has a rapid onset of action (within 30 min), and the effect lasts for 2–3 hours. Both racemic and L-isomer are equally effective. It should be given in moderate and severe croup. The recommended dosage of epinephrine is 0.4–0.5 mL/kg (maximum dose is 5 mL) of 1:1000 preparations. Studies have shown that it decreases hospital admission and leads to improvement in the croup score.

Other Adjunctive Treatments

These include oxygen in a child with severe airway obstruction and hypoxia, and antipyretics or analgesics. According to a recent Cochrane review (2013), in moderate-to-severe croup who have received steroid, Heliox inhalation has some short-term benefits. Since it is a viral disease, antibiotics are not warranted. Antibiotics are only required for bacterial superinfection such as tracheitis, pharyngitis or pneumonia. Cough suppressants are not recommended for the treatment of croup.

Prevention

As croup is a transmissible viral respiratory disease, hand washing is of utmost importance. All people dealing with infected nasopharyngeal secretions should regularly wash their hands. Any potentially infected facial tissue is a potent infectious material and should be discarded immediately. Toys or other objects that have been mouthed by a child with croup should be washed. Visitors or relatives suffering from cold and cough should avoid proximity with children.

IN A NUTSHELL

1. Stridor is a harsh sound due to turbulent airflow through narrowed airways.
2. Presence of stridor requires urgent attention and thorough evaluation to delineate the underlying cause.
3. Croup is characterized by sudden onset of hoarseness, barking cough, stridor with or without the presence of respiratory distress.
4. Assess airway, breathing and circulation and focus on airway management.
5. Corticosteroids are the mainstay of treatment for croup.
6. For moderate, severe or life-threatening croup, add nebulized adrenaline.

Chapter 39.14

Approach to a Child with Fast Breathing

Soumya Tiwari, Varinder Singh

Fast breathing is the most common presentation in children visiting a hospital emergency. It is defined as the respiratory rate more than the normal upper limit for that age group (**Table 1**). Fast breathing can be physiological, e.g., as a result of exercise, strenuous work or crying or due to fever, where the rate though increased may not reach the upper limits described. Fast breathing usually is a cardinal sign of respiratory disease but can result from nonrespiratory causes as well (**Box 1**). In certain pathological states due to underlying respiratory or nonrespiratory causes, fast breathing might be associated with increased work of breathing in the form of chest indrawing, nasal flaring and head nodding. It may also be associated with stridor or wheeze suggesting of upper and lower airway obstruction respectively.

There is a need for an urgent assessment of airway patency and breathing compromise when a child with fast breathing is first evaluated. Stabilization of vital parameters may require intubation, oronasal suctioning, use of oxygen by hood or nasal prongs, intravenous fluid boluses, correction of hypoglycemia, nebulization with bronchodilator, intercostal tube drainage, correction of hyperthermia or hypothermia, etc. Such initial treatment coupled with a thorough history, physical examination

and relevant investigations is followed by establishing a provisional diagnosis and instituting appropriate empirical treatment in the emergency ward itself.

CLINICAL FEATURES

A child with fast breathing may have respiratory symptoms such as cough, coryza or noisy breathing. Presence of fever suggests infectious etiology. In a child presenting with dyspnea on exertion or orthopnea, a cardiovascular etiology should be suspected. To assess the degree of respiratory compromise, one should assess for increased work of breathing (suggested by use of accessory muscles), cyanosis, lethargy or altered sensorium. Alteration in sensorium (in the form of irritability, agitation, lethargy or coma) indicates brain hypoxia and is one of the ominous indicators. A normal or decreased respiratory rate may also be ominous, if it is associated with severe retractions (paradoxical breathing), cyanosis, grunting or altered sensorium. Central cyanosis is a late sign but may not be detected in presence of severe pallor (severe anemia) and dark skin color.

Stridor is a harsh inspiratory sound that indicates upper airway obstruction. Grunt is a loud noise produced by a forceful expiration against a closed glottis. Grunt and wheeze (musical sound) are suggestive of lower respiratory tract involvement.

A complete history should reveal the onset, duration, progression of dyspnea, the aggravating and relieving factors as well as the associated symptoms such as fever, cough, sore throat, chest pain, choking episodes, accidental ingestion of poisons that may suggest the probable etiology (**Table 2**).

Symptoms of impending respiratory failure and red flag signs are listed in **Box 2**.

Table 1 The upper limits of respiratory rate as defined by the WHO

Age group	Respiratory rate cut-off
Young infant (< 2 months)	> 60/min
Infant (2 months to 1 year)	> 50/min
Toddlers and preschoolers (1–5 years)	> 40/min
School children (> 5 years)	> 30/min

Table 2 Clinical features suggestive of likely pathology for fast breathing

Clinical features	Diseases
Fever, cough and rapid breathing	Lower respiratory tract infections like pneumonia, bronchiolitis and virus-associated wheeze
Exercise-induced dyspnea	Asthma, CHF, severe anemia
Nocturnal cough, orthopnea and dyspnea	CHF
Fever, sore throat, stridor	Acute epiglottitis
Severe chest pain with rapid, shallow breathing, decreased air entry	Pneumonia, pneumothorax, pulmonary embolism
Persistent wheezing, recurrent vomiting, failure to thrive	GERD
Acute respiratory distress after sudden choking, hyperinflated chest	Foreign body inhalation
Fever with altered sensorium, convulsions, fast breathing	Encephalitis involving brainstem
Chest wall retractions, paraplegia	Acute flaccid paralysis
Acute respiratory distress with vomiting, altered sensorium	Hydrocarbon poisoning
Anuria, generalized edema, shock, anemia	Acute kidney injury/chronic kidney disease with metabolic acidosis
Fast breathing, altered sensorium, polyuria, dehydration	DKA

Abbreviations: CHF, congestive heart failure; GERD, gastroesophageal reflux disease; DKA, diabetic ketoacidosis.

BOX 1 Causes of fast breathing in children*Upper Respiratory Tract Involvement*

- Croup, acute epiglottitis, Ludwig angina
- Retropharyngeal abscess
- Foreign body aspiration
- Diphtheria
- Laryngospasm

Lower Respiratory Tract Involvement

- Pneumonia
- Bronchiolitis
- Asthma
- Pleural effusion, empyema and hemothorax
- Pneumothorax
- Atelectasis
- Hypersensitivity pneumonitis

Nonpulmonary Causes

- CHF due to heart disease or severe anemia
- CNS infections, cerebral edema, tumor (raised ICT, compression of the brainstem), spinal cord injury, Guillain-Barré syndrome
- Metabolic acidosis due renal failure, DKA, renal tubular acidosis, shock, lactic acidosis, etc.
- Psychogenic hyperventilation, anxiety, panic attacks

Abbreviations: CNS, central nervous system; CHF, congestive heart failure; DKA, diabetic ketoacidosis; ICT, intracranial tension.

BOX 2 Clinical pearls: warning signs in fast breathing*Symptoms of Impending Respiratory Failure*

- Cyanosis
- Silent chest
- Poor respiratory efforts
- Fatigue/exhaustion
- Agitation or reduced level of consciousness

Preterminal Signs

- Bradycardia
- Desaturation
- Altered sensorium

Red Flag Signs

- Respiratory rate (RR) ≥ 70 /min
- Severe chest indrawing
- Head nodding/grunting
- Central cyanosis
- Stridor in a calm child
- Inability to feed

INVESTIGATIONS

Laboratory investigations help to confirm the diagnosis, but the immediate management of a patient should not be delayed pending the reports of the investigations. Use of noninvasive devices such as pulse oximeter and end-tidal (ET) CO₂ detector (fitted in the ventilator) lessen the need for repeated invasive tests for monitoring of the child. **Table 3** shows the relevant investigations to ascertain the cause of fast breathing in a child.

MANAGEMENT

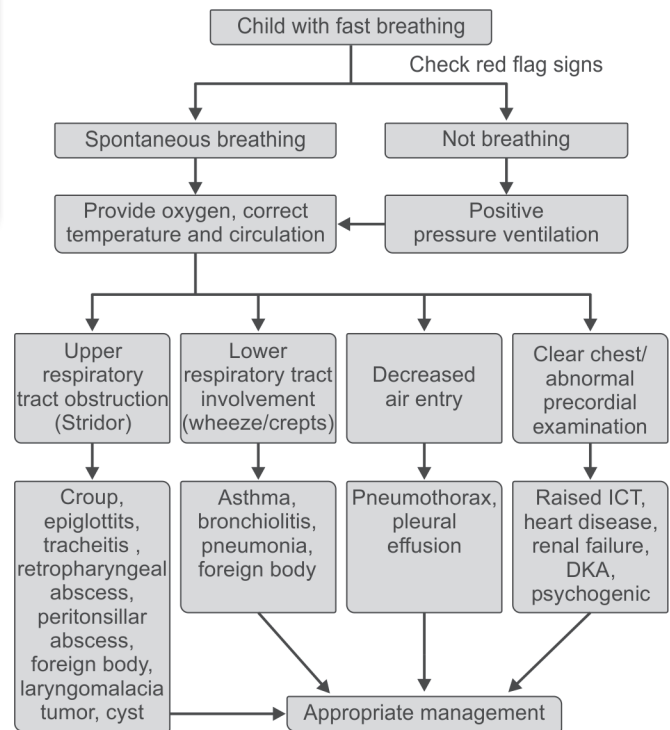

The management of a child with fast breathing includes supportive treatment in the form of stabilization of vital parameters, i.e.,

Table 3 Laboratory investigations in fast breathing

Investigation	Likely diagnosis
Complete blood count with peripheral smear: Leukocytosis/leukopenia, toxic granules, shift to left, low Hb, eosinophilia	Sepsis, anemia, tropical pulmonary eosinophilia
CRP, ESR: Raised	Sepsis, pneumonia, bronchiolitis
Blood culture	Sepsis with pneumonia
Kidney function tests: Deranged	Acute/chronic kidney disease
Arterial blood gas: Hypoxemia, hypercarbia, acidosis (metabolic/respiratory)	Severe pneumonia, pneumothorax, DKA, acute kidney injury, poisoning
Chest X-ray, X-ray soft tissue neck	Pneumonia, pneumothorax, pleural effusion, foreign body, acute epiglottitis, CHF
Bronchoscopy	Foreign body
Echocardiography	Cardiac disease
24 hours pH monitoring	GERD
Pleural tap	Pneumonia (bacterial, tubercular)
Lumbar puncture/cranial CT scan: Pleocytosis, raised protein and decreased sugar	Meningoencephalitis/raised ICT

Abbreviations: CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; DKA, diabetic ketoacidosis; CHF, congestive heart failure; GERD, gastroesophageal reflux disease; ICT, intracranial tension.

temperature, airway, breathing and circulation followed by definitive treatment by instituting appropriate respiratory support, antibiotics, chest tube drainage, decongestive measures, etc. Acute onset of fast breathing, especially following choking, and stridor indicate foreign body and warrant prompt bronchoscopic search and removal of foreign body (**Flow chart 1**).

Flow chart 1 Algorithmic approach to management of fast breathing

Abbreviations: DKA, diabetic ketoacidosis; ICT, intracranial tension.

IN A NUTSHELL

1. Fast breathing is one of the most common disease manifestations in sick infants and children.
2. It is important to promptly identify the cause of fast breathing based on the physical examination (pulmonary/nonpulmonary, upper respiratory/lower respiratory) and quickly manage those demonstrating the red flag signs (signs of nearly impending respiratory failure).
3. Supportive management should be instituted quickly, simultaneously searching for the etiology and planning a definitive treatment.

Chapter 39.15

Approach to a Child with Wheeze

Soumya Tiwari, Varinder Singh

Wheezing is a common complaint in young children with respiratory disorders as it can occur in approximately one-third of children younger than 2 years of age with respiratory diseases. It is described as a continuous musical sound heard during chest auscultation. Although asthma is the most commonly encountered respiratory disorder in children presenting with wheeze, it may indicate a host of other illnesses such as gastroesophageal reflux, bronchiolitis or foreign body aspiration.

ETIOPATHOGENESIS

Wheeze is produced by oscillation of the airway walls when their lumen is severely compromised. Younger children (under 5 years of age) are more prone to wheezing due to several causes. As the resistance to airflow through a tube is inversely related to the fourth power of the tube's radius, smaller children can have wheeze with even a marginal narrowing of their airways. The higher compliance of the chest wall in younger children results in collapse of the intrathoracic airways due to the inward pressure produced in expiration. The airway compliance in younger children is further increased by the different tones of smooth muscle and cartilage rings of the trachea.

Wheezing has been associated with a variety of risk factors that include fetal malnutrition, maternal smoking, allergy, high infant adiposity and viral infections during infancy, the common viruses include respiratory syncytial virus (RSV), rhinovirus, cytomegalovirus and adenovirus.

Wheezing can be monophonic or polyphonic. Monophonic wheeze has a constant character on auscultation in all areas of the chest as it originates from large airway obstruction, while a polyphonic wheeze occurs due to small airway obstruction. Wheezing in infants is commonly produced by inflammation, but many other disease processes can also present with wheezing (**Box 1**).

HISTORY

Sudden onset of wheezing raises the possibility of foreign body aspiration, particularly, if there is a history of choking, while

an insidious increasing wheeze may be a sign of extraluminal compression of bronchi by an enlarged lymph node or growing mass. Persistent wheezing presenting very early in life suggests a structural or congenital problem; in contrast, paroxysmal or intermittent wheezing is a characteristic feature in asthma. Infrequently, the children with interstitial lung disease can present with persistent wheezing, particularly, those with postinfectious bronchiolitis obliterans.

Cough is almost always associated with wheezing. It may be dry or wet depending upon the underlying etiology; wet cough typically is seen in disorders with infection or inflammation (bronchiectasis, cystic fibrosis, primary ciliary dyskinesia and chronic aspiration) resulting from excessive mucus production and dry cough resulting from structural causes for airway narrowing (e.g., asthma, tracheo/bronchomalacia or compression, foreign body or vascular ring). However, the underlying etiology of a dry cough can be complicated by a secondary process (say an allergic or infective sinusitis), making this distinction less useful.

All that Wheezes is Not Asthma

Wheezing is almost considered synonymous with asthma, while there can be several different causes for wheezing. Clinical pointers favoring asthma as a cause of wheezing include episodic wheeze, triggered by upper respiratory infections, seasonal changes, exercise or allergens, particularly in those with a personal or family history of asthma and/or atopy. Such cases will usually have a good response to bronchodilators. On the other hand, clinical pointers favoring a diagnosis other than asthma are many (**Table 1**) including presence of a poor or unpredictable response to bronchodilators, premature babies, particularly, those needing resuscitation or prolonged oxygen or ventilator support, wheezing since birth (congenital abnormality), wheezing associated with feeding or vomiting and presence of clubbing. History of choking, especially with associated coughing or shortness of breath, suggests foreign body aspiration, even if it does not immediately precede onset of wheezing symptoms. Past history of recurrent respiratory tract infections, malabsorption, failure to thrive, poor weight gain and recurrent ear or sinus infections suggest cystic fibrosis, immunodeficiency or ciliary dysfunction. History of progressive dyspnea, tachypnea, exercise intolerance and failure to thrive suggest interstitial lung disease.

PHYSICAL EXAMINATION

The physical examination should include anthropometry, vital parameters including oxygen saturation and inspection for the presence of cyanosis or clubbing. Nasal examination may reveal signs of allergic rhinitis, sinusitis or nasal polyps; the presence of nasal polyps in children necessitates an evaluation for cystic fibrosis.

A detailed chest examination will give clues to the etiology as well as the severity of the disease. Presence of respiratory distress—tachypnea, retractions, signs of hyperinflation such as increased anteroposterior (AP) diameter, Harrison sulcus suggests persistent and/or severe disease. On auscultation, one may hear typical wheeze or in milder instances a prolonged expiratory phase. The presence of focal wheezing is usually indicative of a localized and mostly structural airway abnormality and may warrant further airway evaluation by imaging or bronchoscopy.

Creptations can be present in conjunction with wheezing in asthma and in a variety of other conditions such as those leading to bronchiectasis (e.g., cystic fibrosis, primary ciliary dyskinesia, immune deficiency). Early inspiratory crepts are often present in patients with asthma due to air flowing through secretions or slightly closed airways during inspiration. Late inspiratory crepts are usually associated with early congestive heart failure or interstitial lung disease.

BOX 1 Common causes of wheezing in children

Infection

- *Viral*: Respiratory syncytial virus, parainfluenza virus, adenovirus, influenza virus, rhinovirus.
- *Other infections*: *Chlamydia trachomatis*, tuberculosis, histoplasmosis, papillomatosis.

Asthma

Anatomical Abnormalities

- *Central airway*: Airway malacia, tracheoesophageal fistula (H-type fistula), laryngeal cleft.
- *Extrinsic airway anomalies*: Vascular ring, extrinsic compression by tumor, lymph node or foreign body in esophagus.
- *Intrinsic airway anomalies*: Airway hemangioma, bronchial or lung cyst, congenital lobar emphysema, foreign body.

Others

Gastroesophageal reflux, AIDS, cystic fibrosis, bronchiectasis, burns, interstitial lung diseases.

Table 1 Clinical pointers favoring a diagnosis other than asthma

<i>Atypical features suggesting alternative diagnoses</i>	<i>Consider/Investigate for</i>
1. Onset below 6 months of age	
a. Choking episodes, vomiting, symptoms related to feeds	Aspiration syndromes, e.g., GERD
b. Short prodrome of cough, coryza, wheeze	Bronchiolitis
c. Persistent wheeze/stridor, cardiac failure, cyanosis, murmur	Vascular slings or left to right shunts
2. Persistent respiratory symptoms	
a. Persistent cough, upper airway symptoms, fever	Adenotonsillitis, sinusitis
b. Persistent cough, constitutional symptoms, tuberculosis contact, adenopathy	Tuberculosis
3. Unusual symptoms	
a. Recurrent multifocal bacterial infections including respiratory infections	Immunodeficiency states, (as suggested by SPUR*)
b. Recurrent respiratory symptoms, clubbing, coarse crepitations \pm dextrocardia, situs inversus	Ciliary dyskinesia
c. Recurrent respiratory symptoms, consanguinity, malabsorption, failure to thrive	Cystic fibrosis
4. First life-threatening episode	
a. History suggestive of foreign body inhalation, localized wheeze, unequal air entry	Foreign body
b. History suggestive of diet allergy	Food allergy

*SPUR: Severe, Persistent, Unusual, Recurrent infections.

(From: ABC, Asthma by Consensus, IAP guidelines on asthma management)

INVESTIGATIONS

A chest radiograph (AP and lateral films) should be considered in children with new-onset wheeze of undetermined origin or chronic persistent wheezing not responding to treatment. The presence of generalized hyperinflation suggests diffuse airtrapping (cystic fibrosis, asthma, primary ciliary dyskinesia and tracheal foreign body). A chest radiograph can also detect parenchymal lung disease, atelectasis, bronchiectasis or extraluminal compression by lymph node, tumor. In addition, chest radiographs may reveal cardiomegaly, enlarged pulmonary vessels, pulmonary edema or other signs of cardiac failure. Barium swallow may help in identifying vascular rings, swallowing dysfunction, aspiration syndromes including gastroesophageal reflux and some cases of tracheoesophageal fistula.

Pulmonary function tests (PFTs) are important component of the diagnostic evaluation of a wheezy child. In older children who are cooperative, pulmonary function testing is helpful in determining the presence, degree and location of airway obstruction as well as the response to bronchodilators.

Complete blood count may show eosinophilia, suggesting an underlying allergic process or possible parasitic infection. Elevated IgE can be indicative of an allergic process. Tests for cystic fibrosis (sweat chloride test or mutation analysis) or for immunodeficiencies are needed when clinical clues suggest these diagnoses. Flexible bronchoscopy may be needed to rule out airway malacia, foreign body aspiration or other causes of intraluminal or extraluminal obstructions which can present as persistent and/or localized wheeze.

MANAGEMENT

Treatment depends on the underlying cause; however, the first and foremost is establishing airway and breathing and maintaining oxygenation. Presence of severe respiratory distress warrants hospitalization.

Response to initial bronchodilator therapy suggests a component of bronchial hyper-reactivity. For children less than 3 years of age with demonstrable therapeutic benefit, the inhaled medications can be administered through a metered-dose inhaler (MDI) with mask and spacer. Inhalation therapy should be continued in all patients with viral-induced asthma exacerbation.

Ipratropium bromide is effective as an adjunct therapy, especially in children with significant tracheal and bronchial

malacia. Children with tracheomalacia or bronchomalacia may worsen with use of β_2 -agonists.

A trial of inhaled steroids may be considered in a child with previous response to oral steroids and who has moderate-to-severe wheezing, a significant past history of atopy, or a family history of asthma or atopy. Inhaled corticosteroids are indicated for long-term maintenance therapy in children with known airway reactivity but are controversial when used for episodic viral or acute illnesses. Intermittent, high-dose inhaled corticosteroids are not recommended for intermittent wheezing. Early use of inhaled corticosteroids has not been shown to prevent the progression of childhood wheezing or affect the natural history of asthma in children (for more details see Chapter on Childhood Asthma).

Use of steroids in first-time wheezers or infants without hospitalization is controversial. Steroids are generally reserved for infants with atopic wheezing, who are thought to have asthma that is refractory to other medications.

In cases of inhaled foreign body, the bronchoscopic removal may result in a dramatic improvement in symptoms.

IN A NUTSHELL

1. Wheezing is a common presenting symptom of respiratory disease in children.
2. It may represent either a self-limited or benign process or alternatively may be a sign of significant respiratory disease.
3. Bronchial asthma is most likely diagnosis in children with recurrent wheezing.
4. Anteroposterior and lateral chest radiographs are indicated in children with new-onset wheezing of undetermined etiology or chronic persistent wheezing unresponsive to therapies.

Chapter 39.16

Bronchiolitis

Ilin Kinimi

Bronchiolitis is a lower respiratory tract viral infection that primarily affects the small airways (bronchioles). It is defined as a clinical syndrome that occurs in children less than 2 years of age and is characterized by upper respiratory symptoms (e.g., rhinorrhea) followed by lower respiratory infection with inflammation, which results in wheezing and/or crackles (rales). Bronchiolitis typically occurs with primary infection or reinfection with a viral pathogen. In young children, the clinical diagnosis of bronchiolitis may overlap with recurrent virus-induced wheezing and acute viral-triggered asthma.

For clinical research, bronchiolitis is typically defined as the first episode of wheezing in a child younger than 12–24 months who has physical findings of a viral lower respiratory infection and no other explanation for the wheezing.

EPIDEMIOLOGY

Bronchiolitis typically affects infants and children younger than 2 years, principally during the fall and winter. Bronchiolitis hospitalization has a peak incidence between 2 months and 6 months of age and remains a significant cause of respiratory disease during the first 2 years of life and a leading cause of hospitalization in infants and young children.

In Indian studies, respiratory syncytial virus (RSV) infection was diagnosed in 30–70% of children with bronchiolitis. In a prospective hospital-based study from Southern India, of 114 children with bronchiolitis, 87 (76%) were less than 1 year and 107 (94%) were less than 2 years of age. Bronchiolitis occurs in epidemics during winter months. Outbreaks occur from September to March in India.

ETIOPATHOGENESIS

Bronchiolitis is typically caused by a viral infection. Although the proportion of disease caused by specific viruses varies depending upon the season and the year, RSV is the most common cause followed by rhinovirus. Less common causes include parainfluenza virus, human metapneumovirus, influenza virus, adenovirus, coronavirus and human bocavirus. With molecular diagnostics, two or more viruses are detected in approximately one-third of young children hospitalized with bronchiolitis. The virus typically infects the terminal bronchiolar epithelial cells causing direct damage and inflammation in the small bronchi and bronchioles. Edema, excessive mucus, and sloughed epithelial cells lead to obstruction of small airways and atelectasis.

CLINICAL FEATURES

Children typically present for medical attention 3–6 days after the onset of illness. Bronchiolitis often is preceded by a 1–3 days history of upper respiratory tract symptoms, such as nasal congestion and/or discharge and mild cough. It typically presents with fever (usually $\leq 38.3^{\circ}\text{C}$), cough and mild respiratory distress (e.g., mildly increased respiratory rate, mild retractions). Compared with other viruses that cause bronchiolitis, fever tends to be lower in RSV and higher with adenovirus infections.

Characteristic examination findings include tachypnea, mild intercostal and subcostal retractions, and expiratory wheezing. Additional auscultatory findings may include prolonged expiratory phase and coarse or fine crackles (rales). The chest may appear

hyperexpanded with increased anteroposterior diameter and may be hyper-resonant to percussion. Mild hypoxemia ($\text{SpO}_2 < 95\%$) is common. Other findings may include mild conjunctivitis, pharyngitis and acute otitis media.

Severely affected patients have increased work of breathing (subcostal, intercostal and supraclavicular retractions; nasal flaring and expiratory grunting). They may appear cyanotic and have poor peripheral perfusion. Wheezing may not be audible if the airways are profoundly narrowed or when increased work of breathing results in exhaustion. Serious comorbid infection is rare in children with bronchiolitis.

COMPLICATIONS

In most previously healthy infants, bronchiolitis resolves without complications. However, severely affected patients, particularly those with risk factors (**Box 1**) and those who require mechanical ventilation for apnea or respiratory failure, may develop air leaks including pneumothorax or pneumomediastinum. Bronchiolitis may be complicated by apnea, particularly in infants born prematurely and those less than 2 months of age. Presenting with apnea is a risk factor for respiratory failure and the need for mechanical ventilation. Respiratory failure is another serious complication of bronchiolitis.

BOX 1 Risk factors for severe bronchiolitis

- Prematurity (gestational age < 37 weeks)
- Age < 12 weeks
- Chronic pulmonary disease, particularly bronchopulmonary dysplasia (BPD)
- Congenital/anatomic defects of the airways
- Congenital heart disease
- Immunodeficiency
- Neurologic disease.
- *Environmental and other risk factors:* Passive smoking, crowded household, daycare attendance, concurrent birth siblings, older siblings and high altitude (> 2500 m).

DIAGNOSIS

Bronchiolitis is diagnosed clinically. Characteristic features include a viral upper respiratory prodrome followed by increased respiratory effort and wheezing and/or rales. Chest radiographs and laboratory studies are not necessary to make the diagnosis of bronchiolitis. However, they may support the diagnosis and may be necessary to either assess the severity or evaluate potential complications or exclude other conditions in the differential diagnosis.

Differential Diagnosis

Bronchiolitis needs to be differentiated from wheeze associated lower respiratory tract infections (LRTIs), pneumonia, aspiration pneumonia, congenital heart disease with failure, foreign body aspiration and chronic pulmonary disease. Differentiating points are highlighted in **Table 1**. Severe bronchiolitis also can unmask underlying airway obstruction that existed before the infection (e.g., vascular ring). Clinical features (e.g., lack of preceding upper respiratory tract symptoms, witnessed episode of choking, differential aeration and poor growth) may help to distinguish some of these conditions from bronchiolitis; for others, radiographic or laboratory studies may be necessary.

LABORATORY EVALUATION

Bronchiolitis is largely a clinical diagnosis. Laboratory tests are not routinely indicated in the evaluation of infants and young children with suspected bronchiolitis but may be needed when the diagnosis

Table 1 Differential diagnoses of bronchiolitis

Wheeze associated with LRTIs or multi-trigger wheeze	<ul style="list-style-type: none"> History of recurrent wheezing episodes, a family or personal history of asthma, eczema, and atopy help to support a diagnosis of asthma. However, during the first episode of wheezing, it is difficult to distinguish bronchiolitis from asthma.
Pneumonia	Symptoms and signs of both conditions are nonspecific; children with bacterial pneumonia may be more ill-appearing (e.g., higher fever), but clinical features cannot reliably differentiate bacterial LRTI from viral LRTI.
Foreign body aspiration	<ul style="list-style-type: none"> History of choking (not always present), focal monophonic wheezing, decreased air entry or regional variation in aeration. A high index of suspicion should be maintained for foreign body aspiration.
Chronic pulmonary disease	<ul style="list-style-type: none"> Suspected in children with prolonged or recurrent symptoms such as recurrent wheezing, failure to thrive, recurrent aspiration, stridor or recurrent respiratory infection. Children with underlying pulmonary disease may have a superimposed acute episode of bronchiolitis, and in some cases, the underlying disorder is unrecognized before the acute episode. Clinical course of bronchiolitis in children with underlying pulmonary disorders tends to be severe/require prolonged hospitalization.
Aspiration pneumonia	<ul style="list-style-type: none"> Secondary to GERD and/or swallowing dysfunction. May occur as a complication of bronchiolitis; the risk of aspiration increases during active bronchiolitis and resolves weeks later as tachypnea and the work of breathing subside. Clinical features associated with aspiration may include coughing with feeds, weak suck reflex and cyanosis during feeding and recurrent or chronic stridor.
Congenital heart disease	<ul style="list-style-type: none"> Associated findings may include failure to thrive, poor peripheral perfusion, abnormalities on cardiac examination (e.g., pathologic heart murmur, abnormal S₂, gallop, rub, active precordium). Children with underlying cardiac conditions may have a superimposed acute episode of bronchiolitis and in some cases the underlying disorder is unrecognized before the acute episode. Clinical course of bronchiolitis in children with underlying cardiac disorders tends to be severe/require prolonged hospitalization.
Heart failure	Associated clinical findings may include exercise intolerance, easy fatigue, hepatomegaly, shortness of breath, peripheral edema.
Vascular ring	<ul style="list-style-type: none"> Although stridor is more common, children with vascular rings may also have wheezing (typically with pulmonary artery slings). Anterior bowing of the trachea in the lateral chest radiograph may be a clue, but other modalities (barium contrast esophagogram, bronchoscopy, magnetic resonance angiography) usually are necessary for definitive diagnosis.

Abbreviations: LRTIs, lower respiratory tract infections; GERD, gastroesophageal reflux disease; S₂, second heart sound.

is in doubt. Data demonstrating the utility of complete blood counts (CBCs) in the diagnosis or management of bronchiolitis are lacking. However, laboratory and/or radiographic evaluation may be necessary to evaluate the possibility of comorbid or secondary bacterial infection in the following groups of patients:

- Neonates less than or equal to 28 days of age with fever [temperature $\geq 38^{\circ}\text{C}$ (100.4°F)] and symptoms and signs of bronchiolitis have the same risk for serious bacterial infection as young febrile infants without bronchiolitis.
- *Infants 28–90 days of age with fever:* CBC, urinalysis, urine culture and chest radiograph may be warranted to exclude comorbid or secondary bacterial infection in febrile [$T \geq 38^{\circ}\text{C}$ (100.4°F)] infants with symptoms and signs of bronchiolitis
- Children of any age with unusual or severe course (e.g., failure to improve after 2–5 days, wheezing that persists for > 7 days): CBC and chest radiograph may be warranted to evaluate secondary bacterial infection and other conditions in the differential diagnosis.
- *Children of any age with severe disease:* Arterial or capillary blood gas measurements may be necessary to evaluate respiratory failure.

Chest Radiography

It is not routinely indicated in the evaluation of infants and children with bronchiolitis as radiographic abnormalities are variable and nonspecific. Common findings include hyperinflation and peribronchial thickening. Patchy atelectasis with volume loss may result from airway narrowing and mucus plugging. Radiographic findings are poor indicators of the etiologic diagnosis and must

be used in conjunction with other clinical features in making decisions about diagnosis and treatment.

Virologic Studies

Virologic studies are not routinely required for specific viral agents unless the results will alter management of either patient or patient's contacts (e.g., initiation or continuation/discontinuation of antibiotic therapy, anti-influenza therapy, anti-influenza prophylaxis for high-risk contacts or cohorting of hospitalized patients or caregivers). The identification of a viral etiologic agent may be associated with a decreased utilization of antibiotic treatment and may help to avoid nosocomial transmission. However, direct evidence that this strategy prevents nosocomial transmission of respiratory viruses in children is lacking and it may be more logical to isolate all infants with bronchiolitis.

The recommended approach is screening by antigen detection or immunofluorescence of respiratory secretions obtained by nasal wash or nasal aspirate (rather than nasopharyngeal swabs). Nasal wash specimens are obtained by holding the infant or child upright at a 45° angle. A bulb syringe or a soft plastic catheter attached to suction is used to aspirate nasal secretions after a small amount of normal saline (1–3 mL) is instilled in each nostril. Rapid antigen tests are available for RSV, parainfluenza, adenovirus and influenza viruses. Culture and polymerase chain reaction (PCR) are additional methods that can be used. The sensitivity of most rapid antigen tests ranges from 80% to 90%. Given the little benefit these tests provide to the patient management, none of these is currently in use for routine clinical management of bronchiolitis in our country.

MANAGEMENT

Children can be managed as outpatients if they are adequately hydrated and have no signs of moderate to severe respiratory distress (e.g., nasal flaring, retractions, grunting, respiratory rate > 70 breaths/min, dyspnea or cyanosis) and do not require supplemental oxygen. Infants with bronchiolitis, who are not hospitalized, should be monitored in the outpatient setting by their clinician for progression of disease.

Assessing the Severity

Hospitalization for supportive care and monitoring is indicated depending on the severity of illness. Aspects of the history that help in determining the severity of illness and/or need for hospitalization are outlined in **Box 2**. Repeated observations are necessary to adequately assess the disease severity because examination findings may vary substantially over time. However, there is limited and/or conflicting evidence relating these clinical findings to clinical outcomes.

BOX 2 Assessment of severity of bronchiolitis

- Assessment of hydration status (e.g., fluid intake, urine output)
- Symptoms of respiratory distress (tachypnea, nasal flaring, retractions, grunting, $\text{SpO}_2 < 95\%$ on room air, respiratory rate ≥ 70 breaths/min)
- Cyanosis/toxic or ill appearance
- Episodes of restlessness/lethargy (may indicate hypoxemia/impending respiratory failure)
- A history of apnea with cyanosis or bradycardia
- Assessment of hydration status (e.g., fluid intake, urine output).

Several scores have been developed to assess the clinical severity of bronchiolitis in research settings, but these measures in clinical practice are limited by substantial variability in severity assessment between observers. The need for intensive care depends on the presence and type of risk factors (**Box 1**) for serious disease. Children with congenital heart disease, bronchopulmonary dysplasia (BPD), immunosuppression or those less than 6 weeks of age have up to 40% higher risk of requiring intensive care and thus need active and frequent monitoring.

Hypoxemia

It is associated with mucus plugging and atelectasis and is common in children with bronchiolitis. It may respond to supplemental oxygen alone, although sometimes it requires additional respiratory support. Hypercapnic respiratory failure, associated with fatigue, usually requires additional respiratory support (e.g., intubation and mechanical ventilation).

Secondary Bacterial Infection

With the exception of otitis media, secondary bacterial infection is uncommon among infants and young children with bronchiolitis or RSV infection. The risk of secondary bacterial pneumonia is increased among children who require admission to the intensive care unit, particularly those who require intubation. Routine use of antibiotics is therefore not recommended to prevent secondary bacterial infection.

Anticipatory Guidance and Supportive Measures

In healthy infants and young children, bronchiolitis usually is a self-limited disease. Management in most cases consists of anticipatory guidance and supportive measures to maintain oxygenation and hydration. However, bronchodilator therapy may be beneficial in a subset of patients.

Anticipatory Guidance

Education and anticipatory guidance are important components of the management which includes the expected clinical course; proper techniques for suctioning the nose; explaining the indications to return to medical care: apnea, cyanosis, poor feeding, fever, increased respiratory rate and/or work of breathing (retractions, nasal flaring, grunting); and stressing on the strategies to prevent respiratory infection.

Supportive Care

Supportive care includes maintenance of adequate hydration, provision of respiratory support as necessary and monitoring for disease progression (**Fig. 1**).

Fluids

Children with bronchiolitis may have difficulty in maintaining adequate hydration because of increased needs (related to fever and tachypnea) and decreased intake (related to tachypnea and respiratory distress). Exclusive parenteral fluid administration may be necessary to ensure adequate hydration and avoid the risk of aspiration in infants and children who are hospitalized with bronchiolitis and have moderate to severe respiratory distress. For children who can tolerate enteral feedings, strategies to maintain hydration include small frequent feedings or orogastric or nasogastric feedings.

Plasma antidiuretic hormone levels rarely may be elevated, leading to fluid retention and hyponatremia. Administration of hypotonic intravenous fluids may contribute to mild hyponatremia in some infants without affecting clinical improvement. Fluid overload should be avoided since it may lead to pulmonary congestion.

Nasal Congestion

Saline nose drops and nasal bulb suction may help to relieve partial nasal obstruction. There is little evidence to support routine *deep* suctioning of the lower pharynx or larynx in the inpatient setting.

Medications

Drugs used for the management of bronchiolitis are summarized in **Table 2**.

Inhaled Bronchodilators

Children with bronchiolitis with moderate to severe respiratory distress should receive a trial of inhaled bronchodilators. However, the efficacy of these medications remains uncertain. In a meta-analysis of 28 trials comparing bronchodilators other than

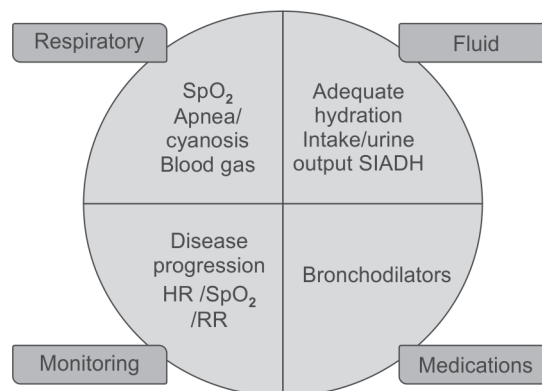

Figure 1 Components of management of bronchiolitis
Abbreviations: HR, heart rate; RR, respiratory rate.

Table 2 Drug treatment for bronchiolitis

	<i>Recommendations or evidence</i>	<i>Additional remarks</i>
Inhaled bronchodilators	Evaluate the child before and up to 1 hour after treatment. Administered with normal (0.9%) saline and with oxygen. Monitored trial of bronchodilator medication is an option, with continuation only if there is a documented objective clinical response.	Administer nebulized epinephrine (0.05 mL/kg of 2.25% epinephrine in 3 mL normal saline). Continue 4–6 hourly until discharge among those who show response.
Systemic steroids	First episode of bronchiolitis—not recommended	The use of glucocorticoids in hospitalized infants with BPD and those with multi-trigger wheeze (personal or family history of atopy) may be warranted.
Bronchodilators plus steroids	Not recommended	
Oral bronchodilators	Not recommended	Oral bronchodilators have neither shortened clinical illness / improved clinical parameters but are associated with adverse effects (increased heart rate). May be used after discharge in those showing response to initial bronchodilator therapy.
Hypertonic saline	Not recommended	
Antibiotics	Not recommended	Warranted only when there is evidence of a coexisting bacterial infection (e.g., positive urine or blood culture, AOM, consolidation on chest radiograph).
Ribavirin	Not recommended	However, in immunocompromised patients and those with severe RSV bronchiolitis, antiviral therapy may play a role.
Anti-RSV preparations	Not recommended	RSV-specific humanized monoclonal antibody (palivizumab) has failed to improve outcomes in infants (with or without risk factors) hospitalized with RSV infection.
Surfactant	Not recommended	However, additional data are needed before reliable estimates of the magnitude of the effects can be made.
Heliox	Not recommended	Administration of heliox is cumbersome and results in a relatively small benefit in a limited group of infants.

Abbreviations: AOM, acute otitis media; RSV, respiratory syncytial virus.

epinephrine with placebo, there were no significant differences in clinical score, oxygenation, hospitalization rate or duration of hospitalization. Another meta-analysis of 19 trials compared nebulized epinephrine with placebo or other bronchodilators. Compared with placebo, epinephrine decreased admissions within 24 hours of administration and was associated with short-term clinical improvements but did not affect admissions within 1 week or length of stay. Compared with salbutamol, epinephrine was associated with short-term clinical improvements but did not affect admission rate. Although epinephrine was associated with decreased length of stay compared with salbutamol, epinephrine did not decrease length of stay when compared with placebo. In a subsequent multicenter randomized trial comparing nebulized epinephrine with nebulized saline in infants (< 12 months) with moderate to severe acute bronchiolitis, length of stay, use of supplemental oxygen, ventilatory support nasogastric tube feeding and improvement in clinical score compared with baseline were similar between groups.

However, a monitored trial of bronchodilator medication is an option with continuation only if there is a documented objective clinical response.

Systemic Glucocorticoids

The anti-inflammatory effects of glucocorticoids are thought to reduce airway obstruction by decreasing bronchiolar swelling. However, most studies show little effect in bronchiolitis. A 2013 meta-analysis evaluating the use of systemic glucocorticoids for acute bronchiolitis in children (0–24 months of age) included 17 trials with 2,596 patients. In pooled analyses, no significant differences were found in hospital admission rate, length of stay, clinical score after 12 hours or hospital readmission rate. Whether glucocorticoids provide

benefit in different subgroups of children with bronchiolitis is uncertain. Some patients presenting the first episode of bronchiolitis may be experiencing inflammation from asthma and these patients can benefit from systemic glucocorticoids. Although patients with asthma can benefit from glucocorticoids, randomized controlled trials have demonstrated no benefit of oral glucocorticoids in young children with virus-associated wheezing. Another meta-analysis of three studies evaluating the use of systemic glucocorticoids in infants with bronchiolitis requiring admission to the intensive care unit found no overall effect on duration of mechanical ventilation or length of hospitalization.

Bronchodilators Plus Glucocorticoids

The possibility of synergy between bronchodilators and glucocorticoids has been evaluated in systematic reviews and meta-analyses. In one multicenter trial, 800 infants presenting to the emergency department (ED) with bronchiolitis were randomly assigned to one of four treatment groups: (i) nebulized epinephrine and oral placebo, (ii) oral dexamethasone and inhaled placebo, (iii) nebulized epinephrine and oral dexamethasone and (iv) nebulized and oral placebo. Outcomes in the dexamethasone and epinephrine monotherapy groups did not differ significantly from those in the placebo group. Treatment with dexamethasone and epinephrine was associated with a decreased rate of hospitalization within 1 week of the ED visit (17 vs 24–26% in the other groups), but the result was not significant when adjusted for multiple comparisons. The rate of hospitalization was not affected by RSV status, personal or family history of atopy, time of presentation or illness severity. The current data do not support combination bronchodilator-glucocorticoid therapy for children with bronchiolitis.

Nebulized Hypertonic Saline

Nebulized hypertonic saline theoretically has the potential to reduce airway edema and mucus plugging, the predominant pathologic features of acute bronchiolitis. A 2013 meta-analysis evaluating nebulized hypertonic saline for bronchiolitis in infants included 11 trials (1,090 patients). In pooled analysis of four trials (380 patients), treatment with 3% or 5% vs 0.9% saline (administered with bronchodilators) was associated with a nonsignificant reduction in hospitalization. Subsequent randomized trials comparing nebulized hypertonic (3% or 7%) and normal (0.9%) saline administered in the ED found mixed results with respect to hospitalization, but no benefit for clinical improvement or length of stay.

Respiratory Support

- **Supplemental oxygen:** It should be provided by nasal cannula, face mask or head box to maintain SpO₂ above 90–92%. Oxygenation by most nonthreatening fashion for delivery of oxygen. Sometimes less efficient and less predictable method like blow by method may be needed initially in a very irritable child. Persisting hypoxemia despite high oxygen flow, with or without severe distress, requires immediate assessment for ventilator assistance. Close monitoring is required as supplemental oxygen is weaned, particularly for children with hemodynamically significant heart disease, bronchopulmonary dysplasia and premature birth. During recovery phase, SpO₂ of 90–92% is accepted, if baby is feeding well and not distressed as sufficient for cessation of oxygen (except in infants with underlying chronic lung disease) and consider discharge.
- **Other measures:** Infants with arterial carbon or capillary dioxide tension more than 55 mm Hg, hypoxemia despite oxygen supplementation and/or apnea may require mechanical ventilation.
- **Continuous positive airway pressure (CPAP):** CPAP with or without helium-oxygen blends has gained favor as a way to decrease work of breathing and prevent endotracheal intubation in children with progressive hypoxemia or hypercarbia. However, additional studies are necessary to clarify the benefits of CPAP.
- **Heated, humidified high-flow nasal cannula therapy (HFNC):** HFNC is a noninvasive well-tolerated method of ventilatory support that permits high inspired gas flows (1–8 L/min) with or without increased oxygen concentration. Currently, there is insufficient evidence to determine the effectiveness of HFNC for treating bronchiolitis in infants. Additional trials are being conducted to determine the effectiveness and effect of various flow rates on airway pressure, breathing patterns and respiratory effort in infants hospitalized with bronchiolitis. Flow rates of more than or equal to 6 L/min (2 L/kg/min) appear to provide positive pressure throughout the respiratory cycle.

Monitoring

Repeated clinical assessment of the respiratory system (respiratory rate, nasal flaring, retractions and grunting) is necessary to identify deteriorating respiratory status in both the outpatient and inpatient settings. Early in the admission, hospitalized infants should have continuous monitoring of heart rate, respiratory rate and SpO₂. Infants with severe distress or who have apnea should be monitored in the intensive care unit. An arterial or capillary blood gas measurement may be indicated in children who require intensive care. A change from continuous to intermittent measurement of SpO₂ may be instituted as the clinical course improves.

Chest Physiotherapy

It is not recommended in the management of acute episode of bronchiolitis. A systematic review concluded that chest

physiotherapy using vibration and percussion or passive expiratory techniques did not improve respiratory parameters, reduce supplemental oxygen requirement or reduce length of hospital stay. The use of chest physiotherapy is discouraged because it may increase the distress and irritability of ill infants.

Minimal clinical criteria for discharge from the hospital, ED or office are listed in **Box 3**.

BOX 3 Discharge criteria for bronchiolitis

- Patient is stable without for bronchiolitis supplemental oxygen for at least 10–12 hours prior to discharge
- Patient has adequate oral intake to prevent dehydration
- The resources at home are adequate to support the use of any necessary home therapies (e.g., inhalation therapy if the trial was successful and this therapy is to be continued)
- Education of the family is complete.

CLINICAL COURSE AND PROGNOSIS

Typical illness with bronchiolitis begins with upper respiratory tract symptoms, followed by lower respiratory tract signs and symptoms on days 2–3, which peaks on days 5–7 and then gradually resolves. The duration of the illness due to bronchiolitis depends upon age, severity of illness, associated high-risk conditions and the causative agent. Bronchiolitis usually is a self-limited disease. Most children who do not require hospitalization recover by 2–8 days.

In previously healthy infants older than 6 months who require hospitalization, the average length of hospitalization is 3–4 days, although it may be longer in children with bronchiolitis due to rhinovirus. The respiratory status typically improves over 2–5 days. However, wheezing persists in some infants for a week or longer.

The course may be prolonged in infants younger than 6 months (particularly those younger than 12 weeks) and those with comorbid conditions; these children often are severely affected and may require assisted ventilation.

Outcome

Bronchiolitis is a self-limited illness and resolves without complications in most previously healthy infants. However, severely affected infants, especially those born prematurely and those with underlying cardiopulmonary disease or immunodeficiency, are at increased risk for complications (e.g., apnea, respiratory failure, secondary bacterial infection).

Mortality

The overall mortality rate in children hospitalized with RSV bronchiolitis in developed countries is less than 2%. Mortality is increased in young infants (6–12 weeks) those with low birth weight and those with underlying medical conditions (e.g., underlying cardiopulmonary disease, immune deficiency).

Long-term Sequelae

Possible association with asthma: Infants hospitalized for LRTI, especially RSV, are at increased risk for recurrent wheezing and reduced pulmonary function, particularly during the first decade of life. In a prospective cohort, LRTI with RSV increased the risk for subsequent frequent and infrequent wheezing and was associated with reduced forced expiratory volume in children up to 11 years of age. However, this association was lost by the age of 13 years, perhaps due to inadequate sample size. In some studies, a correlation exists between infection with RSV and the later development of reversible airways disease. However, this may reflect the multifactorial nature of risk for asthma including a genetic predisposition to airway reactivity, exposure to environmental pollutants such as smoke, immunologic mechanisms, and

disruption of the growth and development of the lungs due to viral infection in early childhood.

IN A NUTSHELL

1. Bronchiolitis is a clinical syndrome in children less than 2 years of age characterized by upper respiratory symptoms followed tachypnea and/or wheezing.
2. Bronchiolitis is primarily caused by respiratory syncytial virus.
3. Risk factors for severe disease and/or complications include gestational age less than 37 weeks, age less than 12 weeks, chronic pulmonary disease, congenital and anatomic defects of the airways, congenital heart disease, immunodeficiency and neurologic disease.
4. Bronchiolitis is diagnosed clinically. Chest radiographs and laboratory tests are not routinely indicated.
5. Anticipatory guidance, adequate clinical monitoring and supportive management are essential. Bronchodilators may have a role in some patients.

Chapter 39.17

Alpha-1 Antitrypsin Deficiency

Kana Ram Jat, Rakesh Lodha, SK Kabra

Laurell and Eriksson first described alpha-1 antitrypsin (AAT) deficiency in 1963. AAT deficiency is relatively less common condition worldwide. This genetic disease results in emphysema and chronic obstructive pulmonary disease (COPD), usually in adults but not in children. In children, AAT deficiency is an important cause for cholestasis. Liver disease including cirrhosis and hepatocellular carcinoma (HCC) may occur both in children and adults. Pediatricians are usually involved in genetic testing of the disease.

EPIDEMIOLOGY

Alpha-1 antitrypsin deficiency is the most common genetic cause of neonatal cholestasis. PiZZ is the most common phenotype in patients with emphysema secondary to AAT deficiency. AAT deficiency is usually under-recognized and mean interval between first symptom and diagnosis of AAT deficiency is reported to be 7.2 years. It is estimated that disease is diagnosed in only 5–10% of affected individuals. It is considered to be rare in India and other Southeast Asian countries.

PATHOGENESIS

Alpha-1 antitrypsin deficiency is co-dominantly inherited condition having more than 100 alleles. Expression of both alleles determines the serum levels of AAT and resulting disease severity. AAT deficiency is classified through protease inhibitor (Pi) system based on banding pattern on isoelectric focusing gel electrophoresis (F-Fast, M-Medium, S-Slow and Z-very slow), e.g., Pi ZZ, Pi SM, Pi MM, etc. Serum level of AAT less than 11 $\mu\text{m/L}$ is a risk factor for development of emphysema. The gene, *SERPINA1*, that encodes AAT is situated on chromosome.14q31-32.3. The most common Z allele is characterized by substitution of lysine for glutamic acid at position 342.

Alpha-1 antitrypsin is primarily produced within hepatocytes and reaches lungs via circulation. It is also produced locally in lungs by bronchial epithelial cells, alveolar macrophages, neutrophils and type II pneumocytes. AAT belongs to serine proteinase inhibitor (SERPIN) family and suppresses activity of trypsin, collagenase, neutrophil elastase and macrophage cathepsin enzymes. In AAT deficiency, liver disease is caused by toxic gain of function and lung disease is caused by loss of function of the protein. AAT deficiency causes polymerization of AAT in hepatocytes resulting in aggregation of misfolded protein that causes liver pathology. The disease causes imbalance between protease and antiprotease leading to enzymatic breakdown of lung tissue that results in emphysema. Mechanical damage and inflammation fueled by enhanced chemotaxis also contributes in development of emphysema. The decreased protease inhibitions

in AAT deficiency have some advantages against infections, but it may enhance ovulation, twinning, fertility and sperm migration. The environment, especially smoking, and genetic components also mediate development of emphysema in AAT deficiency.

CLINICAL FEATURES

Although, AAT deficiency has been detected during neonatal screening programs, it rarely presents with respiratory symptoms in children. AAT deficiency usually causes liver disease in children ranging from neonatal cholestasis to liver failure requiring transplantation.

In adults, AAT deficiency may cause emphysema, bronchiectasis and a spectrum of liver disease including chronic hepatitis, cirrhosis and hepatoma. Mean age of presentation of emphysema secondary to AAT deficiency is 32–41 years. Symptoms mimic COPD and asthma. Characteristic pulmonary features of AAT deficiency include early onset (as compared to COPD), emphysematous changes more in lung bases and panacinar pathology. Liver disease manifestation in children ranges from transaminitis to cirrhosis and liver failure. About 25% children having liver disease die in first decade of life and 50% develop cirrhosis. It is recommended to test for AAT deficiency in all neonates and children having unexplained liver disease.

In adults, AAT deficiency is also found to have associations with necrotizing panniculitis, vasculitis (especially c-ANCA positive vasculitis such as Wegener's granulomatosis), celiac disease, glomerulonephritis, various malignancies and pancreatitis.

DIAGNOSIS

Estimation of serum level of AAT is primary step to diagnose AAT deficiency. If AAT levels are low, isoelectric focusing (phenotyping) should be performed to conform the diagnosis and to identify AAT variants. Recently, genotyping by polymerase chain reaction (PCR) is considered diagnostic test of choice. Testing of asymptomatic children for AAT deficiency has psychological connotations and should be done along with counseling.

MANAGEMENT

Treatment of COPD due to AAT deficiency includes supportive therapy (bronchodilators, oxygen supplementation if needed, smoking cessation, antimicrobials for secondary infection) along with enzyme replacement (intravenous augmentation) therapy. Augmentation therapy consists of infusion of purified pooled human plasma AAT in a sufficient amount to raise AAT levels above threshold value. The usual dose for purified AAT is 60 mg/kg once weekly. Studies and meta-analysis regarding efficacy of augmentation therapy for AAT deficiency have inconclusive results. It is suggested that augmentation therapy may be effective for moderate obstruction as compared to mild and severe obstruction. Therapy is usually well tolerated. There is no specific therapy for liver disease due to AAT deficiency and treatment includes supportive treatment for cholestasis. Liver transplantation may be curative for end-stage liver disease.

OUTCOME

In children with AAT deficiency, liver disease is responsible for morbidity and mortality. AAT deficiency causes gradual decline in lung function in affected adults. Risk factors for rapid decline in forced expiratory volume in 1s (FEV₁) include smoking, moderate to severe obstruction, male sex, bronchodilator responsiveness and decreased serum level of AAT. In adults, respiratory failure is

BOX 3 Discharge criteria for bronchiolitis

- Patient is stable without for bronchiolitis supplemental oxygen for at least 10–12 hours prior to discharge
- Patient has adequate oral intake to prevent dehydration
- The resources at home are adequate to support the use of any necessary home therapies (e.g., inhalation therapy if the trial was successful and this therapy is to be continued)
- Education of the family is complete.

most common cause of death in AAT deficiency followed by liver cirrhosis. Risk factors for death include lower FEV₁, lower education, old age and not getting intravenous augmentation therapy.

IN A NUTSHELL

1. Alpha-1 antitrypsin (AAT) deficiency is not uncommon but an under-recognized entity.
2. In children, it usually manifests as liver disease and respiratory symptoms are rare.
3. AAT deficiency is an important cause for early onset emphysema in adults.
4. Most common Z allele produces low level of AAT that is risk factor for development of disease.
5. Augmentation therapy (intravenous infusion of purified AAT) may slow down decline in lung function and progression of emphysema.

Chapter 39.18

Aspiration Syndromes

*Mahesh Babu Ramamurthy,
Michael Lim Teik Chung*

Aspiration refers to the passage of foreign material into the lower airways. Small amounts of secretions from the nasopharyngeal area are commonly aspirated into the lower airways in healthy subjects, and do not lead to any problems clinically. In infants and children, small amounts of saliva and mucus are normally aspirated mostly when asleep. They are cleared quickly by the mucociliary function of the airways, and therefore do not usually cause problems. However, if the amount that enters the airways is significant enough to overwhelm these protective mechanisms, or if the material is particularly irritant, aspiration into the airways can result in lung disease in children.

Aspiration material into the airways can include foreign bodies, meconium, hydrocarbons and large amounts of water from near drowning. However, aspiration syndromes are usually referred to conditions where there is aspiration of gastric contents, oropharyngeal secretions, or food, and will be the focus of this chapter. Aspiration syndromes can manifest with a variety of clinical presentations, and depends on the type of material and amount, whether acute or chronic.

EPIDEMIOLOGY

The prevalence of gastroesophageal regurgitation among infants at 1–6 months of age in India was found to be 55%, dropping to 15% at 7–12 months and subsequently 10% at 12–24 months. However, little is reported about the prevalence of aspiration syndrome resulting from gastroesophageal reflux disease (GERD) or swallowing dysfunction in India. Chronic microaspiration is commonly underdiagnosed globally, with symptoms often attributed to other diseases of the lungs, and management is frequently suboptimal as a result.

ETIOLOGY

Broadly, aspiration syndromes results from a failure of airway protective mechanisms in preventing foreign material from entering the airways, and comprise two major types: (1) acute large volume (macro-) aspiration, and (2) recurrent small volume (micro-) aspiration. Gastric contents can be aspirated in large volumes, and may happen in children with impaired consciousness. Recurrent aspiration is predisposed by various conditions that either (1) interfere with the normal mechanisms of swallowing or (2) because of the presence of GER.

Swallowing Dysfunction

Conditions which interfere with swallowing are listed in **Table 1**. Infants who are tachypneic have dyscoordinated swallowing in relation to sucking and breathing. Acute illness can exacerbate the swallowing dysfunction in any condition, as it can lead to fatigue more quickly. Children with neurological impairment are also at risk of recurrent aspiration of saliva due to blunted cough reflex, dysfunctional swallowing, and depressed laryngeal sensation. They may not have immediate symptoms of aspiration (i.e., silent aspiration), and often present with symptoms of the lung disease as a consequence.

Table 1 Conditions associated with recurrent aspiration

Anatomical defects
<ul style="list-style-type: none"> • Macroglossia • Cleft palate • Laryngeal clefts • Tracheoesophageal fistula (particularly H-type) • Vascular rings • Achalasia cardia • Cricopharyngeal achalasia • Foreign body in esophagus
Neurological problems
<ul style="list-style-type: none"> • Decreased consciousness • Encephalopathy • Prematurity • Cerebral palsy • Hydrocephalus • Vocal cord paralysis
Neuromuscular disorders
<ul style="list-style-type: none"> • Muscular dystrophy • Spinal muscular atrophy • Myasthenia gravis • Guillain-Barré syndrome
Miscellaneous
<ul style="list-style-type: none"> • Tracheostomy • Endotracheal tube • Babies and young children who are fed with inappropriate techniques or foods

Gastroesophageal Reflux

Gastroesophageal reflux is the movement of stomach contents back up into the esophagus and sometimes into the oropharynx. It is common in young infants due to the immature gastroesophageal junction and their flat posture. In this situation, the GER usually resolves over the next year or two. When GER is associated with clinical effects, it is known as *GERD*. GERD is also commonly present in children with chronic diseases of the respiratory tract. However, the causal relationship between GERD and chronic respiratory disease is often difficult to ascertain. GERD can cause chronic respiratory diseases (by vagally-mediated reflex bronchospasm after esophageal acidification and recurrent microaspiration) and conversely, chronic respiratory diseases can predispose to GER due to:

- Hyperinflation in chronic lung diseases causing diaphragmatic flattening and thereby decreasing the efficacy of lower esophageal sphincter (LES);
- Higher negative pleural pressures in respiratory diseases increasing the incidence of GER; and
- The use of certain smooth muscle relaxants like salbutamol relaxing the LES.

PATHOGENESIS

Large volume aspiration results in hypoxemia over a rapid time-scale. Aspiration of material into the trachea leads to bronchospasm, coughing and mucus production. In infants, material reaching the top of the larynx can cause laryngospasm, while younger neonates and premature babies can experience reflex central apnea and bradycardia as a result of laryngeal receptor stimulation. Large volume aspirations could also block large airways leading to lobar/segmental collapse of distal lung. Sometimes the whole lung is collapsed.

Recurrent aspiration results in repeated damage to airways and lung parenchyma. GER brings up acid which when aspirated is toxic to the respiratory tract and causes desquamation of mucosa, damage to alveolar lining cells and capillaries, and neutrophilic inflammation. In contrast, repeated aspiration of partially digested vegetable matter and saliva with neutral pH—as seen in conditions of swallowing dysfunction—produces a foreign body reaction involving cell-mediated immunity. This results in nodular granulomas, giant cells and bronchiolitis with alveolar organization.

In some children, these pathological processes may break down local defenses against bacteria and lead to secondary bacterial infection of the lungs from organisms originating from the sinuses, nasopharynx and gastric region.

CLINICAL FEATURES

Acute large volume aspiration, especially in the context of foreign material lodged in a main airway, results in acute airway obstruction and hypoxic emergency. Other children will have lobar or segmental lung collapse, which will also give rise to hypoxia and respiratory distress due to ventilation-perfusion mismatch. In a child with GERD, there may be symptoms which suggest its presence, such as abnormal posturing and back-arching in infants (Sandifer's syndrome), abdominal pain, or vomiting with feeds. In infants, apnea may occur, and is either obstructive or due to reflex central apnea. Bradycardia may be present with apnea. Other symptoms suggestive of an aspiration event include coughing or choking soon after a feed. Coughing in a child with recurrent aspiration may occur more at night due to reflux when the child is lying flat.

Recurrent aspiration of food, gastric contents or saliva into the lower airways results in chronic pulmonary aspiration syndrome (CPA) and causes chronic or recurrent respiratory symptoms. These include chronic cough, wheeze, recurrent pneumonia, failure to thrive, and choking on feeds or secretions. CPA can occur coincidentally with other stressors like an upper respiratory infection. It can be difficult to distinguish between recurrent aspiration and other chronic respiratory diseases such as bronchopulmonary dysplasia. This is because a lot of the symptoms are similar—recurrent cough, wheeze, atelectasis and recurrent chest infections. Unless picked up and managed early enough, recurrent aspiration can lead to permanent lung injury and bronchiectasis. Clinical examination of patients with aspiration may reveal fine crackles or wheeze.

DIFFERENTIAL DIAGNOSES

Differential diagnoses of chronic recurrent aspiration can include respiratory conditions that result in chronic cough. These include bronchopulmonary dysplasia, tracheobronchomalacia, primary ciliary dyskinesia, bronchiectasis, cystic fibrosis, foreign body in the airways, and childhood interstitial lung disease.

APPROACH TO DIAGNOSIS

Children with aspiration syndromes often have multisystemic problems, and the evaluation of a child suspected of aspirating should involve a multidisciplinary team. A careful history should be obtained with regards to the presence of GERD. It is worth observing how the child feeds, paying attention to how the child sucks and swallows, and if there is any cough, vomiting, or choking. Drooling or excess saliva pooling in the mouth may suggest a problem with swallowing. Examination may reveal signs of airways or lung aspiration on auscultation, particularly after feeding.

Investigations for the Presence of Gastroesophageal Reflux

A *contrast swallow* is helpful to look for structural abnormalities that may result in narrowing of the esophagus (e.g., vascular rings), hiatus hernia, or tracheoesophageal fistula (particularly H-type fistulae which often require a proper prone esophagram to diagnose). The study allows the assessment of food transport down the esophagus. Extending this to a barium meal allows the investigation for the presence of GER (although limited by the short duration of the study), and also the speed of gastric emptying.

Gastroesophageal scintigraphy (milk scans) involves ingestion of a radiolabeled milk with serial images recorded. This study may be used to diagnose and quantitate reflux, but late images (24 hours) showing isotope in the lungs indicates pulmonary aspiration. The sensitivity of this procedure is very low and hence a normal study does not rule out aspiration.

24-hour esophageal pH monitoring (pH study) has been considered the gold standard for diagnosing GERD, but its limitations are being increasingly recognized. Nonacid reflux, which is equally important, is undetectable by pH monitoring. Also, traditionally, gastroenterologists interpret pH results based on the proportion of time that esophageal pH is less than 4. However, even a single bad reflux can give rise to pulmonary aspiration. For these reasons, pH monitoring is yet to be validated for extraesophageal manifestations of GER.

Multichannel intraluminal impedance study can be used to detect acid and nonacid reflux using a probe that detects change in electrical resistance during the passage of food between electrodes at different levels along the pharynx and esophagus. The study can distinguish between air, liquid and solid reflux, and their direction of flow. As the level of reflux can be measured, the number of high level reflux episodes which are more likely to penetrate into the airways can be defined. Its use is currently limited by its availability in only a limited number of centers, and a lack of evidence on how the study results should be interpreted to diagnose GER in children.

An *esophagoscopy* can be done to evaluate for esophagitis secondary to GER.

Investigations for Aspiration

Investigations for small volume aspiration are generally low on sensitivity and specificity. To assess swallowing, a clinical evaluation by a qualified speech and language therapist can be initially carried out. This can provide information on feeding behaviors of the child, and is a good screening exercise for the possibility of aspiration.

A *video fluoroscopic swallow study* (VFSS) has the ability to evaluate the oral pharyngeal and esophageal phases of swallowing directly. It will help detect aspiration of contrast material into the trachea. Different food textures and amounts can be investigated at various stages of swallowing. Owing to the episodic nature of aspiration, a normal VSS cannot entirely rule out aspiration of feeds.

Fiberoptic endoscopic evaluation of swallowing (FEES) allows the direct visualization of swallowing, and has the benefit of no sedation or radiation exposure, although more invasive than the other tests described earlier. A fiberoptic scope is passed through the nose and placed between the soft palate and epiglottis. The larynx is observed while the patient is fed with various types of foods (varying in consistency, including consistencies of the child's usual foods). Swallows are visualized directly by the physician and the child's home caregivers *via* a video monitor. The ability of the caregiver to observe the aspiration event as well as the effectiveness of feeding techniques directly provides strong feedback and reinforcement. FEES can also be used to assess for salivary aspiration which can also be visualized directly.

If salivary aspiration is suspected, *radionuclide salivagrams* can be used whereby tracer activity in the trachea following application in the buccal space indicates aspiration of saliva.

The suctioning of dye-stained secretions in patients with a tracheostomy who have been given dye on the tongue or mixed into feeds has also been used as a test for CPA in tracheotomized children.

Bronchoscopy can identify structural defects such as a laryngeal cleft and H-type tracheoesophageal fistula and can also reveal inflamed mucosa around the larynx indicating acid contact. The large airways may appear inflamed. A lipid-laden macrophage index (LLMI) based on the number of lipid-filled macrophages in bronchoalveolar lavage (BAL) has been used as a marker of inflammation but not favored due to false-positive results, lack of reproducibility and high interobserver variability.

Chronic aspiration typically presents radiographically as hyperaeration, subsegmental or segmental infiltrates and peribronchial thickening (**Fig. 1**). Bronchiectasis may also eventually be seen. The dependent areas of the lower lobes as well as posterior upper lobe segments are usually involved. Chest X-rays are not sufficiently sensitive to detect subtle changes, and a normal X-ray does not rule out aspiration.

A *computed tomography* (CT) scan of the chest is not usually necessary, but in long-standing or severe cases with chronic aspiration, nonspecific findings like tree-in-bud opacities and bronchiectasis may be seen (**Fig. 2**).

MANAGEMENT

Managing an Acute Event

For an acute aspiration event that is witnessed, immediate therapy should be instituted. These include turning the patient's head to the side, suctioning of the airway, and giving oxygen if the patient's SpO₂ is low. Antibiotics in anticipation of a secondary bacterial infection is not always necessary but may be indicated if the child is at risk of significant deterioration due to poor premorbid state (e.g., with pre-existing severe respiratory disease). Fever, mucopurulent secretions, raised inflammatory markers and leukocytosis are clues to an evolving bacterial infection.

Treatment of aspiration syndromes depends on the cause. If there is a structural problem, this will need to be repaired if possible.

Treating Gastroesophageal Reflux Disease

Medical and conservative therapies are initially chosen for children with GERD. Feeding in a more upright position can be performed, particularly in infants. Feed thickeners or reducing the volume of each feed may help in mild cases. In the older child, foods that exacerbate symptoms of GER should be avoided (e.g., caffeine and spicy foods). If the child is overweight, a weight loss program should be carried out. Acid suppression with H₂ receptor antagonists (ranitidine 2–4 mg/kg BD) or proton pump inhibitors (PPIs [proton-pump inhibitors], e.g., omeprazole 0.7–3 mg/kg OD) will reduce acid reflux. Although the efficacy of PPIs is proven for reflux esophagitis, their efficacy is not established for CPA. Prokinetic drugs to increase gastric emptying such as domperidone (0.25 mg/kg TDS) can also be tried.

Jejunal feeding by way of a nasojejunal tube (NJ tube) is sometimes used either as a bridge to surgery or in children who are not candidates for surgical treatment. NJ feeding allows adequate feeding and may reduce respiratory infections but do not guarantee elimination of GERD and therefore significant aspiration can still occur. Jejunal feeding has to be continuous (no bolus feeding) and risks intestinal obstruction, intussusception, jejunal perforation, and tube displacement.

Figure 1 Bilateral infiltrates on a chest radiograph with subsegmental atelectasis in the upper zones of a supine infant with recurrent aspiration of oropharyngeal secretions

Figure 2 Computed tomography (CT) scan of the chest of a 2-year-old child with a 1-year history of recurrent oropharyngeal and gastric aspiration. There is partial collapse and consolidation of both lower lobes with patchy atelectasis on the right side

Surgery

Surgical options such as fundoplication should be considered if medical therapy is not effective and GERD is present. It can successfully resolve reflux, and subsequent respiratory symptoms of aspiration, in most children. The operation is however less successful in neurologically impaired children, with higher failure rates in this group of patients. If there is esophageal dysmotility, fundoplication may also increase the risk of dysphagia, and impede flow of food and saliva through a tight gastroesophageal junction, worsening aspiration.

Managing Swallowing Dysfunction

In swallowing dysfunction, feeding should be limited to foods with consistencies that are well tolerated, and to an amount and rate that does not result in aspiration (e.g., small frequent feeding). Nasogastric or gastrostomy feeding may be used, as long as there

is not significant GER. Percutaneous button gastrostomy has made this a useful method for those with severe swallowing dysfunction.

If there is a problem with aspiration of saliva, e.g., in children with swallowing dysfunction, several measures can be performed. The child can be nursed with the head positioned such that the secretions can drain out from the mouth (this can be aided with gentle suctioning). Medications to reduce the volume of saliva can be used, e.g., hyoscine, scopolamine (1.5 mg skin patch), and glycopyrrolate (0.04–0.1 mg/kg/dose, 3–4 times a day). However, there is a risk that the thickening of secretions as a result of these medications makes suctioning more difficult, with increased risk of mucus plugging and atelectasis. Anticholinergic side effects such as decreased bowel movements and urinary retention can also occur. Injection of the salivary glands with botulism toxin can reduce the amount of saliva produced; this is guided by ultrasound. The effect of this procedure is short-lasting and repeat injections would have to be given in future.

Surgery

Posterior migration or ligation of the salivary ducts and surgical removal of salivary glands are surgical options to reduce the amount of salivary secretion. Placement of a tracheostomy tube may be required, if other medical or surgical therapies fail, mainly for airway toileting. If aspiration from oral secretions is life-threatening over a prolonged period and unresponsive to the earlier measures, laryngotracheal separation procedures with tracheostomy have been performed in some centers to reduce aspiration into the airways.

Key aspects of treatment are summarized in **Box 1**.

BOX 1 Treatment of aspiration syndromes

- Acute aspiration events should be treated immediately
- Antibiotics are started, if the child already has poor reserves, or when signs of secondary bacterial infection develop
- If the cause is a structural defect, the defect will need to be repaired
- If GER is present in infants, correct positioning, smaller, more frequent feeds, and feed thickeners can help
- Lifestyle modifications such as avoidance of certain foods and weight management can improve GER, if indicated
- Further treatments of GER include medications for acid suppression, prokinetics, jejunal feeding, or fundoplication
- Swallow dysfunction can be managed by limiting foods to those with consistencies that are well tolerated, or with nasogastric/gastrostomy feeding
- Aspiration of oral secretions can be managed with head positioning, suctioning, medications to reduce the volume of secretions, botulism toxin injection of salivary glands, ligation of salivary ducts, or laryngeal closure surgery with tracheostomy.

PROGNOSIS

Most patients will recover within a few weeks, if an aspiration event is adequately treated and managed without complications such as pneumonia. If recurrent aspiration is left untreated, it may lead

to complications such as recurrent pneumonitis, lung damage, bronchiectasis, bronchiolitis obliterans and failure to thrive.

Sometimes, children with clinical evidence of recurrent aspiration will have negative test results for swallowing dysfunction or GERD. A trial of no feeding by mouth and NG feeding could improve their respiratory symptoms. These cases highlight the difficulties in establishing the diagnosis of CPA and the importance of clinical judgment in suspected cases.

PREVENTION

Aspiration syndromes are often underdiagnosed, and early recognition of clues pertaining to an aspiration syndrome is important to reduce the risk of significant airway disease. Prevention of further aspiration is the goal of treatment once an aspiration syndrome is recognized, by having a logical approach to work-up and treatment.

IN A NUTSHELL

1. Aspiration is the penetration of foreign material into the airways and subsequently the lungs.
2. Aspiration syndromes usually result in recurrent aspiration of gastric contents, oropharyngeal secretions or food overtime, and can lead to significant lung disease.
3. Aspiration syndromes are underdiagnosed, and often detected only late in the disease course when permanent lung changes have occurred.
4. Children at risk for recurrent aspiration are usually those with anatomical and neurological defects that interfere with the normal process of swallowing, or with significant GER.
5. The evaluation of a child suspected of aspiration should involve a multidisciplinary team.
6. Work-up should be targeted at finding out the underlying cause for aspiration, and the extent of airways and lung injury as a result of aspiration.
7. The treatment goal is to address the causes of aspiration to prevent future aspiration events from occurring.

Chapter 39.19

Preschool Wheeze and Bronchial Asthma

KR Bharath Kumar Reddy, Samatha Sonnappa

PRESCHOOL WHEEZING

Wheeze is an audible manifestation of airway oscillations caused by airflow limitation, irrespective of the underlying cause. Wheezing in the preschool years is extremely common and it is estimated that approximately one in three children will have at least one episode of wheeze prior to their third birthday, and by 6 years of age, this figure increases to almost 50%. This is likely due to the pathophysiologic properties that predispose infantile lungs to wheeze. Infants' bronchioles (compared to older children and adults) have decreased smooth muscle content, hyperplasia of mucus glands and a smaller radius, which, in turn, increases resistance considerably. These factors increase the risk of obstruction and may manifest as cough, wheeze, chest tightness, shortness of breath, or tachypnea. Wheezing in the preschool years is heterogeneous and the long-term prognosis varies from complete recovery to persistent asthma. This section will focus on preschool children with recurrent wheeze. Recurrent wheezing is defined as more than three episodes of wheezing in the past year that lasted more than a day and affected sleep.

EPIDEMIOLOGY

The most common cause of wheezing, whether primary or recurrent, during the first few years of life is infection with respiratory viruses, most commonly respiratory syncytial virus and human rhinovirus. All children are infected with respiratory viruses during early childhood and nearly one-half wheeze during at least one of these infections. A number of risk factors for wheezing with respiratory viruses during early childhood have been identified by birth-cohort studies. Maternal smoking, male sex, older siblings and daycare attendance during infancy increase the risk for early childhood wheezing illnesses.

ETIOLOGY

Preschool wheeze is a syndrome and not a single entity. Within the syndrome of preschool wheeze, several phenotypes have been proposed, as shown in **Box 1**. These phenotypes are used to study risk factors, prognosis and response to treatment. However, these phenotypes probably represent different facades of the same entity, as there is significant overlap between the phenotypic categories.

PATHOPHYSIOLOGY

Pathological studies have been relevant in determining early structural changes as well as guiding treatment. From the few studies that used bronchial biopsies or bronchoalveolar lavage, it is clear that the inflammatory reactions in preschool children with wheeze differ from those in older children with established asthma. Two cross-sectional studies have suggested that in preschool wheezers, there may be a window of around 18 months between symptom onset and development of airway wall changes consistent with asthma. In the first study, infants (median age 12 months) were investigated for severe respiratory symptoms, using infant lung function, bronchodilator reversibility and rigid bronchoscopy. Despite severity of symptoms, there was no evidence of airway

BOX 1 Preschool wheeze phenotypes

Phenotype based on time course:

- *Transient wheeze:* Wheeze during the first 3 years of life and stops by age 6 years
- *Persistent wheeze:* Wheeze in the first 3 years of life and continue to wheeze at age 6 years
- *Late-onset wheeze:* No wheeze in the first 3 years of life but wheeze at age 6 years

Phenotype based on symptom-pattern:

- *Episodic (viral) wheeze:* Wheeze at discrete times, often with evidence of viral colds and characterized by no symptoms between episodes
- *Multiple-trigger wheeze:* Wheeze with discrete exacerbations and symptoms between episodes

Phenotype based on atopic status:

- *Atopic wheeze:* Various defined as those with elevated IgE and/or allergic sensitization to allergens with or without eczema. Symptomatic at any age but most before age 6 years
- *Nonatopic wheeze:* Children wheeze with viral infections during the first 3 years of life and may continue to do so or stop at school-age.

inflammation or reticular basement membrane thickening, even in infants with documented atopy and bronchodilator reversibility. In the second cross-sectional study, infants (median age 30 months) with confirmed severe wheezing episodes showed evidence of eosinophilic inflammation and reticular basement membrane thickening albeit less marked than in children with severe asthma. Other studies have confirmed that eosinophilic inflammation is not prominent in episodic (viral) wheeze.

Epidemiological evidence has shown that transient wheezers (who may have an episodic [viral] or multiple-trigger phenotype, but are probably more likely to have the former) are born with airflow obstruction, whereas those with persistent wheeze (which again may be episodic [viral] or multiple-trigger phenotype, more likely the latter) have normal lung function soon after birth that becomes abnormal by age 4–6 years. Thus, attention focuses on the antenatal period for the transient wheezers and the immediate postnatal years for the persistent wheezers, the likely future asthmatics in mid-childhood. Risk factors for persistence of wheeze into adulthood include female sex, atopy, airway hyper-responsiveness, poor lung function in childhood and smoking.

CLINICAL PRESENTATION

The typical symptoms include expiratory wheezing and cough. Shortness of breath and dyspnea are the other characteristic symptoms. The physical examination in the preschool child with wheeze may be normal at consultation as intermittent symptoms are most common at this age. If symptomatic at the time of examination, physical findings commonly include polyphonic expiratory wheeze as a manifestation of diffusely narrowed small airways. Coarse crackles may be heard from mucus in the large airways. During an acute exacerbation, labored breathing with intercostal, suprasternal and substernal retractions may be present, along with an audible wheeze. In the preschool child who is asymptomatic on examination, the diagnosis is dependent on a careful history of previous symptoms.

APPROACH TO DIAGNOSIS

Initial evaluation of a child with recurrent wheeze depends on the likely etiology. A thorough history in a wheezy child that includes details of the wheezing episode, such as onset, duration and associated factors often provides clues to allow prioritization of diagnostic possibilities listed in **Table 1**. In a child with a clear history of episodic (viral) or multiple-trigger wheeze, no initial

investigations are necessary. A chest X-ray is not generally required, but may be helpful if other diagnoses need to be considered. A trial of bronchodilator through a spacer may be diagnostic and therapeutic in a child who is seen while symptomatic. Pulmonary function testing, a valuable tool in aiding asthma diagnosis is not frequently used in preschoolers, but can be successfully performed in children as young as 3 years.

Further evaluation with investigations as listed in **Table 1** can be considered in a step-wise manner in wheezers with a more complex history and in those not responsive to a trial of inhaled corticosteroids.

Differential Diagnoses

The younger the child at presentation, the broader the differential diagnosis, emphasizing the importance of a higher index of suspicion for other causes of wheezing in the preschool child, as listed in **Table 1**.

MANAGEMENT

Apart from the environmental control, allergen avoidance and parent education, pharmacological treatment should be focused on symptom prevention and improving the long-term outcome of preschool wheezers. Acute symptoms are treated with short-acting beta-agonists, systemic corticosteroids and oxygen in severe cases. Oral steroids are not indicated in preschool children with attacks of wheeze who are well enough to remain at home and in many such children, especially those with episodic viral wheeze, who are admitted to hospital.

Preventive Therapy

The use of inhaled or oral corticosteroids in preschool wheezers is common in clinical pediatric practice. Most children with preschool wheezing will outgrow their symptoms and do not need any preventive treatment especially when the symptoms are mild

and infrequent. However, when symptoms are severe or frequent, initiating preventive treatment will reduce symptoms and improve quality of life. Treatment options include intermittent montelukast for episodic (viral) wheezers and prophylactic low-dose inhaled corticosteroids with bronchodilators (as per need) and montelukast for multiple-trigger wheeze. Regular, careful re-evaluation of children's symptoms is essential as the wheeze phenotype can change over time in preschool children. An approach to treatment is given in **Table 2**.

PROGNOSIS

Parents frequently want to know whether their child will continue to have symptoms and require drug treatment into school age and beyond. Several randomized controlled trials show that early use of inhaled corticosteroids, whether continuously or intermittently with viral colds, does not affect progression of disease and treatment should be solely focused on control of current symptoms.

The asthma predictive index (API) is a commonly used clinical tool that allows for identification of children at maximum risk for persistent wheeze at school age (**Table 3**). To have a positive API, a child must wheeze before age 3 years and have either one of two major criteria or two of three minor criteria. Children with recurrent wheeze before age 3 years and a positive API at age 3 years were nearly 10 times more likely to have active asthma at age 6 years and nearly 6 times more likely to have asthma at age 13 years than children with a negative API. Even children with only one wheezing episode before age 3 years were 2.6–5.5 times more likely to have persistent symptoms at ages 6 years and 13 years, respectively, if their APIs were positive. Thus, this index can be used to guide caregivers and clinicians as to the likely course of a child's subsequent wheezing.

However, it should be noted that API and other clinical predictive indices for future risk of asthma while useful in group

Table 1 Differential diagnosis of recurrent wheezing in preschool children and suggested investigations

Diagnosis	Main clinical features	Evaluation
Episodic (viral) wheeze	Triggered only by viral infections (colds)	Good history and examination
Multiple-trigger wheeze	Triggered by colds and other factors such as allergy, exercise	Good history and examination
Aspiration syndromes	Chronic cough, vomiting or poor weight gain	pH study and contrast studies to assess swallowing disorders and gastroesophageal reflux
Inhaled foreign body	Chronic cough usually with a history of prior episode of acute coughing or choking	Chest X-ray, bronchoscopy
Airway malacia	Stridor and wheeze poorly responding to bronchodilators and inhaled steroids	Flexible bronchoscopy
Congenital anomalies (vascular ring)	Stridor and wheeze poorly responding to bronchodilators and inhaled steroids	Contrast studies, echocardiogram, CT chest
Bronchiectasis	Recurrent cough and wheeze frequently but not always associated with gastrointestinal symptoms and poor weight gain Chronic rhinosinusitis and/or otitis media	Bronchiectasis work-up to rule out immunodeficiency, primary ciliary dyskinesia, cystic fibrosis

Abbreviation: CT, computed tomography.

Table 2 Approach to treatment in preschool children with recurrent wheeze

Step 1: Trial of inhaled corticosteroids or montelukast in standard dose for 4–8 weeks
Step 2: Stop treatment—either there has been no improvement, in which case further escalation is not valuable; or symptoms have disappeared spontaneously or as a result of treatment If there is no benefit and the symptoms are troublesome, further investigation is recommended
Step 3: Restart treatment only if symptoms recur; then reduce treatment to the lowest level that achieves symptom control

Table 3 Asthma predictive index

Major criteria	Minor criteria
<ul style="list-style-type: none"> • Parental history of asthma • Physician diagnosed atopic dermatitis 	<ul style="list-style-type: none"> • Physician diagnosed allergic rhinitis • Wheezing unrelated to colds • Peripheral eosinophilia > 4%

Note: A child with either one major or two major criteria; and presentation for 3 years of age is considered positive for API.

studies are of little use in individual patient care. They have a high negative predictive value and a poor positive predictive value (typically positive predictive values 44–54, negative 81–88).

IN A NUTSHELL

1. Several phenotypes of preschool wheezers are described based on wheeze onset and duration, symptom pattern and atopic status.
2. Individual children can change phenotypes with time.
3. It is difficult to predict which infants and preschoolers with wheeze will subsequently develop asthma.
4. Scoring systems are available but are of limited predictive value, and may not apply at individual level.
5. Inhaled corticosteroids control symptoms and exacerbations in recurrent wheezers, but are not disease modifying.

BRONCHIAL ASTHMA

Asthma is one of the most common chronic diseases of childhood. It is defined as a chronic inflammatory disorder of the lower airways characterized by recurrent episodes of variable, reversible airflow obstruction and airway hyper-responsiveness (AHR) manifested as recurrent wheeze and cough. AHR is the inherent tendency of the bronchi to narrow in response to different stimuli, such as allergens, irritants or infections.

EPIDEMIOLOGY

The prevalence of asthma is increasing worldwide with an estimate of 1–18%. The International Study of Asthma and Allergies in Childhood estimated asthma prevalence in India to be 6.2–6.8% in the 6–7 year olds and 6.4–6.7% in 13–14 year olds, with more males affected than females.

PATHOLOGY

The pathological changes in asthmatic lungs are characterized by edema, increased mucus secretion with mucus plugging, smooth muscle contraction, infiltration with inflammatory cells, predominantly eosinophils and bronchiolar epithelial cell desquamation and denudation. These changes are acute and reversible. Chronic changes associated with airway remodeling in children include an increased vascularity of subepithelial tissue with smooth muscle hyperemia, hypertrophic smooth muscle, thickening of basement membrane, subepithelial deposition of structural proteins like type IV collagen, and loss of airway distensibility.

Airway obstruction in asthma results from a combination of bronchospasm, mucosal edema and mucus plugging. This leads to increased resistance to airflow through the larger airways and decreased flow through the smaller airways due to narrowing and early closure resulting in hyperinflation and retention of air. Due to regional differences in the resistance and uneven circulation to the alveoli, there exists a ventilation-perfusion mismatch. This leads to decreased oxygenation and hypoxemia, hyperventilation and respiratory alkalosis in early stages followed by CO₂ retention and respiratory acidosis in more severe cases.

IMMUNOPATHOGENESIS

Asthma is influenced by an interaction between genetic and environmental factors which leads to AHR with structural and functional changes in the airways. Genetically predisposed individuals are shown to react to certain *inducers* (Table 4), which generate an immune response. Common genes associated with asthma include the interleukin-4 (*IL-4*) gene on chromosome 5 (proinflammatory), *ADAM-33* (metalloproteinase family), *IL-12* on chromosome 5q31, genes for prostanoid DP receptors and polymorphisms in the beta-adrenergic receptors.

Th2 cytokine-mediated predominance is seen with a chronic activation of different cell lines which include inflammatory cells like mast cells, eosinophils, lymphocytes, macrophages and dendritic cells and structural cells like epithelial cells and smooth muscle cells. These stimulate the production of Th2 mediators, IgE, IgG4 and IgG1. *Enhancers* (Table 4) are known to aggravate this response on repeated exposure and stimulate a heightened Th2 reaction with T helper cells, mast cells and eosinophils, resulting in AHR. The role of anti-inflammatory therapy and immunotherapy is targeted at this stage of pathogenesis. *Triggers* (Table 4) are agents that stimulate symptoms in a child predisposed to wheezing due to prior sensitization with these *inducers*. As per the *Hygiene Hypothesis*, this induction can be prevented by avoidance of allergens or early exposure to endotoxins.

Allergens

There are numerous indoor and outdoor allergens of clinical significance which are shown to be associated with asthma. Allergen proteins which have a sequence homology with other proteins in the body, a molecular weight of 15–40 kD, soluble in aqueous solutions and with a tertiary structure and biologic properties foreign to the body are shown to stimulate an IgE response in children on inhalation. Indoor allergens and those with a larger size (> 5 microns in diameter) are shown to create a more intense allergic reaction (e.g., mite fecal particles and pollen).

Response to Allergens

An *early response* on subsequent exposure to a sensitized allergen is seen with an immediate hypersensitivity reaction and an IgE-mediated response associated with decline in forced expiratory volume in one second (FEV₁). A *late response* includes infiltration with eosinophils and release of eosinophil products, like major

Table 4 Factors that potentially influence pathogenesis of childhood asthma

Inducers	Enhancers	Triggers
<ul style="list-style-type: none"> Dust mite (<i>Dermatophagoides pteronyssinus</i>) Cockroach (<i>Blattella germanica</i>) Grass pollen (<i>Sorghastrum nutans</i> and <i>Parthenium hysterophorus</i> in India) Fungus (<i>Alternaria</i> and <i>Aspergillus</i>) Cat (<i>Felis domesticus</i>) Dog (<i>Canis familiaris</i>) Mouse (<i>Mus domesticus</i>) Rat (<i>Rattus norvegicus</i>) 	<ul style="list-style-type: none"> Viral infections Ozone Sulfur dioxide Particulate matter Diesel particles Endotoxins Comorbid conditions: Rhinitis, sinusitis and gastroesophageal reflux 	<ul style="list-style-type: none"> Exercise Cold and dry air Environmental tobacco smoke Pollution Histamine/methacholine Strong and noxious odors or fumes of perfumes and cleansing agents Crying, laughter or hyperventilation

basic protein and eosinophils cationic protein, which are toxic to the epithelium. Mast cells are activated, which release histamine, cysteinyl leukotrienes, platelet activating factor, IL-5 and other chemokines.

Viral Infections

Viruses which have shown to have an association with asthma include rhinovirus, respiratory syncytial virus, influenza, parainfluenza, adenovirus and human metapneumovirus. Possible hypotheses of how these viruses could induce asthma include the virus stimulating an exaggerated allergic response in an atopic individual, or the upper respiratory tract infection triggering a neurologic, cellular or cytokine-mediated effect in the lungs. Thus, the viral infection starts off a cascade of atopic events which maintains the persistent airway inflammation.

An increase in the eosinophils within the airway with release of inflammatory markers such as TGF- β and Ki67 is thought to induce changes in the extracellular matrix. Repeated bronchoconstriction generates mechanical forces contributing to tissue remodeling. This results in a decline in lung function over time and a subsequent loss of bronchodilator reversibility. Based on the immunopathogenesis of asthma, limited treatment options are available:

- Anti-inflammatory agents, such as oral and inhaled corticosteroids, leukotriene antagonists and anti-IgE monoclonal antibodies (omalizumab);
- Allergen-specific treatment, such as avoidance and immunotherapy.

CLINICAL FEATURES

Symptoms

Cough

Intermittent, chronic and a dry nature characterize the cough in asthma. Early morning worsening of cough or following physical exertion is classical. Chronic wet cough should raise the possibility of other etiological factors and needs to be investigated.

Wheeze

Expiratory wheeze noted at night or following exercise characterizes asthma. Improvement following bronchodilator use increases the possibility of asthma. Lack of improvement with bronchodilator and steroid medication requires aggressive investigation to rule out other mimickers of asthma.

Shortness of breath, chest tightness or chest pain are other symptoms in acute exacerbation.

Signs

Chest examination may be normal, with an occasional expiratory wheeze or prolonged expiratory phase elicited on deep breathing. Improvement of wheeze with inhaled short-acting beta-2 agonists within minutes is diagnostic of asthma. Accessory muscles use,

intercostal retractions and nasal flaring can be seen in severe cases with an acute exacerbation. Inflammatory obstruction of the airways can lead to right middle or lower lobe collapse. Crackles can be heard due to increased mucus and exudates in the large airways or associated segmental collapse.

DIFFERENTIAL DIAGNOSIS

All that wheezes is not asthma. Many conditions present with wheezing in early childhood, as described in previous chapters. Persistent chronic dry cough for more than 4 weeks with specific triggers and exacerbating factors can raise the suspicion of asthma. The three most common causes of night-time coughing in children include—(1) asthma, (2) gastroesophageal reflux disease (GERD), and (3) sinusitis with postnasal drip. The time of the night at which cough is predominantly present can give a clue to differentiate them. Early morning cough (between 3 am and 5 am) or just prior to waking up is classical of asthma; cough present immediately following feeding and lying down early at night is suggestive of GER and that which presents late at night following a postnasal drip suggests rhinosinusitis.

DIAGNOSIS

The diagnosis of asthma in children is predominantly made on a clinical basis. A typical symptom pattern which includes history of recurrent episodes of cough, wheeze, hurried breathing and shortness of breath which is triggered on exposure to specific stimuli is a starting point to the diagnosis of asthma. Personal history of atopy such as allergic rhinitis, eczema, allergic conjunctivitis, and food or aeroallergen sensitization should be enquired into. Family history of atopy and/or asthma increases the possibility of the diagnosis.

Chest X-ray is not routinely indicated in asthma, unless other conditions which mimic asthma need to be ruled out. Radiographs show bilateral hyperinflation and peribronchial thickening.

Pulmonary Function Tests

Pulmonary function tests (PFTs) represent an integral component of clinical management in school-aged children with asthma, and are being increasingly used in preschool children. Spirometry is the most commonly applied lung function test and can be applied in a wide variety of locations and across the ages. Spirometric indices commonly measured are forced vital capacity (FVC), FEV₁ and forced expiratory flow rate over 25–75% of FVC (FEF_{25–75}). FEV₁ less than or equal to 80% predicted for age, sex and ethnicity is suggestive of airflow obstruction. While spirometry is useful for determining the severity of asthma, monitoring and guiding treatment, *normal spirometry* does not necessarily infer normal lung function. Many intermittent or mild asthmatics have normal spirometry between acute exacerbations. Documentation of bronchodilator reversibility (BDR) of airflow obstruction following inhalation of a bronchodilator is central to the definition of asthma.

If airway obstruction is demonstrated at baseline, an inhaled bronchodilator (salbutamol 200 µg) should be administered and spirometry repeated after 15–20 minutes. An improvement of at least 12% in FEV₁ is considered as positive BDR and is consistent with a diagnosis of asthma.

In children less than 5 years of age, other techniques that require only tidal breathing for assessing lung function include impulse oscillometry or specific airway resistance.

Use of peak flow meter to measure peak expiratory flow rate (PEFR) although commonly used should not be used to diagnose or monitor asthma as it is reflective of obstruction only in the large airways.

Bronchial Provocation Tests

Airway hyper-reactivity to methacholine, histamine or hypertonic saline in a child with *normal* FEV₁ can aid in the diagnosis of asthma. A 20% fall in FEV₁ induced by a concentration of methacholine less than 4 mg/mL is considered positive. However, these tests are not routinely used in clinical practice, as airway stimulants should be carefully dosed and monitored.

Exercise Tolerance Test

An exercise test such as running on a treadmill can be useful in diagnosing asthma in children with a history suggestive of exercise induced bronchospasm. PFT should be measured at baseline and serial measurements every 5 minutes for 20 minutes postexercise. A more than or equal to 12% drop in FEV₁ or more than or equal to 25% in FEF_{25–75} is diagnostic of exercise induced asthma.

Fractional Exhaled Nitric Oxide

Fractional exhaled nitric oxide (FeNO) is a surrogate marker of eosinophilic airway inflammation and a good predictor of corticosteroid response. It aids in the assessment, management and long-term monitoring of asthma. Normative values in the Indian population are inadequate. Western data indicate values more than 20 ppb to be suggestive of airway inflammation.

TREATMENT OF ASTHMA

There are a large number of guidelines on the management of asthma; however, the key messages of most of them remain similar. The principal goal is disease control using least possible medication.

Education of Parents and Caregivers

Asthma education is a continuous and dynamic process. Education should highlight chronic nature of the disease, the recognition of asthma symptoms, different types of medication, need for long-term medication, importance of compliance and adherence and a demonstration of use of inhalers and spacers. Self-management will help maintain good control of asthma and also identify and avoid triggers. A written personalized *Asthma Action Plan* should be issued to each patient indicating the daily medication regimen along with management of asthma exacerbations.

Identification and Avoidance of Triggers

Avoidance of triggers may have a beneficial effect on disease activity. Reduction or elimination of problematic environmental exposures is the key in asthma control. Efforts need to be focused on avoiding perennial and indoor allergens which can potentially decrease asthma symptoms, medication requirements, AHR and exacerbations. This however requires avoidance of the offending agent for a sustained period of days to weeks. Avoidance and control of the exposure to environmental tobacco smoke and other fumes has shown to significantly control and reduce exacerbations

in children with asthma. Prior to advising avoidance of specific allergens, significant proof needs to be ascertained by a careful clinical history, skin prick testing and/or specific IgE measurement. Skin prick testing and/or specific IgE measurement can help, particularly if there are few identified or suspected triggers.

Treating Comorbid Conditions

The most common causes of chronic coughing in children include rhinitis, sinusitis and GER in addition to asthma. Effective management of these comorbid conditions is shown to reduce medication requirement, disease severity and asthma symptoms. Seasonal or perennial allergic rhinitis complicates asthma in nearly 90% children. Mouth breathing in patients prevents the function of humidifying, warming and filtering of irritants performed by the nose. An associated sinusitis significantly contributes to failure in response to asthma medication. Treatment of these conditions by topical therapy with nasal saline irrigation, intranasal corticosteroids and a 2–3 weeks course of antibiotics in children with sinusitis significantly improves AHR, asthma symptoms, medication use and inflammation.

Regular Assessment and Monitoring

Regular clinic visits every 2–4 weeks depending on severity of symptoms is recommended until good asthma control is achieved. Subsequently, 2–4 check-ups per year can maintain good asthma control. Spirometry is recommended annually in well-controlled patients and more frequently if required.

Pharmacotherapy

A *step-wise* management strategy for pharmacotherapy is recommended (**Figure 1**).

- Initial assessment of asthma severity if no medication has been used previously
- Choose the step at which treatment needs to be initiated
- Achieve early and rapid control
- Reassess disease control regularly
- Step-up therapy when control is not achieved in 1–3 months and step-down therapy when control is good in 3 months.

Assessment of Severity

The National Asthma Education and Prevention Program (NAEPP) expert panel report classifies asthma severity as mild intermittent, mild persistent, moderate persistent and severe persistent, based on frequency of day-time and night-time symptoms, degree of airflow obstruction on spirometry and peak flow variability. This guideline insists on controller therapy in children with the following:

- Needing reliever medication at least three times per week
- Night awakenings at least three times per month
- Refill of reliever medication three times a year
- Acute exacerbations at least three times per year and
- Short course oral steroids at least three times a year.

All persistent forms of asthma are treated with inhaled corticosteroids (ICS) either alone or with combination depending upon the severity of disease.

Reliever Medication

Relievers produce bronchodilation and immediate relief of symptoms. Short-acting bronchodilators like salbutamol act on beta-receptors in the airway producing bronchodilation and are the first line of management in children of all ages. Other drugs include levosalbutamol and terbutaline. They act immediately and the effect lasts for 4–6 hours. Due to their quick and better effect on airway smooth muscle and reduced systemic effects, inhaled

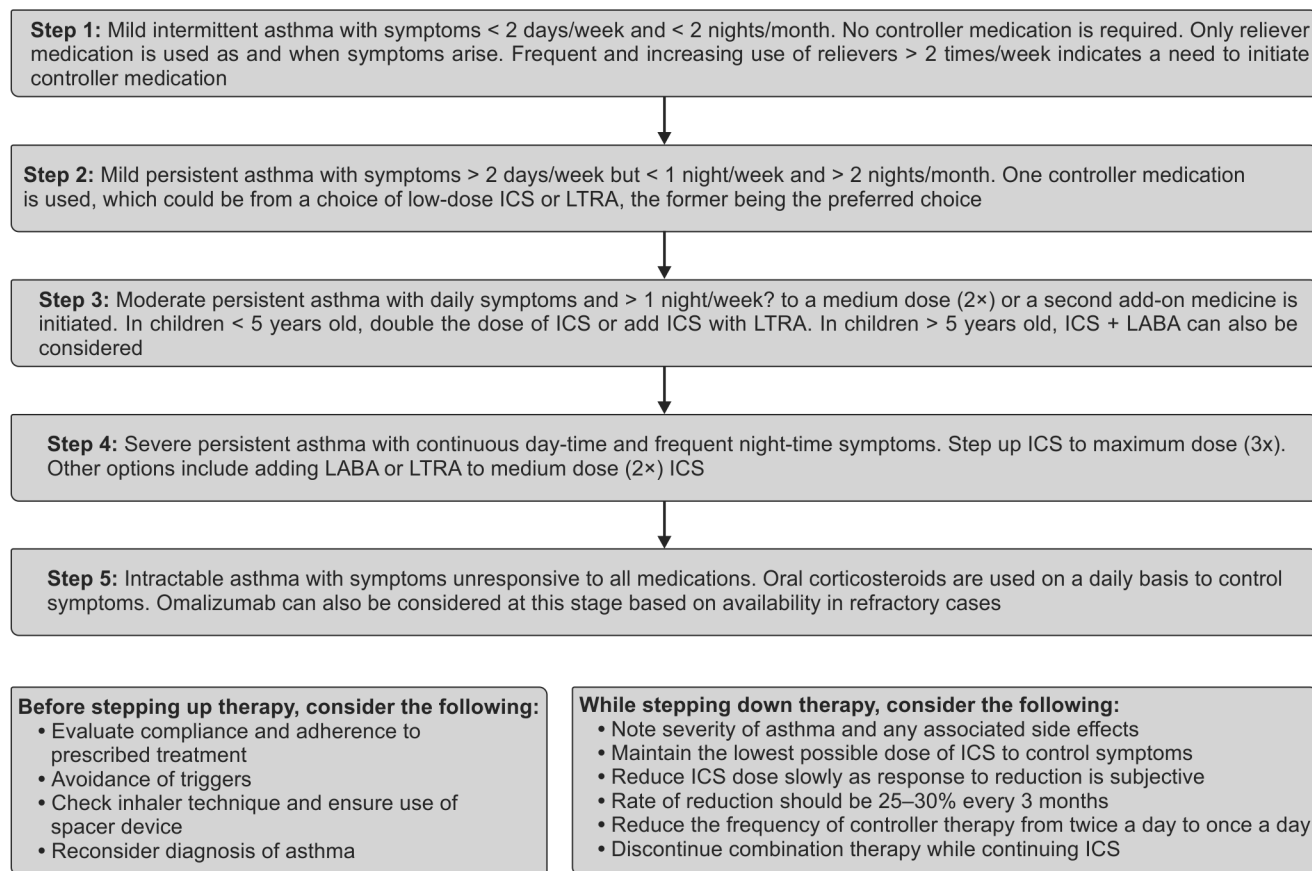

Figure 1 Step-wise approach to the management of asthma in children

Abbreviations: ICS, inhaled corticosteroids; LABA, long-acting beta-2 adrenergic agonists; LTRA, leukotriene receptor antagonists.

bronchodilators are preferred over oral bronchodilators. Side effects include tachycardia and tremors, both of which are dose dependent. Anticholinergics like ipratropium bromide are less potent than beta-agonists and are used along with short-acting bronchodilators in severe asthma and in exacerbations, to improve lung function and reduce hospitalization.

Inhaled Corticosteroids

Inhaled corticosteroids are the most potent and effective controller treatment for asthma and the cornerstone of good asthma control. ICS benefits include: (1) decrease in symptoms, (2) improvement of lung function, (3) decreased AHR, (4) reduction in asthma exacerbations and admission rates, (5) reduced need for prednisolone by 50%, and (6) decreased risk of mortality. Second generation ICSs, such as fluticasone propionate, mometasone furoate and budesonide are preferred due to their increased anti-inflammatory potency and decreased systemic bioavailability. Dose equivalence of different ICS is shown in **Table 5**.

Mild intermittent asthma can be managed by the use of low-dose ICS. More severe forms can be controlled by medium dose of steroids which are double (2X), while high doses are quadruple (4X), with the exception of flunisolide and triamcinolone which are triple (3X). The clinical benefits of ICS outweigh the side effects. When using other forms of steroids for allergic rhinitis and eczema, the cumulative dose of steroids should be taken into account.

Side effects of ICS include (i) Oral candidiasis—due to the propellant-induced mucosal irritation and local immunosuppression, which can be overcome by the use of a spacer and rinsing the mouth following use; (ii) Dysphonia—associated with

Table 5 Dose equivalence of inhaled corticosteroids

Drug	Low daily dose (µg)
Beclomethasone dipropionate HFA	100
Budesonide	100
Ciclesonide	80
Flunisolide	500
Flunisolide HFA	150
Fluticasone propionate HFA	100
Mometasone furoate	100
Triamcinolone acetonide	400

vocal cord myopathy, which is dose-dependent and seen only in high doses of ICS and oral steroids; and (iii) Growth suppression—A 1.1 cm transient growth retardation is reported in children on long-term ICS. However, no significant difference in adult height is reported.

Leukotriene Receptor Antagonists

Leukotrienes are the main mediators shown to produce inflammation, bronchospasm, airway edema and mucus secretion in children with asthma. Montelukast, zafirlukast and pranlukast are the leukotriene receptor antagonists used in children. LTRAs are shown to effectively reduce symptoms, acute exacerbations and improve lung function. However, they are recommended as the second choice to ICS in many guidelines or as an add-on

therapy to ICS. Their efficacy is reported to be better in exercise-induced asthma and in the presence of rhinitis with asthma. ICS is shown to improve lung function by 5–15% and LTRA by around 2–7.5%. LTRAs have no significant side effects reported other than case reports of Churg Strauss-like vasculitis and behavioral symptoms. Zileuton is another drug which acts by leukotriene synthesis inhibition. However, it is licensed for use only in children more than 12 years, and needs to be used four times a day. Hence, it is not widely used for the management of asthma in children.

Long-acting Beta-2 Adrenergic Agonists in Combination with Inhaled Corticosteroids

Long-acting beta-2 adrenergic agonists (LABAs) such as salmeterol and formoterol are beta-agonists which are not routinely used as reliever medication. The onset of action of salmeterol is around 1 hour, whereas formoterol acts within 10 minutes, with an action lasting for 12 hours in both. It is well established that LABAs should be used always in combination with ICS and are licensed for use only in children more than 5 years. Formoterol is shown to have a fast action and, hence, a strategy of using a single inhaler for both control and reliever medication is proposed. Side effects of LABA include an increase in severe exacerbations and sudden death, especially when not used in conjunction with ICS.

Omalizumab

Immunoglobulin E binds to allergens and triggers the release of substances from mast cells and basophils that can cause inflammation. Omalizumab is a humanized monoclonal antibody that specifically binds to free IgE in the blood, thereby preventing antibodies from binding to IgE receptors on mast cells and basophils. As a result, these cells do not release histamine and other inflammatory substances, thereby preventing an allergic reaction and inflammation. Omalizumab is licensed for use in children more than 12 years of age with moderate to severe asthma, documented hypersensitivity to aeroallergens and in refractory cases of allergic asthma unresponsive to ICS. The dosage is determined by baseline IgE before start of treatment and body weight. It is given every 2–4 weeks subcutaneously.

Other Medications

Theophylline acts as a bronchodilator as well as anti-inflammatory due to its phosphodiesterase inhibitory action. It is not recommended as a controller medication in children due to its narrow therapeutic index, serious side effects and need to monitor blood levels. Cromolyn sodium and nedocromil are chromones which are nonsteroidal anti-inflammatory drugs known to stabilize mast cells. They are less effective than ICS, but have fewer side effects and are not easily available in India.

Choice of Drug Delivery Devices

Medications in asthma can be delivered by nebulizers, metered dose inhalers (MDI) or dry powder inhalers (DPI). A spacer is recommended for all MDI medications, as it overcomes the need for coordination of breathing, improves drug delivery to the lower airways and reduces oral thrush. Ideal method of using the spacer would be to emit a puff from the MDI into the spacer, followed by a slow inhalation and then a 5–10 sec breath hold. Alternatively, in younger children, following a puff, wait for regular tidal breathing of 30 sec or 10 breaths. DPI devices are breath actuated and the medication is delivered following a deep inspiratory breath with adequate flow. Rinsing of the mouth following use of MDI or DPI containing ICS is recommended to prevent development of oral thrush and reduce systemic absorption from the buccal mucosa.

Control of Asthma

On initiation of asthma treatment, patients are regularly monitored and assessed for control. Definition of asthma control in school-aged children is outlined in **Box 2**. Classification based on control is more dynamic, clinically relevant and helps to guide therapy. They include well controlled, partly controlled and uncontrolled (**Table 6**). Based on achieving control, treatment is either stepped up or stepped down.

Vaccination in Asthmatics

Indian Academy of Pediatrics (IAP) recommends influenza vaccination for severely asthmatic children and parents should be counseled regarding the benefits of preventing serious forms of influenza in these children. Other respiratory vaccines, such as the different pneumococcal vaccines are optional.

ACUTE SEVERE ASTHMA

Asthma exacerbation is defined as an acute or subacute episode of progressive increase in asthma symptoms, associated with airflow obstruction. Status asthmaticus is defined as severe asthma that necessitates hospitalization and fails to respond to initial treatment with inhaled beta-2 agonists and oral or IV steroids. Asthma attacks or exacerbations can be of varying severity, from mild to life-threatening. Clinical signs suggestive of acute severe asthma and life-threatening asthma are outlined in **Box 3**.

Assess the Severity of Exacerbation

The severity of asthma exacerbation can be estimated using the Becker's asthma severity score (**Table 7**). Asthma training module of IAP recommends a similar score. The same score is also used in facility-based Integrated Management of Neonatal and Childhood Illness (IMNCI) (**Table 8**). Based on the severity, an exacerbation

Table 6 Asthma control in children less than 5 years (Derived from GINA under-5, 2009)

Characteristics	Well controlled (all of the following)	Partly controlled (any measure present)	Uncontrolled (three or more features of partly controlled)
Daytime symptoms, wheezing, cough, difficult breathing	None or less than twice/week	More than twice/week (lasts for minutes and relieved rapidly by bronchodilators)	More than twice/week (lasts for hours and recurs, partly relieved by bronchodilators)
Limitation of activities	None	Any (may cough, wheeze or difficult breathing during play, exercise or laughing)	Any (may cough, wheeze, difficult breathing during play, exercise or laughing)
Nocturnal symptoms/awakening	None	Any (coughs during sleep or wakes up with cough, wheezing or difficult breathing)	Any (coughs during sleep or wakes up with cough, wheezing or difficult breathing)
Need for reliever/rescue treatment	Less than twice/week	More than twice/week	More than twice/week

BOX 2 Definition of asthma control in school-aged children

- Absence of daytime symptoms
- Absence of awakening at night due to symptoms
- No exacerbations
- No need for use of reliever medication
- No functional limitations in physical activity or exercise
- FEV₁ > 80% of predicted
- Minimal side effects on medication.

Abbreviation: FEV₁, forced expiratory volume in one second.

BOX 3 Clinical signs suggestive of acute severe and life-threatening asthma*Acute severe asthma*

- SpO₂ < 92% and/or PEF 33–50% and
- Cannot complete sentences in a single breath
- Breathless on feeding
- Pulse rate > 125 (> 5 years) and > 140 (2–5 years) per minute
- Respiratory rate > 30 (> 5 years) and > 40 (2–5 years) per minute

Life-threatening asthma (Red flag signs)

- SpO₂ < 92% and/or PEF 33–50%
- Hypotension and/or bradycardia
- Fatigue and exhaustion with increasing use of accessory muscles
- Silent chest
- Poor respiratory efforts
- Cyanosis
- Confusion or altered sensorium
- Dyspnea.

Abbreviations: PEF, peak expiratory flow; SpO₂, oxygen saturation.

Table 7 Becker's asthma severity score

Score	Respiratory rate/minute	Wheezing	Inspiratory: Expiratory ratio	Accessory muscle use
0	< 30	None	1:1.5	None
1	30–40	Terminal expiration	1:2	1 site
2	41–50	Entire expiration	1:3	2 sites
3	> 50	Inspiration and entire expiration	> 1:3	3 sites or neck strap use

Interpretation:

- Score > 4—moderate asthma; requires hospital admission
- Score > 7—severe asthma; requires pediatric intensive care unit (PICU) admission

can be managed at home, clinic, wards or intensive care units (ICUs). Management of asthma exacerbation at home is outlined in **Box 4**.

Oxygen saturation (SpO₂) less than 92% indicates a need for hospitalization. An arterial blood gas (ABG) should be obtained at baseline and monitored subsequently. Partial pressure of oxygen dissolved in arterial blood (PaO₂) less than 60 mm and normal or increasing partial pressure of carbon dioxide (PCO₂) more than 45 mm indicates respiratory failure and requires ICU admission and possible intubation with mechanical ventilation.

Hospital Management of a Severe Asthma Exacerbation

- *Airway, breathing and circulation* are established as with every other emergency. Intravenous access, continuous pulse oximetry and regular cardiorespiratory monitoring are initiated. Sedation is strictly avoided.

Table 8 Pulmonary severity score for acute severe asthma (Asthma Training Module, Indian Academy of Pediatrics)

Score	Respiratory rate/minute		Wheezing present*	Accessory muscle usage
	< 6 years	> 6 years		
0	< 30	< 20	None	No apparent activity
1	30–40	21–35	Terminal expiration with stethoscope	Questionable increase
2	41–50	36–50	Entire expiration with stethoscope	Increase apparent
3	> 50	< 50	During inspiration and expiration without stethoscope	Maximum activity
Add Score	0–3 Mild 4–6 Moderate > 6 Severe		*If wheezing absent (due to minimal) air flow), score = 3	

BOX 4 Home management of acute asthma exacerbations

- All parents are instructed to strictly follow a written *Asthma Action Plan* as it is shown to reduce the risk of death by 70%
- Rescue medication with 2–4 puffs of short-acting bronchodilators using MDI with spacer given at 3–5 min gaps, repeated at 20-min intervals in first hour is initiated
- Response is monitored for resolution of symptoms within 1 hour and no signs or symptoms after 4 hours
- In case of no response with short-acting bronchodilators, an oral steroid can be started at 1–2 mg/kg which should be maintained for 3–4 days
- The child needs to be transferred to the hospital immediately where:
 - There is no improvement after 10 puffs of short-acting bronchodilator
 - Deterioration despite optimal treatment
 - Risk factors for mortality—red flag signs and life-threatening asthma
- Oxygen with nebulized salbutamol is given during transport
- Monitor pulse rate, respiratory rate, use of accessory muscles of respiration, degree of wheezing, degree of agitation and level of consciousness.

Abbreviation: MDI, metered dose inhalers.

- *Oxygen* is administered via nasal cannula or mask. Children with SpO₂ less than 94% need to be treated with high-flow oxygen via mask or nasal cannula until levels more than 95% are attained. In severe cases, PCO₂ also needs to be monitored to look for impending respiratory failure.
- *Fluids*: Usually normal fluids are needed. In cases with severe distress, normal saline to restore euvoolemia or Ringers lactate to correct dehydration may be needed. Serum electrolytes, especially potassium needs to be monitored when systemic beta-2 agonists are being used.
- *Inhaled beta-2 agonists* are the cornerstone of management in asthma. In mild to moderate cases, an MDI with spacer is preferred. LABAs should be discontinued in cases where relievers are required every 4 hourly. Two to four puffs of salbutamol (100 µg each) every 20 min are given via MDI spacer for the first 1 hour. Instead, one could use three doses of nebulized salbutamol at a dose of 0.15 mg/kg at 20 min interval as well. In severe cases, back-to-back salbutamol nebulization can also be used. Continuous nebulization at 0.15–0.5 mg/kg/hour or 10–20 mg/hour is superior to intermittent doses in children, who require frequent nebulization.
- *Systemic steroids* are recommended early in acute severe asthma. Different guidelines recommend 1–2 mg/kg/day for

3–5 days. This approximately amounts to 10 mg in children less than 2 years, 20 mg in 2–5-year olds and 40 mg in more than 5-year olds. Those on maintenance oral steroids should receive 2 mg/kg up to a maximum of 60 mg. No tapering doses are needed. In children who vomit, a repeat dose of steroid or IV steroids can be considered with hydrocortisone at 10 mg/kg stat followed by 4–5 mg/kg thrice daily.

- *Anticholinergics* such as ipratropium bromide (250–500 µg/dose) can be alternated with nebulized beta-2 agonists in children refractory to initial therapy. Three doses can be repeated every 20 min followed by every 6 hourly.
- *Intravenous magnesium sulfate* ($MgSO_4$) inhibits calcium uptake and subsequently causes smooth muscle relaxation and reduces histamine-induced airway spasm. $MgSO_4$ can be utilized in patients who fail to respond to frequent inhaled beta-agonists and systemic corticosteroids. Doses used include a 50 mg/kg/dose over 30 min or a continuous infusion at 10–20 mg/kg/hour. It is repeated every 4–6 hourly. Complications include hypotension, cardiac arrhythmias, central nervous system depression and flushing with high-serum magnesium levels (> 10 – 12 mg/dL).
- *IV beta-2 agonists* are used in patients unresponsive to continuous inhaled therapy. Terbutaline which is widely available is given as a 10 µg/kg bolus over 10 min followed by a continuous infusion at 0.1–10 µg/kg/min. Subcutaneous terbutaline at 0.01 mg/kg/dose (maximum of 0.3 mg) is used in the absence of IV access.
- *Heliox*, a mixture of 80% helium and 20% oxygen, is a specialty gas that can decrease airway resistance in obstructed airways. It may be useful for the severely ill patient in an ICU setting.
- *Mechanical ventilation* in severe asthma is indicated in the following situations: (1) cardiorespiratory arrest; (2) rapid deterioration of mental state; (3) severe hypoxia with rising PCO_2 ; or (4) poor response to initial medication. Ventilation strategies aim to minimize hyperinflation and air-trapping, which include slow ventilator rates with prolonged expiratory phase, short inspiratory time and minimal positive end-expiratory pressure (PEEP). Adequate oxygenation, permissive hypercarbia and arterial pH more than 7.2 is maintained.

LONG-TERM OUTCOME OF CHILDHOOD ASTHMA

The outcome of childhood asthma can be evaluated in terms of asthma symptoms, such as wheezing and asthma attacks, by presence of obstruction on lung function assessment or by AHR.

While the prevalence of asthma is greater in boys in childhood, asthma is more prevalent in women in adulthood. Remission of symptoms sometimes occurs during puberty, particularly in boys. Risk factors in childhood which predispose to persistent symptoms in adulthood include severe childhood asthma, later age at onset, female gender, atopy, allergic rhinitis and lower lung function. However, with contemporary asthma treatment and care, most asthmatic individuals are able to lead a normal, healthy life.

IN A NUTSHELL

1. Childhood asthma most often starts before school age and is increasing in prevalence across the world.
2. All that wheezes is not asthma. Likewise, isolated cough without wheeze or chronic wet cough needs evaluation.
3. Allergic rhinitis, GERD and sinusitis are common comorbid conditions and, if present, require concurrent treatment.
4. Spirometry is an integral component of asthma management.
5. Inhaled corticosteroids are the mainstay in the treatment of childhood asthma.
6. Strict adherence to an asthma action plan reduces exacerbations, morbidity and mortality.

Chapter 39.20

Aerosol Therapy

Bruce K Rubin, Ronald W Williams

Aerosol therapy has been used for thousands of years with the burning and inhalation of tobacco and herbs. Aerosols have been an integral part of Ayurvedic medicine and are a cornerstone of modern therapy for airway diseases. Aerosol therapy allows targeting the airways often better than can be achieved by systemic administration. Because of the blood airway barrier, many medications either remain at the airway or are inactivated after uptake and thus their systemic side effects can be minimized.

Aerosol medication's formulation, stability and the requirement for airway tolerability are important for their efficacy and safety. Only medications that have been designed to be administered as an aerosol, and tested for safety and effectiveness when delivered by inhalation should be used by this route. It may be dangerous to take medications intended for intravenous (IV) administration and to nebulize these for inhalation.

There are also novel applications for aerosol therapy, including acinar deposition for systemic administration of proteins and peptides (e.g., insulin), devices for administering aerosols to the paranasal sinuses, engineered particles targeting cancer chemotherapy to involved airways, and also for immunization, gene transfer and delivering biologics through the airway. The focus of this chapter will be on the more commonly used medications for respiratory diseases.

WHAT IS AN AEROSOL?

An aerosol is a group of particles that remain suspended in air because of a low terminal settling velocity. The terminal settling velocity of an aerosol is determined by the aerodynamic size, usually denoted as the particle mass median aerodynamic diameter (MMAD), which is a function of the size, geometry and density of the particle. In practical terms, larger and heavier particles that are inhaled quickly are more likely to settle in the mouth than in the lung. Particles with MMAD less than 2 μm are exhaled unless there is a breath hold. Those larger than 5–10 μm preferentially deposit in the oral pharynx, or are never effectively nebulized.

MMAD describes the median particle size, but ignores size variability. Particle size distribution is described by the geometric standard deviation (GSD). When GSD is less than 1.22, this is a monodisperse. Most medications for therapeutic administration are heterodisperse. A larger GSD means fewer particles will be in the respirable mass, i.e., the proportion of particles with 2–5 μm MMAD. Different devices can produce aerosols with the same MMAD but different GSD, and thus number of particles that are available for the patient to inhale may vary a lot.

AIRWAY DEPOSITION

Particles are deposited in the airway by inertia, sedimentation, and Brownian diffusion. Large particles with high inertia impact in the mouth, increasing side effects while limiting lower airway deposition and therapeutic benefit. Impaction can be reduced by decreasing the MMAD of the particle or by decreasing inspiratory flow. High inspiratory flow will produce turbulence, which, in turn, dramatically increases impaction. Sedimentation is enhanced by allowing time for particles to settle on the airway after inhalation. This requires very low flow and is the reason why a breath hold is recommended after inhaling an aerosol. Brownian motion affects the smallest of particles and often these are exhaled. Particle

deposition in the lower airway is increased when aerosols are inhaled slowly and deeply, followed by a breath hold. A corollary to this is that there is almost no pulmonary deposition of an aerosol given to a crying baby or child. It is important to know that in severe airway disease, there is inhomogeneous ventilation leading to preferential deposition of medication at sites where airways are patent, which are often the less severely involved airways.

DEVICES

Many devices have been used for aerosol administration. The most commonly used are jet nebulizers, pressurized metered dose inhalers (pMDIs) and dry power inhalers (DPIs). It is important that devices be used correctly, and that patients are taught their operation by a knowledgeable practitioner. It is also important that this be checked each time the patient returns for clinic visits.

Jet Nebulizers

Jet nebulizers operate by the Venturi principle, where particles are pulled into the airstream for inhalation. Air flow must be fast enough (at least 8 LPM) to produce particles with an appropriate MMAD, and there should be minimal residual volume remaining after the medication has been nebulized. Inexpensive nebulizers often generate low flows and leave large residual volumes, thus producing poorly effective aerosol therapy. Overall, nebulizers are inefficient, as even the best jet nebulizers give no more than 15% deposition in the airway. This is why much more medication must be administered when a jet nebulizer is used (in mg) as compared with a pMDI or DPI (in μm).

Nebulizers should not be used when a child is crying or distressed, nor should they be placed in front of the face (so called *blow by*) as either will decrease the amount of medication inhaled to almost nothing. Whenever possible, aerosol from a jet nebulizer should be inhaled using a mouthpiece, as this doubles the amount of medication when compared to using a mask. Nearly all children over the age of 3 years can use a mouthpiece when trained. A critical problem with jet nebulizers is that adherence to therapy is much worse as compared to other devices. Presumably this is due to the time it takes to set up the device, administer the medication and clean the device after each use.

Jet nebulizers are more effective for aerosolizing solutions than suspensions, but many of the inhalational corticosteroids (ICs) are suspensions. The result is often delivery of less than 2% of the dose to infants and small children. Because the total volume of particles inhaled increases as the child grows, there is no need to adjust the amount of medication given based on the child's weight. This is true for jet nebulizers, pMDIs and DPIs.

To reduce medication wastage, there are breath-activated nebulizers that only flow when the patient inhales, but there must be a sufficient inspiratory flow to trigger the valve. Vibrating mesh nebulizers produce a more uniform particle size and operate without an external air source. Because the mesh can be clogged by viscous or hypertonic solutions, it is important that these devices *only* be used with the drugs that were intended.

Pressurized Metered Dose Inhalers

The pMDI was developed nearly 60 years ago and has undergone only minor changes. Medication is metered into a valve, and released when the canister is depressed in the boot. This is then inhaled slowly and deeply into the lungs. Pulmonary deposition can be improved and oral deposition and side effects can be decreased by always pairing a pMDI with a valved holding chamber (VHC). A spacer is a hollow tube that gives the aerosol plume time to mature before inhalation. When using a spacer, it is important to time inhalation with actuation of the pMDI. A VHC is a spacer

with a one-way valve at the inhalation orifice so that medication remains suspended in the chamber until the patient inhales. Data show aerosol medications, such as salbutamol or ICS, are more effective and have fewer side effects when given by pMDI and VHC than by jet nebulizer. This is true even in the youngest of children, and even for children in the critical care unit.

Dry Powder Inhalers

Dry powder inhalers produce a fine powder of medication usually from scraping a reservoir or having individual doses encapsulated and punctured before inhalation. Because the medication must be dispersed to form the aerosol, lactose is often added as a carrier, and a minimum peak inspiratory flow is needed. Low resistance devices like the Diskus[®] (GSK) require only 30 LPM inspiratory flow for dispersion while higher resistance devices, e.g., the Turbuhaler[®] (Astra), require greater than 60 LPM inspiratory flow. Children under the age of 6 years may find it difficult to achieve such flow rates, and the high flow can also lead to proximal deposition of medication.

DPIs are intrinsically breath-activated, as patients do not get medication until inhalation begins. Once a DPI is primed, the medications should be inhaled immediately as there is a risk of spilling the drug if tipped downward before inhalation. High humidity can cause the dry particles to stick together and clog the flow channel. This can happen with ambient high humidity or when the patient exhales into the device.

Nasal Delivery

The paranasal sinuses and nose can also benefit from aerosol medications. Typical nasal pumps have been used to deliver antihistamines, decongestants and ICS to the nasopharynx but these do not deliver medication to the sinus cavities. Recent devices using pulsatile aerosol flow or sound waves have made sinus delivery possible.

AEROSOLIZED DRUGS

The most common use of aerosol medications has been in the treatment of asthma. The beta agonist bronchodilators are effective and easily administered as a solution by nebulization or as a pMDI. Medication delivery is faster, and costs and side effects are less, when using pMDI with VHC or else a DPI. This is true even in an emergency setting or in the critical care unit.

Cystic fibrosis (CF) is a condition of chronic airway infection, inflammation and secretion retention. There is almost no true mucus in the CF airways; these secretions are full of polymeric deoxyribonucleic acid (DNA) more characteristic of pus than mucus. Thus, typical mucolytics, like N-acetylcysteine (NAC) are ineffective for treating CF. Dornase alfa (Pulmozyme, Genentech) aerosol can depolymerize the abnormal DNA network. While effective in CF, dornase has been shown to worsen lung function in persons with non-CF bronchiectasis. The expectorants, hypertonic saline aerosol and DPI mannitol have been used to treat CF by drawing water into the periciliary fluid unbinding secretions from the epithelium and inducing an effective cough. Because these medications can produce bronchospasm, a short-acting bronchodilator like salbutamol should be administered first.

Aerosol antibiotics have also been developed for treating airway infection in CF. Although high levels of antibiotics, far exceeding the MIC₉₀, are deposited in the proximal airway, the antibiotic concentration rapidly decreases in distal airways and this can induce resistance. Therefore many of these antibiotics are given on

alternate months so that bacteria can again become susceptible. Antibiotics currently available are tobramycin, aztreonam and colistin. These are concentration dependent medications and thus aerosolized cephalosporins or penicillins are not recommended.

Other Aerosols

Bland aerosols have no place in the treatment of airway disease as these do not improve mucus clearance or hydration. Similarly, sodium bicarbonate inhalation is irritating to the airway and should not be used; it is ineffective as a mucoactive medication. Although NAC is available for nebulization, it is also irritating to the airway with pKa 2.2 and a foul odor. There are no published data showing that aerosol NAC improves the course of any lung disease, and, therefore, we recommend that it should not be used in children.

ADHERENCE TO THERAPY

Although research has brought us excellent medications and highly effective aerosol devices, the key to effective therapy is adherence. This first requires that the caregiver and patient understand proper use of the medication and device. Education should be provided by a knowledgeable practitioner, and should be ongoing. Handing a patient an aerosol device without a demonstration is a recipe for therapeutic failure.

Some forms of therapy produce better adherence than others. Bronchodilators give a sensation of immediate relief and tend to be used more consistently than ICs. As mentioned earlier, we rarely use jet nebulizers because adherence is so much worse than with other forms of aerosol therapy. The key to effective aerosol therapy is to understand the device, teach it well, and ensure that the patient is using it correctly.

IN A NUTSHELL

1. Particles with mass median aerodynamic diameter (MMAD) between 2 μ m and 5 μ m are best suited for aerosol therapy.
2. It is dangerous to nebulize medications intended for IV administration for inhalation therapy.
3. Aerosol medications, such as salbutamol or inhaled corticosteroids are more effective and have fewer side effects when given by pMDI and VHC than by jet nebulizer.
4. Aerosol antibiotics have also been developed for treating airway infection in cystic fibrosis.
5. There are no published data showing that aerosol N-acetylcysteine improves the course of any lung disease, and, therefore, we recommend that it should not be used in children.
6. The key to effective aerosol therapy is to understand the device, teach it well, and ensure that the patient is using it correctly.

Chapter 39.21

Pneumonia

Swati Dublish, Varinder Singh

Pneumonia is an inflammation of the parenchyma of the lungs. Usually pneumonia is caused by microorganisms; however, noninfectious causes include aspiration of food or gastric acid, foreign bodies, hydrocarbons, and lipid substances, hypersensitivity reactions, and drug- or radiation-induced pneumonitis. The present chapter focuses on pneumonia resulting from acute infections.

EPIDEMIOLOGY

Acute respiratory infections (ARI) encompass viral and bacterial infections of the respiratory tract. The Third National Family Health Survey (NFHS-3) data suggests that as many as 6% children under age of 5 years in India showed symptoms of ARI at some time in the 2 weeks preceding the survey. While upper respiratory infections are often self-limiting, lower respiratory infections, in particular, pneumonia, pose life-threatening situation. Most pneumonia deaths are caused by bacteria. Pneumonias are the number one cause of under-5 child mortality, responsible for nearly 400,000 deaths in India annually. These deaths can be prevented by appropriate treatment with antibiotics. Pneumonia can be distinguished from other respiratory tract infections by the use of simple clinical signs, such as respiratory rate and lower chest in-drawing.

DEFINITIONS

There are several ways in which pneumonia can be defined. From *pathological viewpoint*, pneumonia results from invasion of lungs by an infectious agent which may start an inflammatory response and ensuing damage may involve airways, alveoli, connective tissue, visceral pleura and vascular structures. A more *practical definition* of pneumonia will include fever, respiratory symptoms, and evidence of parenchymal involvement by either physical examination or the presence of infiltrates on chest radiography. Most experts define pneumonia as association of clinical findings with radiographic evidence of infiltrates. Since in many developing countries and also in many peripheral settings, radiological services may not be easily available, a more pragmatic term, lower respiratory tract infection (LRTI), is used wherein the diagnosis is made on the basis of simple clinical signs (e.g., fast breathing). This simple definition cannot and does not make any distinction between viral bronchiolitis, croup, asthma and pneumonia.

CLASSIFICATION OF PNEUMONIA

Pneumonia may be classified as simple and complicated pneumonia. Simple pneumonia can be bronchopneumonia—patchy involvement of the lung, which can be unilateral or bilateral; and lobar pneumonia—which involves almost whole of a single lobe. Complicated pneumonia refers to a situation where the pulmonary parenchymal infection is complicated by parapneumonic effusions, empyema, necrotizing pneumonia abscesses or cavities, pneumothorax or bronchopleural fistula.

Given the difficulties in making an etiological diagnosis, pneumonia etiology is often inferred from epidemiology. Therefore, another reasonable classification is *community acquired pneumonia (CAP)* and *hospital acquired pneumonia (HAP)*. CAP is defined as the presence of signs and symptoms of pneumonia in a

previously healthy child due to an infection contracted outside of the hospital, i.e., child should not have been hospitalized within 14 days prior to the onset of symptoms, or has been hospitalized less than 4 days prior to onset of symptoms. HAP can be early-onset and late-onset. Early HAP is a pneumonia occurring within the first 4 days of hospitalization and is more likely due to antibiotic-sensitive bacteria. It usually carries a better prognosis. Truly, early onset HAP is a misnomer as definition of CAP covers it adequately. Late-onset HAP (occurring 5 days or more after admission) is more likely nosocomial; due to polymicrobial and multidrug-resistant pathogens; and is associated with increased patient mortality and morbidity.

A typical pneumonia occurs with acute onset of fever, cough and rapid breathing while few can have a more gradual onset associated with low-grade fever or no fever, headache, nonproductive cough and malaise, which is referred to as atypical pneumonia.

PATHOGENESIS

Most pulmonary pathogens are transmitted from person to person by droplet infection. Bacteria may be transmitted by inhalation or microaspiration. Droplet particles larger than 10 μm are usually large enough to be deposited in the pharynx, whereas those from 3 μm to 10 μm may lodge in the larger airways while particles between 0.5 μm and 3 μm reach the alveolar surface. Viruses are among the common causes of pneumonia in early infancy. Most of the children are infected with the respiratory viruses but only few develop pneumonia.

Any breach in the normal defense mechanisms against pneumonia in the body like altered mucociliary clearance or cough reflex or humoral and cellular immunity, or an obstructed airway predisposes to pneumonia. The risk factors predisposing to pneumonia are detailed in **Table 1**, whereas **Table 2** details risk factors associated with increased mortality due to pneumonia.

The pathogenesis of pneumonia is variable. The classical stages of lobar pneumonia (especially pneumococcal) include congestion, red hepatization, gray hepatization and resolution (**Flow chart 1**). In viral pneumonia, there is infection of the perialveolar cells leading to thickening of alveolar walls. This leads to occlusion of alveolar space with exudates, slough and activated macrophages, leading to poor gas exchange. In many cases, there may be inflammation of the bronchioles leading to air trapping and contributing to poor gas exchange. In interstitial pneumonia, the walls of the alveoli and interstitial septae are involved, and the alveolar space is spared. The interstitial infiltrate predominantly includes lymphocytes, macrophages and plasma cells.

ETIOLOGY

In pediatric age group, the developing immunity and age-related exposures result in infection caused by varied yet consistent set of bacterial and viral pathogens. The potential pathogens are, therefore, defined separately for each age group (**Table 3**). The pneumonia in neonatal period is mostly caused by group B streptococci or gram-negative enteric bacteria.

Viruses are among the frequent pathogens in children younger than 2 years. Of the viral pathogens, respiratory syncytial virus (RSV) is detected in up to 40% of children younger than 2 years. Other viruses detected are adenoviruses, influenza A and B viruses, bocavirus, human metapneumovirus, parainfluenza viruses, coronaviruses and rhinovirus. RSV and influenza virus infections commonly predispose infants and young children to bacterial infections. *Chlamydia trachomatis* is an important pathogen in infants between 3 weeks and 19 weeks of age.

Among the bacterial causes of pneumonia in young children, *Streptococcus pneumoniae* is most common (30–50% cases), followed by *Haemophilus influenzae* (10–30% cases),

Table 1 Risk factors for the development of pneumonia

Definite risk factors	Likely risk factors	Possible risk factors
<ul style="list-style-type: none"> • Malnutrition • Low birthweight • Lack of exclusive breastfeeding during the first 4 months • Lack of measles immunization • Indoor air pollution • Overcrowding 	<ul style="list-style-type: none"> • Parental smoking • Zinc deficiency • Maternal inexperience • Underlying comorbid conditions: <ul style="list-style-type: none"> – Congenital heart disease – Esophageal obstruction or dysmotility, e.g., vascular rings, tracheoesophageal fistula – Gastroesophageal reflux disease – Mucociliary dysfunction, e.g., cystic fibrosis, primary ciliary dyskinesia – Neuromuscular disorders – Asthma – Immunodeficiency (congenital or acquired) – Diabetes mellitus – Bronchopulmonary dysplasia and chronic lung disease – Sickle cell disease 	<ul style="list-style-type: none"> • Maternal illiteracy • Day-care attendance • Rainfall (humidity) • High altitude (cold air) • Vitamin A deficiency • Higher birth order • Outdoor air pollution

Table 2 Risk factors of mortality in children with severe pneumonia

Staphylococcus aureus and *Klebsiella pneumoniae*. Multiple serotypes of *S. pneumoniae* are present with different prevalence rates. According to a serotyping study done in India, among 150 clinical isolates from invasive and life-threatening pneumococcal infections, 59.3% belonged to serotypes 1, 6, 19, 5, 23 and 7. Serotype 1 was the most common isolate in meningitis and empyema. According to another study, among 42 pneumococcal strains, over one-third in children and nearly half in adults were serotypes 5, 6 and 7. The remaining 11 of 14 strains in children and 20 of 28 strains in adults belonged to 8 serogroups/types, namely 3, 4, 10, 11, 12, 13, 19 and 20. Prevalence of penicillin resistance is currently reported to be low in most of the countries.

Among severely malnourished children, *K. pneumoniae*, *S. pneumoniae*, *Escherichia coli*, *S. aureus* and *H. influenzae* are common organisms. Other bacterial infections like *Bordetella pertussis* and *Mycobacterium tuberculosis* should also be considered in differential diagnosis.

Fungal pneumonia (due to *Histoplasma*, *Coccidioides*, *Blastomyces* and *Cryptococcus*) in normal immunocompetent hosts is uncommon.

CLINICAL FEATURES

Children with pneumonia usually present with fever, tachypnea, cough, abdominal and/or chest pain. In pneumonia caused by atypical pathogens, a more gradual onset associated with low-grade fever or no fever, headache, nonproductive cough and malaise may be present. The presence of wheezing is more often seen in younger children though may be more often associated with a nonbacterial pathogen. Tachypnea is a simple yet fairly specific and sensitive sign for pneumonia if asthma and bronchiolitis have been excluded (**Table 4**). In infants with pneumonia, tachypnea

Flow chart 1 Pathogenesis of lobar pneumonia

may correlate with hypoxemia. Other causes of tachypnea could be fever, dehydration or metabolic acidosis. Intercostal, suprasternal or subcostal retractions indicate severe pneumonia. Nasal flaring and *head bobbing* have also been statistically associated with hypoxemia. Fever is the most sensitive sign while grunting and retractions are the most specific signs corresponding to presence of alveolar infiltrates on chest radiograph. In the absence of cough, possibility of pneumonia is very low.

Table 3 Common etiological agents causing community-acquired pneumonia in different age groups

<ul style="list-style-type: none"> • Group B <i>Streptococcus</i> • Enteric gram-negative bacilli • <i>Streptococcus pneumoniae</i> • <i>Haemophilus influenzae</i> • <i>Chlamydia trachomatis</i> • Group D streptococci • <i>Listeria</i> spp. • Anaerobes 	<ul style="list-style-type: none"> • Adenoviruses • Bocavirus • Human metapneumovirus • Influenza A and B viruses • Parainfluenza viruses • Coronaviruses • Rhinovirus <i>Streptococcus pneumoniae</i> • <i>Haemophilus influenzae</i> • <i>Staphylococcus aureus</i> • <i>Bordetella pertussis</i> 	<ul style="list-style-type: none"> • <i>S. pneumoniae</i> • <i>S. aureus</i> • <i>M. pneumoniae</i>

Table 4 Age-specific respiratory rates as per World Health Organization (WHO)

Age	Respiratory rate
< 2 months	≥ 60/min
2–12 months	≥ 50/min
> 12 months–5 years	≥ 40/min

The clinical presentation of viral pneumonia may include tachypnea, retractions (supracostal, intercostal or subcostal) with or without nasal flaring. Low-grade fever is common; fever higher than 39.5°C (103°F) is uncommon. The presence of concomitant upper respiratory infection (rhinorrhea, sneezing or otitis media) supports a probability of a viral etiology, though these at times can be associated with superimposed bacterial infection. Mild to moderate dehydration may be present due to increased insensible losses and poor oral intake. Systemic toxicity is less common though influenza may lead to high fever and toxic appearance. Children can develop acute otitis media, sinusitis and bacterial tracheitis, febrile seizures, encephalitis or encephalopathy, myositis, myocarditis or Reye's syndrome during an episode of influenza pneumonia.

In atypical pneumonia due to mycoplasma, initial manifestation is pharyngitis followed by hoarseness of voice. Fever, usually low-grade, and cough are predominant symptoms; vomiting and diarrhea may be seen in up to 20% patients. Rhinitis is less common. Crepitations or wheezing may be audible on auscultation. The mean duration of illness is around 2 weeks, although cough may persist for more than a month. Mycoplasma infection may be associated with sinusitis, otitis media, myocarditis, pericarditis, mucocutaneous eruptions, hemolytic anemia, arthritis, glomerulonephritis, and nervous system diseases (aseptic meningitis, encephalitis, cerebellar ataxia, transverse myelitis, peripheral neuropathy, psychosis and Guillain-Barré syndrome).

Streptococcus pneumoniae is the most common bacterial pathogen causing pneumonia in children, responsible for more than 50% cases. The onset may be preceded by a mild upper respiratory tract infection, purulent unilateral conjunctivitis, or otitis media. In infants, a sudden high-grade fever accompanied by a seizure, and diarrhea or vomiting may be the earliest manifestations. Irritability, nasal flaring, rapid and shallow respirations, grunting, abdominal distention, perioral cyanosis, tachycardia and unilateral diminished respiratory excursion may be seen during the course of the illness. Cough may be absent as alveoli have few cough receptors. In the older child and the adolescents, the onset is abrupt and the patient may appear ill with high-grade fever along with chills or rigors, fever, headache, dyspnea, pleuritic pain and cough. Sputum production may be apparent in children older than 8–10 years of age. Occasionally,

signs and symptoms suggestive of bacterial pneumonia may be absent; fever may be the only sign.

Haemophilus influenzae B pneumonia is more common in children younger than 5 years of age, particularly in children under 2 years. *S. aureus* pneumonia presents as an acute and severe rapidly progressive illness. In almost 50% of cases, pneumatocele formation may occur due to destruction of bronchial walls leading to air-trapping. Empyema, pneumothorax and pyopneumothorax are common complications. It can also lead to pyemia and metastatic lesion in the pericardium, joint, muscles, etc. Many strains of community-associated methicillin-resistant *Staphylococcus aureus* (CA-MRSA) carry the gene for Panton-Valentine leukocidin, an exotoxin lethal to leukocytes and, therefore, leading to tissue necrosis, skin lesions, necrotizing pneumonia and necrotizing fasciitis. Group A *streptococcus* and *Streptococcus pyogenes* are infrequent causes of pneumonia, usually presenting with bacteremia and scarlet fever. Infection with measles, varicella and influenza predispose to coinfection from group A *streptococcus* because of impairment of host immunity.

Chlamydia pneumoniae infection usually occurs in children between the ages of 5 years and 15 years and the usual route of transmission is via respiratory secretions and fomites. The illness begins with a nonspecific prodrome of low-grade fever, malaise, sore throat, headache and cough. Patients may initially show signs of upper respiratory tract infections, such as pharyngitis, laryngitis or sinusitis later progressing to pneumonia or bronchitis. *C. pneumoniae* leads to an IgE-mediated bronchial reactivity. The physical examination of patients may show nonexudative pharyngitis, wheezes and fine or coarse crepitations. Pneumonia is more common in adolescents. Complications associated with chlamydia infection are pneumatocele, pneumothorax, interstitial fibrosis and lung abscess. Pleural effusion is uncommon. Other complications include erythema nodosum, reactive arthritis, Guillain-Barré syndrome, meningoencephalitis, myocarditis, and endocarditis. Chest X-rays show a single subsegmental lesion of only one lobe as the most common lesion, though alveolar infiltrates or subsegmental pneumonitis without consolidation may be seen.

It is difficult to distinguish viral from bacterial pneumonia on the basis of clinical features, radiology or laboratory investigations but presence of an upper respiratory catarrh, a lymphocytic predominance in leukocyte count is more likely in viral pneumonias. Radiological evidence of lobar, segmental, or rounded well-defined consolidation affecting a single lobe, large pleural effusion, abscess, bullae or pneumatoceles points to a possible bacterial etiology. Bacterial superinfection of a viral pneumonia can be suspected when there is an abrupt change in symptoms with appearance of generalized toxicity, marked and changed leukocytosis and new X-ray findings of parenchymal consolidation or pleural effusion.

COMPLICATIONS

The complications of pneumonia include parapneumonic effusions, empyema, necrotizing pneumonia, pneumatoceles, lung abscess and pneumothorax. The complications are to be suspected in cases not responding to treatment or showing deterioration.

DIAGNOSIS

Etiological Diagnosis

Early identification of the etiologic agent is important for all infectious diseases to provide a target-oriented and narrow spectrum treatment to rationalize the usage of antibiotics and minimize the emergence of drug resistance. However, the bacteriological diagnosis for pneumonia is neither routinely feasible nor useful as the yield is very low.

Blood culture positivity in children being treated as inpatients is around 8%. It is more likely to be positive in the presence of sepsis or organ dysfunction. The culture of respiratory specimens can be done but can have major drawbacks which limit their utility for any routine clinical use. Firstly, younger children are unable to expectorate; even when sputum is available, its contamination by the upper airway microbiome limits its utility; and lastly, the isolate may reflect the colonizing bacteria rather than the invading bacteria. It is worth remembering that many a common bacterial and viral pathogens may be carried in the respiratory passages of the normal population as well.

Gram stain and culture of induced or expectorated sputum can be attempted in older children (> 8 years old) and adolescents. Specimen produced by cough and containing excess squamous rather than epithelial cells indicates an upper tract origin. Specimens with more than 25 squamous cells per low-power field are not considered adequate. Other useful parameters are the presence of neutrophils and a monotonous or relatively monotonous morphology of the bacteria in the specimen. However, it is still difficult to differentiate the colonizing bacteria from the real culprit.

In adults, urinary antigen tests for the detection of *S. pneumoniae* correlate well with sputum culture and, therefore, are routinely used to diagnose pneumococcal pneumonia in adults. However, in children, positive results of pneumococcal urinary antigen test do not reliably distinguish infection from mere, colonization and are, therefore, not recommended.

Testing for viral pathogens can be done using nasopharyngeal aspirate for reverse transcription-polymerase chain reaction (RT-PCR), viral antigen detection or acute and convalescent sera for serology.

The diagnostic tests utilized for *Mycoplasma pneumoniae* infections include serology, cold agglutinating antibodies, culture and molecular-based methods, such as PCR assays. Serologic tests include complement fixation, enzyme-linked immunosorbent assays (ELISAs), and rapid enzyme immunoassay cards. Cold agglutinin titers more than 1:64 are present at the time of acute illness in adults but the test is less well studied in children. Serology is the primary means of diagnostic testing for *C. pneumoniae*. Confirmation of primary acute infection requires documenting an IgM titer of 1:16 or greater or a 4-fold rise in IgG titer between acute and convalescent serum specimens. In case of reinfection, IgM antibody may not appear, and the level of IgG antibody titer may rise quickly within 1–2 weeks of infection. The organism or its deoxyribonucleic acid (DNA) can also be directly identified by means of culture or PCR testing in specimens from nasopharyngeal or throat swabs, sputum, blood or tissue.

In children with severe or life-threatening pneumonia, invasive samples can be tried like bronchoscopy with bronchoalveolar lavage or brush biopsy, percutaneous lung aspiration (blind or computed tomography [CT] guided) or open lung biopsy. In

children who are mechanically ventilated, endotracheal aspirates for Gram stain and culture as well as for viral pathogens like influenza can be done.

Ancillary tests like complete blood count with WBC differential may help to guide therapy and also may give an indication regarding anemia or thrombocytopenia heralding hemolytic-uremic syndrome associated with pneumococcal infection. Acute phase reactants like C-reactive protein (CRP), erythrocyte sedimentation rate (ESR) and procalcitonin do not clearly distinguish bacterial from viral infection when used in isolation. Low values may be helpful in distinguishing viral pneumonia from bacterial pneumonia associated with bacteremia. Declining values of CRP or procalcitonin may correlate with improvement in clinical symptoms.

Oxygen saturation measurements through pulse oximetry provide a noninvasive estimate of arterial oxygenation and are useful for monitoring the severity of respiratory dysfunction, but have no role as an etiological test.

Imaging

Chest radiographs are less reliable in distinguishing viral from bacterial pneumonia and also do not reliably distinguish among the various possible bacterial pathogens. The usual patterns seen on a chest radiograph in a bacterial pneumonia are alveolar or airspace processes, and interstitial patterns usually reflect other etiologies; however an overlap is possible. A large lobar or diffuse consolidation (**Figs 2A and B**), a bulging fissure indicating extensive exudate or occult abscess in a lobar pneumonia, and associated pleural effusion are some findings highly suggestive of bacterial pneumonia. A diffuse, bilateral, fluffy infiltrate extending into the periphery suggests a bacterial process, central peribronchial infiltrate with or without atelectasis suggests a viral or *Mycoplasma* infection (**Fig. 3**). A peribronchial infiltrate with or without peripheral patchy alveolar opacification suggests a viral process (**Fig. 4**); a reticulonodular infiltrate confined to one lobe suggests *Mycoplasma pneumoniae*. Bronchopneumonia associated with lung necrosis, cavitation, pneumatoceles, and abscesses is more likely to be due to *S. aureus* (**Figs 5A and B**). Less commonly, *S. pneumoniae*, *H. influenzae*, and enteric gram-negative bacilli like *K. pneumoniae* and hydrocarbon aspiration can also result in necrotizing pneumonia.

Alveolar consolidative pneumonias can be further subclassified into two groups—airspace pneumonia and bronchopneumonia. Airspace pneumonia starts in the peripheral parenchyma and is acquired by the inhalation of small particles, e.g., pneumonia caused by *S. pneumoniae*, *Legionella*, and *K. pneumoniae*. Consolidation spreads concentrically because of the production of exudate and results in a spherical infiltrate (round pneumonia). Bronchopneumonia starts adjacent to centrally located bronchi and is acquired by the aspiration of infective particles.

Chest X-rays are not routinely necessary in patients being treated on OPD basis with a strong clinical suspicion of pneumonia. However, frontal views of chest radiographs should be performed in patients with suspected or documented hypoxemia or significant respiratory distress and in patients with failed initial antibiotic therapy to verify the presence or absence of complications of pneumonia, including pneumothorax, parapneumonic effusions and necrotizing pneumonia. Chest radiography for the diagnosis of pneumonia is not routinely recommended in patients with wheezing in the absence of fever or hypoxemia. It may however be obtained in those with severe disease requiring admission to document the presence, size, and character of parenchymal infiltrates and identify complications that may require other therapy. Lateral X-rays are not routinely required in pediatric age group and lead to unnecessary radiation exposure. Routine follow-

Figures 2A and B (A) Consolidation right superior basal segment; (B) Right middle lobe segmental pneumonia

Figure 3 Parahilar pneumonia caused by *Mycoplasma*

Figure 4 Interstitial pneumonia caused by viral infection

Figures 5A and B (A) Staphylococcal pneumonia complicated by right side pleural effusion with areas of breakdown; (B) Staphylococcal pneumonia complicated by multiple pneumatocele and left pleural effusion

up chest radiographs are not warranted in cases of uneventful recovery. Indications of repeat chest radiograph are:

- Failure to demonstrate clinical improvement
- Progressive symptoms or clinical deterioration within 48–72 hour after initiation of antibiotic therapy
- Complicated pneumonia with worsening respiratory distress or clinical instability
- Persistent fever that is not responding to therapy over 48–72 hours
- Recurrent pneumonia involving the same lobe
- Lobar collapse on initial chest radiography with suspicion of an anatomic anomaly, chest mass, or foreign body aspiration.

Ultrasonography of chest is an operator dependent modality which is now coming up as a bedside modality for intensive care unit settings. It is helpful in identifying early cavitation and in distinguishing a pneumonic process from avascular cavities and to identify fluid collections. CT chest, due to its high radiation, has no role in routine cases.

TREATMENT

An effort should be made to identify the possible etiologic agent based on the clinical and laboratory criteria so that the use of antibiotics can be minimized and the danger of antibiotic resistance curtailed (**Table 5**).

Table 5 Antimicrobial treatment as per suspected or documented etiology

<i>Disease</i>	<i>Pneumonia</i>		
<i>Setting</i>	Domiciliary		
<i>Age</i>	<i>First line</i>	<i>Second line</i>	<i>Suspected Staphylococcal disease</i>
Up to 3 months of age	Usually severe, treated as inpatients		
3 months to 5 years of age	Amoxycillin	Co-amoxyclav OR Cefuroxime	Amoxycillin + Cloxacillin (1:2) OR Cefuroxime OR Co-amoxyclav
Above 5 years of age	Amoxycillin	Co-amoxyclav OR Macrolide (atypical pneumonia)	Amoxycillin + Cloxacillin (1:2) OR Cefuroxime OR Co-amoxyclav
<i>Disease</i>	<i>Severe pneumonia</i>

Outpatient Treatment

In previously healthy children with suspected bacterial pneumonia being treated on OPD basis, amoxicillin is the first-line antibiotic in a dose of 50 mg/kg/day, given in two or three divided doses. If epidemiology is suggestive of resistant pneumococci (currently this is not the status in India), higher doses (90 mg/kg/day) with 8 hourly dose intervals may be used. No oral cephalosporin at doses studied in children provides activity against resistant pneumococci at the site of infection that equals high-dose amoxicillin. *S. pneumoniae* and *H. influenzae* strains are often resistant to macrolides (about 35% of isolates in our country) and therefore, macrolides are not recommended as empiric therapy. In case of nonserious allergy to β -lactams, trial of amoxicillin or oral cephalosporin (cefuroxime or cefpodoxime) under medical supervision can be done. If there is history suggestive of serious allergy including anaphylaxis, other options like macrolide, fluoroquinolone or linezolid can be tried.

Cefixime is not recommended as a respiratory antibiotic as it has poorer action against *Pneumococcus* as compared to other second and third generation oral cephalosporins.

Role of Micronutrients and Vitamins

A randomized controlled trial (RCT) in pneumonia cases (age group 2 months to 5 years) showed no beneficial effect of short-term supplementation of vitamin D for resolution of severe pneumonia. Vitamin A and zinc supplementation also appear to have no role in either prophylaxis or management of childhood pneumonia.

Indications of Hospitalization (Table 6)

The children with severe pneumonia should be hospitalized for management. World Health Organization (WHO) defines *pneumonia* as cough or difficulty breathing plus one of the following: lower chest in-drawing, nasal flaring, or grunting. Severe pneumonia is defined as *cough or difficulty breathing plus one of the following: cyanosis, severe respiratory distress, inability to drink or vomiting everything, or lethargy/unconsciousness/convulsions*. Infants less than 3 months have nonspecific signs and often can have associated sepsis/meningitis and are therefore almost always be hospitalized and treated as severe disease with a combination therapy.

Inpatient Supportive Therapy

Patients whose oxygen saturation is less than 92% while breathing air should be treated with oxygen given by nasal cannulae, high-flow delivery device, head box or face mask to maintain oxygen saturation more than 92%. Nasogastric tubes may compromise breathing and should therefore be avoided in severely ill children. Where needed, using orogastric tubes for feeding may be preferred to avoid blocking a nostril. Intravenous fluids should be used judiciously and serum electrolytes monitored. Antipyretics should be used to control fever and it helps in decreasing the oxygen demand in such cases.

Inpatient Antibiotic Therapy

Children with severe and life-threatening bacterial pneumonia should be started on parenteral antibiotics to achieve optimal

blood and tissue concentrations. Around 1% of children with pneumococcal pneumonia may have meningitis as well; therefore, the antibiotics are required in higher doses. The empiric antimicrobials being recommended are for the bacterial pathogens most likely to cause pneumonia, especially *S. pneumoniae*. Routine use of antibiotics is not indicated in preschoolers as many cases of pneumonia are due to a viral etiology. Clinical decision, as discussed earlier, and good follow-up in such cases can be useful in rationalizing antibiotic usage.

Infants and school-aged children with severe pneumonia requiring admission should be started on injection ampicillin or penicillin G. If penicillin resistance in *S. pneumoniae* is suspected or in infants and children with life-threatening infection where *H. influenzae b* could be the offending organism, patients should be started on parenteral third generation cephalosporins (cefotaxime or ceftriaxone). Intravenous co-amoxycyclavulanate is as effective as third generation cephalosporin. A macrolide can be added to a β -lactam antibiotic in children whom *M. pneumoniae* or *C. pneumoniae* is suspected.

If there is a suspicion of infection due to *S. aureus*, cloxacillin can be added to the β -lactam therapy or else co-amoxycyclavulanate can be used. In failure or resistant cases, vancomycin or clindamycin can be added to the β -lactam therapy.

Duration of Treatment

Total course of therapy depends on severity, rapidity of response and the likely organism. Most community acquired pneumonia will need treatment for 5 days while severe admitted cases shall need 7–10 days of therapy. In the presence of complications or infection with *S. aureus*, duration of therapy might be prolonged to 4–6 weeks. In the absence of bacteremia, or in children with bacteremia in whom secondary foci of infection have not been found, transition to oral therapy can take place as soon as the patient is stable and able to take orally, which may be as early as 2–3 days after the start of parenteral therapy.

Response to Therapy

Children receiving adequate therapy should demonstrate clinical and laboratory signs of improvement within 48–72 hours. It must be ensured that the correct drug(s) and dosages were prescribed and there was adherence to therapy. If there is no response to adequate medical management, further investigations may need to be carried out to look for any evidence of complications or presence of resistant pathogens. However, in case of complicated pneumonia, particularly with staphylococcal disease, the response is usually slower and can take up to 4–6 days and may not require any investigation unless a complication is suspected due emergence of new signs or symptoms.

Criteria for terming nonresponse to treatment at 48–72 hours are as follows:

- *Vital signs and parameters*
 - Persistence or increase in the general fever pattern
 - Increased respiratory rate, grunting, chest retractions, cyanosis

Table 6 Indications for hospitalization in children with pneumonia

1.	Moderate to severe pneumonia defined by respiratory distress (tachypnea > 70/min, retractions, grunting, nasal flaring or head bobbing) and hypoxemia ($SpO_2 < 90\%$)
2.	Children less than 6 months of age with suspected bacterial pneumonia
3.	Dehydration, vomiting or inability to take oral medication
4.	Presence of comorbid conditions, e.g., immunologic disorders, hematologic, cardiac, and chronic pulmonary conditions, genetic syndromes, neurocognitive disorders, reactive airway disease
5.	Children or infants with concerns regarding compliance with proper therapy or follow-up

- Persisting or increased heart rate
- Oxygen saturation less than 90% with room air, need for supplemental oxygen or ventilation
- *Systemic or focal symptoms or signs*
 - Clinically defined *toxicity* based on clinical judgment or change in mental status
 - Chest pain, splinting of the chest
 - Inability to maintain oral intake and hydration
 - Change in the extent of abnormal or absent breath sounds at auscultation or dullness in response to percussion
- Laboratory and/or radiologic results
 - Raised WBC count, both total count and percentage of immature forms of neutrophils
 - Increasing levels of inflammatory markers (e.g., procalcitonin, CRP)
 - Isolation of a pathogen by culture; nonresponsive pathogens include either those with antimicrobial resistance to current therapy or those susceptible to current therapy but with inadequate drug exposure in infected tissues, inadequate drainage of empyema or abscess, or inadequate duration of therapy
 - Increased parenchymal involvement, presence of or increase in pleural fluid, or development of pulmonary abscess or necrotizing pneumonia as documented on imaging.

Apart from drug resistant infection, other important reasons to be kept in mind in case of nonresponse are suspicion of tuberculosis, human immunodeficiency virus (HIV)/acquired immune deficiency syndrome (AIDS), or presence of severe malnutrition.

CRITERIA FOR DISCHARGE

- Improvement in general condition, activity and appetite and stable or baseline mental status,
- Pulse oximetry more than 90% at room air for at least 12–24 hours,
- No evidence of increased work of breathing in the form of tachypnea, tachycardia, retractions and nasal flare,
- Patients are able to tolerate oral medications and feeds,
- No social issues regarding observation at home, compliance to therapy or regular follow-up by parents/caregivers.

PREVENTION

Primary Prevention

Key primary measures to reduce deaths due to ARI include promoting adequate nutrition, increasing immunization coverage rate, reducing indoor air pollution and imparting health education. Preventing childhood pneumonia is critical to millennium developmental goal-4 target of reducing child deaths.

Promotion of exclusive breastfeeding till 6 months of age, and appropriate initiation of complementary feeds can reduce mortality due to ARI. Similarly, improving maternal nutrition status and micronutrient (vitamin/mineral) supplementation reduces the risk of low birthweight infants which in turn improves the overall survival associated with ARI in infants and children.

Immunization Effective implementation of expanded program on immunization (EPI) would in turn strengthen the ARI control program. Vaccines against diphtheria, pertussis and measles when given appropriate coverage can drastically decrease the mortality associated with ARI. Vaccination against *Pneumococcus*, and *H. influenzae* type B may decrease the incidence and deaths associated with pneumonia in children.

Health education about ARI begins from parents who need to learn to recognize severe forms, understand when to take their child to health-care center and make use of appropriate health-care

facilities. They need to be sensitized for promotion of breastfeeding, cessation of parental smoking and reducing indoor air pollution. It needs to be extended to primary health-care (PHC) worker to identify which children require home care, and which cases need to be referred. Education needs to be imparted to hospital/first referral unit (FRU) staff to manage complicated cases.

Secondary Prevention

Early diagnosis and treatment with antibiotics can prevent large proportion of deaths due to ARI. Case management of ARI essentially consists of

- Differentiation or identification of clinical condition by degree of severity,
- Initiation of appropriate antibiotics,
- Timely and appropriate referral monitoring and follow-up.

ACUTE RESPIRATORY INFECTION CONTROL PROGRAM

Acute respiratory infection control program was initiated officially by WHO in the year 1978 with the main objective of reducing the mortality from childhood pneumonia. It was recommended that by 1989 most of the developing countries should have formulated national programs for control of ARI within PHC. ARI control program was started by government of India in 1990 as a pilot project in four districts. Ten new districts were added in the year 1991. It sought to introduce scientific protocols for case management with rational and judicious use of antibiotics.

The main objective of ARI program is to reduce high mortality from ARI in children under-5 years through health education, effective case management and immunization against diphtheria/pertussis/measles which contribute substantially to overall ARI morbidity and mortality. Since 1992 the program was implemented as a part of Child Survival and Safe Motherhood (CSSM) program of Government of India. By the year 1997, ARI control activities were integrated with Reproductive and Child Health (RCH) program where efforts to improve ARI control program and effective management of infection were the focus of child health services at PHC. Generation of technical guidelines (WHO-ARI treatment guidelines) is simple classification for use by community health workers. ARI has been covered under the integrated management of childhood and neonatal illness (IMNCI). Based on selected clinical signs the child is placed in a classification and treated accordingly (see Chapter 51.5).

GLOBAL ACTION PLAN FOR PNEUMONIA

Global action plan for pneumonia (GAPP) was proposed by WHO following a meeting of experts on 5th–7th March, 2007 at France. The objectives of the plan include:

1. To identify topics for review in developing technical consensus on interventions to be promoted and strategies for accelerating their use in developing countries.
2. Develop outlines for each review and identify groups to develop the reviews.
3. Reach consensus on the process and timelines for development of GAPP.

GAPP was proposed to increase the awareness of pneumonia as a major cause of death, to scale up the use of interventions of proven benefit and to develop a plan to achieve this. Key strategies for control of pneumonia include effective case management at community and at health facility, achieve global immunization vision and strategy, improvement of nutrition and low birthweight, reduction in indoor air pollution, prevention and management of HIV infection.

IN A NUTSHELL

1. Pneumonia may be classified as simple and complicated pneumonia. Simple pneumonia can be bronchopneumonia and lobar pneumonia. Complicated pneumonia refers to effusions, empyema, necrotizing pneumonia abscesses or cavities, pneumothorax or bronchopleural fistula.
2. Viruses are among the frequent pathogens in children younger than 2 years. RSV is most commonly implicated virus.
3. Among the bacterial causes of pneumonia in young children, *Streptococcus pneumoniae* and *Haemophilus influenzae* are the most common.
4. Malnutrition, low birthweight, and lack of exclusive breastfeeding, predispose to pneumonia. Maternal education and awareness influence the care seeking behavior for children with pneumonia.
5. Tachypnea is a simple yet fairly specific and sensitive sign for pneumonia if asthma and bronchiolitis have been excluded.
6. Children with pneumonia usually present with fever, tachypnea, productive cough, and chest pain. In pneumonia caused by atypical pathogens, a more gradual onset associated with low grade fever or no fever, headache, nonproductive cough and malaise may be present.
7. Chest X-rays are not routinely necessary in patients being treated on OPD basis with a strong clinical suspicion of pneumonia.
8. In previously healthy children with suspected bacterial pneumonia being treated on OPD basis, amoxicillin is the first-line antibiotic in a dose of 50 mg/kg/day, given in two or three divided doses.
9. Children with severe or very severe pneumonia (as per WHO definitions) should be hospitalized for management.
10. Children with severe and life-threatening bacterial pneumonia should be started on parenteral antibiotics and offered supportive therapy.

Chapter 39.22

Parapneumonic Effusion and Empyema

Kamal Kumar Singhal, GR Sethi

Empyema is defined as pus within the pleural space. Usually a complication of bacterial pneumonia, it can occasionally occur as a consequence of infection at other sites. Recent reports indicate that the incidence is increasing worldwide. The condition rarely resolves without medical therapy, which includes antibiotics and chest tube drainage. Other forms of treatment include use of fibrinolytics, video-assisted thoracoscopic surgery (VATS), open thoracotomy and decortication.

EPIDEMIOLOGY

Parapneumonic effusion and empyema have an incidence of 3.3 per 100,000 children and occur in 0.7% of children with pneumonia. The mean age of affected children is between 4 years and 6 years. Historically, the rate of empyema in pneumonia has shown much fluctuation. The preantibiotic era rate of about 10% diminished greatly in the antibiotic era and then again surged in the middle of the 20th century to about 14% to decrease in 1970s to about 2%. Many recent reports have again indicated an increase in worldwide incidence of empyema. The reasons for this rise are not clearly understood.

Pleural infection is most commonly a complication of bacterial pneumonia. Thus patients at risk for pneumonia are also at risk of pleural infection. Causes of pleural infection other than pneumonia, are largely iatrogenic, including thoracic (20%) and esophageal surgery, esophageal perforation, and trauma (5%). Empyema may occur due to thoracocentesis, intervention for primary spontaneous pneumothorax and abdominal sepsis or spontaneous bacterial peritonitis in 2%, 2% and 1% cases, respectively. Rarely, a primary infection of the pleural space may occur. Cause in up to one-third of cases is idiopathic.

ETIOLOGY

The most common organisms that cause effusions or empyemas associated with community-acquired pneumonia (CAP) in children are *Streptococcus pneumoniae* and *Staphylococcus aureus*. Pneumococcal infection is the most common cause in developed countries and *S. aureus* in the developing world. In one of the studies, anaerobic bacteria were isolated in 13%, and mixed aerobic and anaerobic bacteria in 23% patients, indicating a greater role of anaerobes in empyema. There is marked variability in the reported microbiology of empyema depending on the reported series and clinical settings. Resistant organisms (particularly methicillin-resistant *Staphylococcus aureus* [MRSA]) are a common cause of hospital-acquired pleural infection. Empyema secondary to external introduction of organisms, e.g., trauma, surgery, thoracocentesis is more likely due to *S. aureus* or aerobic gram-negative bacilli. Empyema secondary to subdiaphragmatic abscess may be due to mixed organisms and may include enteric gram-negative bacilli, other aerobic intestinal flora, or anaerobes.

PATHOGENESIS

The pleura is a serous membrane divided into parietal and visceral pleura. The visceral pleura covers the lung parenchyma while the parietal pleura covers the diaphragm, mediastinum and rib

cage. Pleura allows for mechanical coupling of the lung and chest wall throughout the respiratory cycle. Approximately 0.3 mL/kg of fluid is normally present in the pleural space and it lubricates the movement of visceral pleura on the parietal pleura during respiration. This pleural fluid is the result of a dynamic balance between fluid filtered from subpleural capillaries and removed via lymphatics. Between the mesothelial cells of the mediastinal and intercostals aspect of costal pleura, 2–12 μm openings called *stomata* are present. It is through these stomas that the lymphatic vessels communicate with the pleural space. Pleural fluid accumulates if there is an imbalance in its formation and absorption.

Transudate versus Exudate

Pleural effusion can be either a *transudate* or *exudate*. Transudative effusion are due to altered systemic factors influencing the formation and absorption of pleural fluid (e.g., cardiac failure, nephrotic syndrome), whereas exudative effusions are due to altered pleural surface or capillaries (e.g., infections). Exudative effusion meets at least one of the following criteria given by Light: pleural fluid protein divided by serum protein greater than 0.5, pleural fluid lactate dehydrogenase (LDH) divided by serum LDH greater than 0.6, and pleural fluid LDH greater than two-thirds of upper limit of normal for serum LDH. Since light criteria was developed and tested in adults, its applicability in children has been questioned.

Evolution of Empyema

Although the progression of pleural fluid associated with infections to empyema is a continuum: it has been classically divided into three stages—(1) exudative, (2) fibrinopurulent and (3) organizing.

Exudative Stage

In this stage the inflammatory process associated with the underlying pneumonia leads to the accumulation of clear fluid with a low white cell count within the pleural cavity (simple parapneumonic effusion). It usually lasts 3–5 days.

Fibrinopurulent Stage

Usually starts 7–10 days after the first signs of the acute disease. In this stage there is bacterial invasion across the damaged epithelium and accumulation of fibrinous strands in the pleural fluid leading to septations and loculations. Further there is an increase in white cells, with the fluid thickening (complicated parapneumonic effusion) and eventually becoming overt pus (empyema). All empyemas are complicated effusions but not *vice versa*. This combination of events leads to increased lactic acid production, associated with a fall in pleural fluid pH, accompanied by increased glucose metabolism and a rise in LDH levels due to leukocytes death.

Organizing Stage

This stage involves proliferation of fibroblasts and starts in 2–3 weeks. Due to these fibroblasts a solid, thick, fibrous pleural peel replaces the soft fibrinous membrane. This nonelastic pleural peel prevents the re-expansion of lung and impairs lung function, creating a persistent pleural space with continuing potential for infection.

CLINICAL FEATURES

The clinical presentation of empyema may be acute or chronic. The acute presentations of empyema are of two types. The first type clinically resembles acute pneumonia and presents with cough, fever, tachypnea, respiratory distress, exercise intolerance,

poor appetite, abdominal pain, lethargy and malaise. However, compared to simple pneumonia these children are often more unwell and have pleuritic chest pain. The second type, and the more common one, resembles a worsening or nonresponding pneumonia. These patients present with persistence of fever, and respiratory symptoms in a child with of pneumonia or feature of relapse in a resolving pneumonia. Chronic empyema may have only nonspecific constitutional symptoms like weight loss and low grade fever without any local chest symptoms. Very young children with empyema may present with predominantly abdominal signs and symptoms. They may have pain abdomen and even abdominal distension.

On inspection pleural effusion may be suggested by unilateral signs of bulging of the intercostal spaces, decreased chest expansion, splinting of chest, preference to lie with normal side up and affected side in dependent position, focal chest wall heat, erythema, swelling and scoliosis. On palpation the trachea and cardiac impulse may be shifted away from the side of effusion with decreased tactile fremitus, and chest wall expansion on affected side. The affected side may be stony dull on percussion. Auscultation will reveal decreased breath sound on affected side. There may be pleural friction rub, bronchophony or egophony above pleural effusion. This paradoxical increase of breath sounds near the upper border of the fluid is due to increased sound conductance in the partly atelectatic area under the fluid.

Complications of empyema include bronchopleural fistula (communication between bronchial airway and pleural space), empyema necessitans (extension of pus out of the pleura into the chest wall and surrounding soft tissue) and pneumothorax. Infective complications include pericarditis and bacteremia.

DIAGNOSIS

Acute Phase Reactants

These cannot differentiate simple pneumonia from complicated pneumonia with empyema, or empyema from simple parapneumonic effusion.

Blood Culture

Recommended in all cases for identification of the organism, although yield is low (10–22%).

Pleural Fluid Cytology, Biochemistry and Culture

This should be aimed in all cases. Thoracentesis is required for differentiation of uninfected parapneumonic effusion from empyema. Pleural fluid thus obtained should be sent for cytology, Gram stain, microbiological and biochemical investigations, culture. The following characteristics of pleural fluid strongly suggest presence of empyema; thick pus, bacteria on Gram stain, glucose level less than 60 mg/dL or pleural fluid to serum glucose ratio of less than 0.5, LDH levels of more than 1,000 IU/L, and pH below 7.3.

Chest X-ray

On erect frontal view small pleural fluid is seen as obliteration of the costophrenic angle and larger fluid as meniscus sign (a rim of fluid ascending the lateral chest wall). In supine position, pleural fluid is seen as homogeneous increase in opacity over the whole lung field. Big pleural effusions are seen as complete white-out of one lung field (**Fig. 1**). Scoliosis with concavity to the side of the effusion may also be seen in chronic cases.

Three features described here may distinguish simple parapneumonic effusion from empyema on chest X-ray. Firstly, shift of pleural fluid location with change in position of patient (erect to lateral decubitus or *vice versa*) indicates simple parapneumonic effusions. Presence of loculations in empyema

Figure 1 Right-sided pleural effusion seen as complete white-out of one lung field

hinders this free shift of fluid location. Secondly, presence of lung abscess or cavitary pneumonia or an adjacent pulmonary alveolar consolidation favors presence of empyema. Thirdly, pleural collection having a lenticular shape with internal convexity may indicate loculations because a freely moving collection should form an internally concave meniscus paralleling the chest wall.

On chest X-ray pulmonary abscess and empyema can be differentiated by obtaining two X-ray views perpendicular to each other, usually lateral and frontal projections. The length of air-fluid level is equal in case of abscess and unequal in case of empyemas.

Although useful for diagnosis of empyema in a patient showing inadequate resolution or worsening of pneumonia, chest X-ray is not useful for follow-up, since radiological resolution takes time. Almost 80% chest X-ray shows resolution at 3 months and almost all by 1½ year.

Ultrasonography

Typically, pleural effusions on ultrasonography can be classified into three groups: (1) anechoic, (2) complex nonseptated, and (3) septated. The anechoic and complex nonseptated patterns can be seen in both transudates and exudates. The septated pattern can be seen only in exudates. Moreover the term *septated* is not the same as *loculated*. While loculated collections do not communicate, septated ones simply mean presence of fibrinous strands within the pleural fluid.

Ultrasonography is a better modality than computed tomography (CT) scan to assess for fibrinous septations in the pleural fluid and to differentiate free from loculated fluid. It can be conveniently used bedside to mark the best site for insertion of intercostals drainage tube. It can also give a good estimate of the amount of pleural fluid. In cases of white-out lung, due its good ability to distinguish solid from liquid structures, it can be used to differentiate between atelectasis, consolidation, and effusion. Ultrasonography can readily distinguish pleural fluid from pleural thickening.

CT Scan

Computed tomography (CT) scan allows complete examination of the thorax. Although unnecessary for most cases of pediatric empyemas, it is indicated in complicated cases or when an alternative diagnosis is suspected, e.g., tumor or abscess. Performed before thoracotomy or thoracoscopy, it gives greater

anatomic details to a surgeon. It is the best method to differentiate a peripheral lung abscess from empyema. Abscesses have an irregular thick wall which is not uniformly wide and do not have a discrete boundary between the lesion and lung parenchyma. In contrast, empyemas have a regularly shaped lumen, a smooth inner surface, and a sharply defined border between the lesion and lung. Since CT cannot visualize fibrin strands or loculations, as they are too thin, it cannot differentiate simple parapneumonic effusion from empyema.

MANAGEMENT

The general care of the patient would include judicious use of oxygen, antipyretics, intravenous (IV) fluids, and IV antimicrobial. Pus drainage and appropriate antibiotic therapy is the mainstay of all therapeutic options.

Treatment goals in empyema include sterilizing the pleural cavity with antibiotics (preferably IV), with drainage of fluid, re-expansion of the lung, and restoration of normal lung function. The treatment approach should be based on clinical status, radiological staging and the results of pleural fluid examination. It is important to document the stage of pleural effusion (exudative, fibropurulent or organizational stage) before selecting the most appropriate intervention.

Currently available treatment options for pediatric parapneumonic effusion and empyema include antibiotics alone or antibiotics with thoracentesis, chest tube drainage (alone or in combination with fibrinolytics), and surgery (VATS or open thoracotomy with decortication).

Antibiotic Therapy

Small stable pleural collections can be managed with antibiotics alone. Antibiotic treatment is empiric since the majority of patients do not have any positive culture results. Generally, IV broad-spectrum high dose antibiotics (amoxycillin with clavulanic acid, cloxacillin with gentamicin, or cloxacillin with ceftriaxone) are started. If MRSA is suspected then one prefers vancomycin. In suspected hospital-acquired infection or in patients with a prior transthoracic procedure a combination of carbapenems (e.g., meropenem) and a drug with anti-MRSA activity (e.g., vancomycin) may be needed. The antibiotics may need to be changed with the availability of culture sensitivity pattern. The recommended duration is for 2–4 weeks after discharge (which is usually after 2 weeks of IV treatment) or even longer when there is residual disease.

Chest Tube Drainage

Enlarging exudative collections would need drainage in addition to antibiotics. This requires intercostals chest tube placement. Repeated ultrasonography guided needle thoracentesis causes repeated trauma, and has not been found to be more effective than chest tube placement. If there is inadequate clinical response (fever spikes, rising total leukocyte counts [TLC], poor oral intake) despite antibiotic cover and adequate intercostal drainage, there may be a need for review antibiotics. If pleural fluid drainage is inadequate, it may merit adjustment of existing chest tube or insertion of another chest tube, or consideration of fibrinolytic therapy or surgery. A CT scan is required only in such patients.

If there are loculations on imaging, intrapleural fibrinolytic therapy may be considered, but benefit from use of fibrinolytics in empyema is inconsistent across various studies. Evidence is still not sufficient to recommend routine use.

Surgical Options

Surgery is indicated in cases with failure of medical therapy (persisting sepsis and large pleural collection), chronic empyema, and persistent bronchopleural fistula. Surgical modalities in use include: (i) video-assisted thoracoscopic surgery (VATS); and (ii) open thoracotomy.

Studies reporting conservative management (antibiotics and chest tube drainage) in children are few, mostly from west. And now with new management strategies such studies have become even less common. Further availability of local resources and cost limits the surgical option, especially in developing countries. Studies comparing intercostal chest drain and urokinase with VATS for the treatment of empyema in children did not find any difference in clinical outcome but cost of treatment was significantly lower in the urokinase group. Nonetheless, VATS or thoracotomy may be considered in complicated empyema, where it is available. The success rate with thoracoscopy and thoracotomy is 60–90% respectively. Thoracotomy with decortication remains the initial treatment of choice in all chronic and multiloculated empyemas.

What is of utmost importance is the fact that the primary goal of all initial interventions is the control of the pleural infection. If it is controlled then pleural adhesions on imaging or abnormal lung functions do not merit any immediate surgical procedure. These patients can be conservatively observed since a number of studies have reported that children with empyema almost always recover, irrespective of the treatment they receive.

IN A NUTSHELL

1. Empyema is mostly a complication of bacterial pneumonia.
2. *Streptococcus pneumoniae* and *Staphylococcus aureus* are the most common causative pathogens.
3. Very young children may present with predominantly abdominal signs and symptoms.
4. Ultrasonography is a better modality than CT scan to differentiate free from loculated fluid.
5. Thoracentesis is ultimately required for differentiation of uninfected parapneumonic effusion from empyema.
6. Appropriate antibiotic therapy (for 4–6 weeks) with chest tube drainage is the mainstay of therapy.

Chapter 39.23

Pneumothorax and Air Leaks

Mandeep Walia, Abhishek Somasekhara Aradhya

Air leaks are now increasingly encountered in pediatric patients, with increased use of assisted ventilation. Accumulation of air in the intrapleural space is defined as pneumothorax and is the most common air leak syndrome in children, followed by pulmonary interstitial emphysema. The other causes of air leak include pneumomediastinum, pneumopericardium, pneumoperitoneum, and subcutaneous emphysema. In many patients air leaks may present as a life-threatening event warranting prompt recognition and expedited drainage.

PNEUMOTHORAX

By convention, a small pneumothorax occupies less than 15% of lung volume, while moderate and large pneumothorax occupies 15–60% and more than 60%, respectively.

ETIOLOGY

Pneumothorax can be classified as spontaneous, iatrogenic, traumatic or catamenial. Based on intrapleural air pressure, it can be simple or tension pneumothorax. Spontaneous pneumothorax is further classified as primary or secondary. Primary spontaneous pneumothorax involves no underlying lung disease or trauma. Pneumothorax occurring due to an underlying lung disease, but without trauma is defined as secondary spontaneous pneumothorax.

Primary Spontaneous Pneumothorax

Primary spontaneous pneumothorax occurs more commonly in tall, thin males with marfanoid habitus. In these children, periods of active growth are accompanied by an increase in the vertical dimensions of the chest that may affect intrathoracic pressure at the apices and drive subpleural cyst formation. Other genetic conditions which pose a risk factor for primary spontaneous pneumothorax include Ehlers-Danlos syndrome, homocystinuria, Birt-Hogg-Dube syndrome and rheumatological conditions like ankylosing spondylitis. Birt-Hogg-Dube syndrome is a rare autosomal dominant condition with folliculin gene mutation with benign skin tumors, renal and gastrointestinal malignancies, with thin wall cysts in the lung which can rupture to cause pneumothorax in one-fifth of the cases. Spontaneous pneumothorax can also be seen with substance abuse (heroin addiction).

Conventionally primary pneumothorax is defined to occur in the absence of lung disease; however a majority of them have been detected to have subpleural blebs and localized emphysematous changes on computed tomography (CT) of the chest. With the availability of novel techniques like fluorescein-enhanced autofluorescence thoracoscopy (FEAT), increased lung porosity has been identified in primary pneumothorax. Leakage from these porous sites leads to intrapleural accumulation of air.

Secondary Pneumothorax

Secondary pneumothorax occurs in presence of underlying lung disease. In a tropical country like India, necrotizing pneumonia, especially due to *Staphylococcus aureus* is one of the most common

inciting causes. Pulmonary tuberculosis is also associated with secondary pneumothorax, due to rupture of pleural adhesions allowing air leak into pleural space. Other causes include, but not limited to lung abscess, cystic fibrosis, asthma, interstitial lung disease, *Pneumocystis jirovecii* pneumonia, histiocytosis, sarcoidosis, lung infarct, congenital malformations like cystic adenomatoid malformation, lobar emphysema, and rare tumors (**Table 1**). Children are more predisposed to pneumothorax than adults following trauma, even in the absence of external injury or rib fracture, due to greater distensibility of the chest wall. The incidence of iatrogenic pneumothorax has considerably increased with assisted ventilation (due to barotrauma) and other procedures like thoracentesis, tracheostomy, subclavian venous lines and transbronchial lung biopsy.

Neonatal Pneumothorax

Newborns have a higher incidence of pneumothorax approximately 0.5–3%, however, only 10% of these are symptomatic. Their increased predisposition is due to greater compliance and uneven alveolar distension owing to poorly developed pores of Kohn, which allows interalveolar air distribution. Aspiration syndromes, respiratory distress syndrome and sepsis are important risk factors for air leak. Air leaks in the newborn infants have been discussed in detail in Section 17.

Table 1 Causes of secondary pneumothorax in children

Primary spontaneous	Idiopathic
Secondary spontaneous	
Infection	Necrotizing pneumonia Measles Tuberculosis <i>Pneumocystis jirovecii</i> Echinococcal HIV
Increased intrathoracic pressure	Asthma Bronchiolitis Cystic fibrosis Airway foreign body
Congenital lung/airway anomalies	Congenital cystic adenomatoid malformation Bronchogenic cyst Congenital lobar emphysema
Inflammatory/connective tissue disorders	Marfan syndrome Ehlers-Danlos syndrome SLE Langerhans cell histiocytosis Dermatomyositis Polymyositis Sarcoidosis
Malignancy	Lymphoma Metastatic lung lesions
Traumatic	Blunt trauma Penetrating lung injury
Iatrogenic	Mechanical ventilation Thoracotomy Thoracentesis Thoracoscopy Tracheostomy Needle aspiration
Catamenial	

Abbreviations: HIV, human immunodeficiency virus; SLE, systemic lupus erythematosus.

Catamenial Pneumothorax

Catamenial pneumothorax is an unusual variety of recurrent pneumothorax predictably occurring during menstruation. It occurs due to transperitoneal migration of pelvic endometriosis through pores in right diaphragm. This entity is rare in adolescent girls.

PATHOPHYSIOLOGY

Pneumothorax occurs whenever there is uneven alveolar ventilation, air trapping and high transpulmonary pressure swings. The lung normally has an intrinsic property to collapse inwards. In the presence of intrapleural air there is uncoupling of the lung from the chest wall leading to further collapse, until equilibrium is achieved leading to alveolar hypoventilation and ventilation-perfusion mismatch thereby leading to hypoxia and hypercarbia.

In *tension pneumothorax*, pressure in the pleural space remains positive throughout the respiratory cycle due to a check valve leading to collapse of the ipsilateral lung. The contralateral lung is overinflated, further increasing the intrathoracic pressure. Consequently venous return is decreased, leading to poor peripheral perfusion. Compensatory tachycardia occurs which further restricts the stroke volume. Kinking of the inferior vena cava is thought to be the initial event in tension pneumothorax decreasing the preload to heart. The end result is cardiac arrest with electromechanical dissociation on electrocardiography.

CLINICAL FEATURES

Clinical presentation of pneumothorax mainly depends on age, rapidity of air accumulation, intrapleural pressure and consequent lung collapse. Symptom spectrum may range from asymptomatic accumulation of air in the pleural space to sudden cardiorespiratory collapse in tension pneumothorax. In asymptomatic children, diagnosis is first evident on a chest radiograph.

Primary spontaneous pneumothorax usually presents with pleuritic chest pain, although explanation for increased frequency of chest pain is not available. In contrast, breathlessness is the predominant presenting symptom in secondary pneumothorax, presumably due to an underlying reduced lung reserve and further lung collapse due to pneumothorax resulting in dyspnea.

Older children usually present with acute chest pain, breathlessness and cyanosis. On examination they have tachycardia, tachypnea, shallow breathing, hyperinflated chest on the ipsilateral side, shift of trachea to opposite side (late sign) with hyper-resonant note on percussion, absent breath sounds and decreased vocal resonance on same side. Tension pneumothorax additionally has features of mediastinal shift, jugular venous dilation, pulsus paradoxus, and cardiorespiratory compromise.

Children with spontaneous pneumothorax may be asymptomatic and are usually tall and thin adolescents with or without marfanoid habitus. Up to 10% of spontaneous pneumothorax has positive family history. Usually spontaneous pneumothorax present late as symptoms improve usually over 1–3 days.

Children on assisted ventilation and neonates usually present with tachycardia, tachypnea, irritability and chest bulge. Pneumothorax should be ruled out in any mechanically ventilated child developing sudden and unexplained alterations in hemodynamic or respiratory parameters.

DIAGNOSIS

Diagnosis of pneumothorax is suspected on clinical history and examination, confirmed on an erect chest radiograph in older children (**Fig. 1**). Contrary to adults, children often do not have peripheral lucency in supine films as gas collects anteriorly in anterior pleural reflection. Increased clarity of cardiac outline may

Figure 1 Right-sided pneumothorax

be the only finding in supine radiographs. Small pneumothorax not detected on posterioranterior view, may be revealed on a lateral or lateral decubitus views.

Radiographic findings of pneumothorax on an erect film include a thin white line of visceral pleura, usually seen in the apex of the lung, absence of lung markings beyond this white pleural line. Evidence of tension pneumothorax includes shift of the mediastinal structures to the contralateral side, flattening of the ipsilateral diaphragm. If tension pneumothorax is detected clinically, waiting for confirmation on a chest X-ray will waste crucial time. Air should be evacuated immediately.

Estimation of the size of pneumothorax has been described by several methods, including the Light, Rhea and Collin methods. However, their accuracy in child patients has not been assessed. British Thoracic Society guidelines for adult patients defines a large pneumothorax as more than or equal to 2 cm space between the lateral lung edge and chest wall and this approximates to a pneumothorax size of 50%.

Cystic lung lesions and lobar emphysema may mimic a pneumothorax on chest radiograph. Both these entities however have crescentic lower border of radiolucency. To differentiate diaphragmatic hernia, pass a nasogastric tube. The radiopaque tip of the tube, when visualized in the thoracic cavity indicates a diaphragmatic hernia, which can be confirmed on ultrasonography.

MANAGEMENT

The decision to treat pneumothorax depends on its extent, symptomatology of the patient and underlying lung reserve. Small pneumothorax (less than 15–20%) in an otherwise asymptomatic child with normal lungs does not usually require evacuation and it spontaneously resolves in about 10–14 days. In symptomatic patients intrapleural air must be evacuated before air travel, as reduced atmospheric pressure during ascent may expand the pneumothorax, increasing the probability of a tension pneumothorax.

In symptomatic patients, mechanical evacuation of the intrapleural air with an intercostal chest catheter insertion using Seldinger technique with underwater seal drainage is warranted. Evidence indicates that small bore chest catheters are equally comparable to large bore catheters in effectively evacuating the intrapleural air. Administering 100% oxygen hastens absorption of the air. The use of suction pressure to expedite air removal is not required in most cases. The initial

use of suction has been associated with increased risk of re-expansion pulmonary edema. Patients with chest catheters in situ should be closely monitored, clinically and with arterial blood gases and analgesics should be prescribed to reduce pleuritic pain. In secondary pneumothorax due to infection, treat with appropriate antibiotics.

Follow-up

Children after pneumothorax drainage in follow-up are monitored for recurrence, lung functions and improvement of lung collapse. Children with primary spontaneous pneumothorax require long-term follow-up for recurrence. Air travel should be avoided for at least 6 weeks.

OTHER AIR LEAK SYNDROMES

Air leaks are usually common in newborn period especially preterms than any other age. In the postsurfactant era, incidence is decreasing. They are also associated with increased risk of intraventricular hemorrhage in preterm neonates.

PULMONARY INTERSTITIAL EMPHYSEMA

It is common in mechanically ventilated children and newborns especially low birthweight babies. Risk factors are low birthweight babies, high peak inflation pressures and malpositioned endotracheal tubes. It manifests with slow deterioration and hypoxemia in ventilated children. Diffuse pulmonary interstitial emphysema (PIE) can increase the risk of bronchopulmonary dysplasia in preterms. It is diagnosed on a radiograph by presence of hyperinflation and cystic lucencies (multiple/small) on the ipsilateral side. There is no definitive treatment. Supportive treatment in the form of use of lower peak inflation and positive end-expiratory pressures and use of high frequency ventilation prevents progression of PIE.

PNEUMOMEDIASTINUM

It occurs when air dissects from the visceral pleura into the connective spaces of the mediastinum. Usually it occurs in association with other air leaks. It presents with tachypnea, desaturation and muffled heart sounds. On the radiograph it manifests as halo of air adjacent to the heart. It is differentiated from pneumopericardium by absence of air beneath the cardiac shadow. On lateral chest film *spinnaker sign* (elevation of thymus by air away from the pericardium) may be seen (**Fig. 2**). It does not require treatment and usually resolves spontaneously.

PNEUMOPERICARDIUM

It occurs when air dissects from the mediastinum into the parietal pericardium through a defect located at pleural reflection near the ostia of pulmonary veins. It presents with features of pericardial tamponade. It can also be differentiated from pneumomediastinum by transillumination—there will be flickering of light with heart rate. Management involves drainage through subxiphoid route; however it is associated with mortality of up to 80%.

Figure 2 Spinnaker sail sign (elevation of thymus by air away from the pericardium) in a neonate with respiratory distress
Source: Varinder Singh.

IN A NUTSHELL

1. Air leak syndromes include pneumothorax, pneumomediastinum, pulmonary interstitial emphysema, pneumopericardium, pneumoperitoneum, and subcutaneous emphysema.
2. Incidence of iatrogenic air leaks has increased with assisted ventilation and other procedures like thoracentesis, tracheostomy.
3. Secondary pneumothorax occurs in presence of underlying lung disease. In a tropical country like India, secondary pneumothorax due to necrotizing pneumonia, especially *Staphylococcus aureus* is one of the most common causes.
4. Clinical presentation and decision to treat pneumothorax mainly depends on age, rapidity of air accumulation, intrapleural pressure and consequent lung collapse.
5. Accuracy of estimation of size of pneumothorax on chest radiographs has not been assessed in pediatric patients.
6. Small bore chest catheters are equally comparable to large bore catheters in effectively evacuating the intrapleural air. Administering 100% oxygen hastens absorption of the air.

Chapter 39.24

Persistent and Recurrent Pneumonia

Ankit Parakh, Varinder Singh

Pneumonia is clinically defined as combination of respiratory symptoms (cough, dyspnea or tachypnea) and signs (fever, crepitations, focally-reduced breath sounds, fremitus or wheeze).

Persistent or nonresolving pneumonia is defined as the persistence of symptoms and radiographic abnormalities in a child with lower respiratory tract infections (LRTIs) for more than a month despite a course of adequate antibiotic therapy. *Recurrent pneumonia* is defined as at least two distinct episodes of radiologically established pneumonia within the same year or three or more such episodes over anytime period. For the diagnosis of recurrent pneumonia, there must be complete resolution of clinical and radiological findings between acute episodes.

These two entities are sometimes difficult to distinguish clinically and radiologically because the radiographs are usually obtained during acute episodes with no documentation during well periods. While comparing the chest radiographs taken over different times, one must keep in mind that the images may look different not only due to the disease process but also due to variation in the radiological factors, quality and phases of respiration. Given the difficulties in clinically differentiating these two, they are often dealt together. Henceforth, in the present chapter, the term persistent pneumonia shall be used to imply persistent and recurrent pneumonia.

Beyond infections the persistent lung infiltrates can also occur due to various noninfective causes as well. These noninfectious causes have to be teased out carefully. It is equally important to remember that superadded infection could also bring up a patient with an underlying noninfectious etiology, e.g., a congenital pulmonary airways malformation (CPAM) can get recurrently infected.

ETIOPATHOGENESIS

The usual fate of childhood pneumonia is either of the following: recover, slowly resolve, progress, persist, or recur. Most cases of acute childhood pneumonia improve clinically within 5–10 days, while the radiological clearance lags behind. The radiological shadows usually clear within a period of 2–4 weeks, but in a substantial number of children these infiltrates fail to clear completely within 4 weeks.

The rate of resolution of the radiological shadows depends on the causative agent. Infiltrates caused by common viral agents like respiratory syncytial virus (RSV) and parainfluenza virus usually takes 2–3 weeks for clearance, those associated with pneumococcal pneumonia can take 6–8 weeks, and those associated with adenoviral disease can take up to 12 months for clearance. Sometimes the causative organism can leave behind residual radiographic abnormalities (pneumatocoles) like in staphylococcal pneumonia which takes up to weeks to resolve.

For the better understanding of the etiology and pathogenesis, the patients with persistent pneumonia are further divided into those which a single lobe involved and those in which multiple lobes are involved. Infiltrates that recur in a single lobe or segment of the lung may be caused by localized pathology like local airway obstruction—intra/extraluminal, structural abnormalities of airway or lung parenchyma. Multilobar involvement is more

often a result of a systemic problem. Persistent pneumonia usually results from deficiencies in the local pulmonary or systemic host defenses or from underlying disorders that modify lung defenses.

Unilobar Persistent Pneumonia

The causes of unilobar persistent pneumonia can be (1) persistent parenchymal shadow secondary to infections (tuberculosis [TB], hydatid cyst); (2) structural abnormalities: CPAM, sequestration, bronchogenic cysts, hypoplastic lung; or (3) airway obstruction: intraluminal (foreign body, endobronchial TB, endobronchial tumor), luminal (bronchomalacia), extraluminal (enlarged lymph nodes, cardiomegaly, vascular rings). This obstruction leads to local airway narrowing which causes leads to retained secretions in the area distal to the obstruction, impaired mucociliary clearance leading to accumulation of secretions distal to obstruction in which infection supervenes (**Table 1**).

Congenital anomalies such as CPAM, congenital lobar emphysema (CLE), bronchogenic cyst, and pulmonary sequestration, can get infected and lead to recurrent LRTI. Most congenital abnormalities are now diagnosed by prenatal ultrasonography or present shortly after birth as respiratory distress, but can present later in life with recurrent or persistent pneumonia.

Retained foreign body is the most frequent cause of intraluminal obstruction in children age 6 months to 3 years, while TB is the most common cause of infectious lymphadenopathy causing extraluminal compression, leading to chronic or recurrent focal pulmonary disease.

Tracheobronchial tree abnormalities either congenital like tracheal bronchus, bronchial stenosis, or bronchomalacia or acquired conditions like postinfectious bronchiectasis are other important causes. Causes of unilobar persistent pneumonia are listed in **Table 1**.

Multilobar Persistent Pneumonia

Pneumonia that occurs in multiple locations or affects more than one lobe indicates a disease process which is more generalized and therefore a systemic consideration must be taken for evaluation, e.g., primary or secondary immunodeficiency, diffuse alveolar hemorrhage, hypersensitivity pneumonitis, etc. Aspiration into the lung secondary to gastroesophageal reflux (GERD) or anatomical abnormality like cleft or H-type tracheoesophageal fistula (TEF)

Table 1 Causes of unilobar persistent pneumonia

Intraluminal obstruction	Foreign body; endobronchial granuloma—tuberculoma; bronchial tumor—hemangioma, lipoma, adenoma, papilloma
Extraluminal compression	Lymphadenopathy—infectious (tuberculosis, histoplasmosis, etc.) Noninfectious (Malignancy-Hodgkin's disease) Vascular rings and slings Esophageal foreign body Cardiomegaly Inflammatory pseudotumor
Structural abnormalities	Tracheal bronchus Bronchiectasis Right middle lobe syndrome Bronchial stenosis Bronchomalacia may be segmental Congenital pulmonary airway malformation (CPAM) Pulmonary sequestration Congenital lobar emphysema Pulmonary hypoplasia Bronchogenic cyst

Clinical History and Examination

Detailed history includes information regarding the age of onset, frequency, duration and severity of symptoms along with neonatal course, subsequent hospitalizations and operations. History regarding birth problems, developmental delay, feeding problems, immunization status, foreign body aspiration and allergy/atopy needs to be obtained. Family history of any hereditary disorder, sibling deaths, allergy/atopy and environmental history is also important. Physical examination includes vitals, detailed anthropometry along with changes in skin and extremities (cyanosis, clubbing, rashes), any signs of pyogenic infections, presence of conjunctivitis or telangiectasia, ear discharge, sinuses, candidiasis, etc. Detailed systemic examination is also vital. Respiratory system examination—evaluating upper as well as lower airways, cardiovascular system for congenital heart disease, dextrocardia (associated with immotile cilia syndrome), central nervous system for neuromuscular diseases, and abdominal examination for organomegaly is done.

The aim of the earlier evaluation (although sometimes with investigations) is to establish the following:

1. *Does the child truly have recurrent respiratory tract infections?* Many a times children have episodes of recurrent wheezing which with some nonspecific shadows or unrelated shadows in the chest skiagram gets identified as persistent/recurrent pneumonia. They do not need any specific investigations except possibly a lung function testing.
2. *If it is recurrent respiratory tract infections then whether is it based in upper or lower airways or both?* This simple question might require repeated examinations on different occasions.
3. *Is there any involvement of other organ systems?* Multiple organs might be involved in conditions like cystic fibrosis (malabsorption, meconium ileus), immunodeficiency, and primary ciliary dyskinesia (PCD).
4. *Are the frequency and severity of recurrent LRTI sufficient to warrant additional investigations?* The usual indications for evaluating are: more than three episodes of pneumonia in lifetime or more than two episodes over 1 year. The mnemonic *SPUR* is useful to identify those needing further evaluation and this refers to infections that are *severe, persistent, unusual, or recurrent*.
5. Where is the localization of the disease in the lung(s)—unilobar or multilobar?

Investigations

Routine Investigations

These are done as baseline work-up in a case of persistent pneumonia, before deciding the specific investigation which helps in final diagnosis and treatment.

- **Complete hemogram** A complete blood count is used to assess anemia or polycythemia, abnormal numbers, differential makeup of leukocytes and thrombocytopenia (associated with immunological disorders such as Wiskott-Aldrich syndrome (characterized by recurrent infections and autoimmune disorders). Differential count could reveals lymphopenia (seen in RSV infection, acute stress in sepsis, measles infection, *Legionella pneumophila* infection), granulocytopenia (viral infections, drug induced, HIV infection), and eosinophilia (asthma, parasitic infestations, tropical pulmonary eosinophilia).
- **Chest X-ray** Forms an important basis of diagnosis and classification of infiltrates while defining disease, also helps

in confirming the diagnosis, area involved, suggesting etiology and facilitates follow.

- **Investigations for TB** Tuberculin skin test, gastric aspirate or induced sputum for acid fast bacilli (AFB), etc.

Special Investigations

- **Flexible bronchoscopy** In the patients with unilobar involvement, the first in the diagnostic work-up usually is diagnostic flexible bronchoscopy for likely intraluminal obstructive lesions (endobronchial TB, bronchial adenoma, lipoma, foreign body), structural abnormalities like tracheal bronchus, hypoplastic bronchus, etc. Flexible bronchoscopy is a useful investigation also with multilobar pneumonia to evaluate the airways for clefts, H-TEF.
 - A bronchoalveolar lavage can also be taken which could be helpful in identification of pathogen, lipid laden macrophages in aspiration, and hemosiderin laden macrophages in diffuse alveolar hemorrhage. This also makes therapeutic intervention possible like foreign body extraction or biopsy.
- **Contrast enhanced computed tomography (CECT) chest** CECT chest offers several advantages over chest radiography due to its exquisite demonstration of pulmonary architecture without superimposition of overlying structures. CT allows a better assessment of the lesion than is possible on the plain radiograph as it helps in; defining the consistency of lesion—cystic, solid, vascular, in finding or defining a lesion that is obscured by the mediastinum. High-resolution (HR) CT is more sensitive (could detect abnormalities when the chest radiograph was normal); and reportedly showed greater accuracy in characterizing diseases into interstitial, airway and airspace processes; and gave a more accurate depiction of the extent of disease. It is very helpful in evaluation for extrabronchial obstruction, bronchiectasis, distal intraluminal obstructions, structural lesions like sequestrations, congenital cystic adenomatoid malformation (CCAM), etc. The amount of radiation which goes in a CECT chest is equivalent to approximately 50–200 plain radiographs. This hazard should always be considered before ordering this investigation.
- **Further investigations** The guidance for choosing further investigation for children with multilobar pneumonia is less defined and has to be individualized on case to case basis. Children suspected of aspiration syndromes will need a GER scan/24 hour esophageal pH study for GERD, while those with suspected aspiration from above would need a modified barium swallow or video fluoroscopic swallowing studies. Children with findings suggestive of suppurative lung disease would need detailed investigation for cystic fibrosis (sweat chloride estimation, mutation studies, evidence for any metabolic alkalosis), studies for PCD (ciliary studies, Nasal FeNO) and a primary immunodeficiency work-up (detailed in chapter on primary immunodeficiency) or HIV.
 - Pulmonary function tests help to differentiate restrictive from obstructive diseases and have limited utility like for suspected wheezers or interstitial lung disease (ILDs). Spirometry, lung volumes and diffusion capacity; impulse oscillometry for younger children are the modalities used.
 - Echocardiography might be required to rule out cardiac lesions like congenital heart lesions, vascular slings, abnormally dilated heart chambers, etc. which can lead to persistent or recurrent pneumonias. Lung biopsy sometimes might be required in children with suspected ILDs.

IN A NUTSHELL

1. Persistent or nonresolving pneumonia is defined as the persistence of symptoms and radiographic abnormalities in a child with lower respiratory tract infections for more than a month despite a course of adequate antibiotic therapy.
2. Recurrent pneumonia is defined as at least two distinct episodes of radiologically established pneumonia within the same year or three or more such episodes over anytime period.
3. Infiltrates that recur in a single lobe or segment of the lung may be caused by localized pathology like local airway obstruction—intra/extraluminal, structural abnormalities of airway or lung parenchyma. Multilobar involvement is more often a result of a systemic problem.
4. Besides routine investigations, the child may require a fiberoptic bronchoscopy, CECT chest, pulmonary function tests, and investigations to rule out immunodeficiency, GERD, cystic fibrosis or congenital heart disease.

Chapter 39.25

Interstitial Lung Disease

A Bush

Childhood interstitial lung disease (chILD), sometimes termed as diffuse lung disease (DLD) comprises a rare and disparate group of disorders about which very little is known in any setting, least of all in the developing world. Around 200 different entities have been described under its umbrella, and undoubtedly many more will be found. Pathologically, chILD may result in any or all of filling of the alveolar spaces; and inflammation and fibrosis in the interstitium of the lung and the distal most airways. The barrier between very distal airway disease and the lung disease which is truly confined to the interstitium, is blurred in most classifications.

Why then are these rare and esoteric diseases important to pediatricians in a developing world setting, or general pediatricians in any setting? Firstly, they mimic many pediatric respiratory conditions, and a correct diagnosis will mean that inappropriate treatments are not given, and allow specific therapies to be utilized, which may be dramatically effective in some cases. A diagnosis of a genetic cause of chILD has implications for the extended family. The general pediatrician will have a key role supporting the family and collaborating with the specialist center. Identification of an unusual chILD may mean that a novel environmental agent, specific to a particular region, is implicated, allowing prevention and treatment. This is definitely an area where all pediatricians and all parts of the world need to learn together.

EPIDEMIOLOGY

The data are at best an approximation. Compared with adult ILD prevalence of 60–80/100,000, the estimated prevalence of chILD in the developed world is 0.36/100,000. The most common age of presentation is 0–2 years. There are no reliable developing world data, in part due to the difficulty of establishing the diagnosis. Given the many potential genetic and environmental causes, and the differences in the environments and parental consanguinity across the world, these figures should not be extrapolated uncritically from where they were obtained. However, an unexpected upsurge of cases should trigger a search for a new causative agent.

ETIOLOGY

There are numerous causes of chILD and a discussion of all is beyond the scope of this chapter. It should be noted that overlaps are not uncommon; and more than one histological pattern may be present. In general, classifications report 0 to less than or equal to 2 years and 2–16 years separately, although in fact many conditions are common to both. Many classifications are based solely on lung biopsies, and thus exclude conditions which very appropriately may not come to biopsy.

Etiology in the First 2 Years of Life

- *Diffuse developmental disorders:* A spectrum of alveolar-capillary dysplastic disorders, presenting with neonatal respiratory distress in a term baby, which are usually rapidly fatal.
- *Growth disorders:* The pulmonary hypoplastic syndromes, in which some include bronchopulmonary dysplasia (which is not usually difficult to diagnose).
- *Conditions specific to infancy:* Neuroendocrine cell hyperplasia of infancy (NEHI) usually presents with tachypnea and

hypoxemia; high-resolution computed tomography (HRCT) shows ground glass shadowing in the perihilar regions, middle lobe and lingula. If lung biopsy is performed, it looks normal but if appropriately stained, increased numbers of cells positive for the neuropeptide bombesin are seen. Pulmonary interstitial glycogenosis (PIG) has a similar presentation, HRCT is nonspecific and biopsy shows the interstitium to be widened by glycogen containing (PIG) cells. PIG is unrelated to any glycogen storage disease. It should be noted that PIG and NEHI cells are found during normal lung development, and also in other chILD.

- *Surfactant protein (Sp) gene mutations* *Sp-B* and *Sp-C* are responsible for maintaining alveolar surface tension, *Sp-A* and *Sp-D* being part of the collectin system. chILD is caused by mutations in *Sp-B* and *Sp-C*, in *ABCA3* (responsible for post-translational modification of *Sp*, and thyroid transcription factor-1 (*TTF-1*), a transcription factor for the other three genes; this last may be associated with brain and thyroid disease.
- *Pulmonary alveolar proteinosis:* There are numerous underlying causes in children, including the *Sp* mutations, mutations in the granulocyte-macrophage colony-stimulating factor (GM-CSF) receptor gene, GM-CSF autoantibodies, metabolic diseases such as lysinuric protein intolerance, and immunodeficiency.
- *Disorders of the normal host:* Airway diseases, aspiration (which may coexist with chILD) and hypersensitivity pneumonitis.
- *Disorders of the immunocompromised host:* Which may be the first presentation of the immune deficiency, or occur in a child with known immune compromise.
- *Mimics of chILD* (see later).
- *Unclassifiable:* The biopsy is technically unsatisfactory, or merely shows end-stage fibrosis.

Child Age 2–16 Years

- *Disorders seen in infancy:* May present at this age, especially *Sp* gene mutations (*Sp-C*, *ABCA3* and *TTF-1*); indeed around 25% come into this category.
- *Airway disease:* Follicular bronchiolitis (which may be associated with immunodeficiency), and chronic bronchiolitis negative for NEHI cells.
- *Lymphoproliferative disorders:* Associated with immunodeficiency, e.g., lymphoid interstitial pneumonia (LIP).
- *Miscellaneous:* Diffuse diseases (hemosiderosis, hypersensitivity pneumonitis, sarcoidosis, Langerhans cell histiocytosis and pulmonary alveolar microlithiasis).
- *Mimics of chILD:* chILD complicating systemic disease, vascular disease, other disorders of the normal host.

These groupings are by no means exhaustive in either age range.

PATHOGENESIS

Little is known about the exact pathophysiology in children. *Sp* gene mutations that increase oxidative stress in the endoplasmic reticulum may lead to cell damage. At least some *Sp-C* mutations lead to increased cytotoxicity of viruses, particularly respiratory syncytial virus (RSV); and nearly half such patients present with nonresolving RSV bronchiolitis. There are animal and cellular models, for example GM-CSF autoantibody disease, but as yet they have not delivered clinically relevant data. A little more is known about hypersensitivity pneumonitis. Here an allergen is thought to trigger an exaggerated mixed Type 3/Type 4 immunological response because of a genetic predisposition, leading to a

granulomatous inflammation. If the antigen exposure is chronic and low-grade, then presentation is with a fibrotic picture.

CLINICAL FEATURES

Presentation is nonspecific. In one large series, the most common presenting symptoms and signs were hypoxia, tachypnea, retractions, gastroesophageal reflux (GER), pulmonary hypertension, cough, crackles, wheeze and failure to thrive. Chest auscultation may be normal. The chest radiograph is nonspecifically abnormal, and may reveal diffuse ground glass appearance, or bilateral patchy abnormalities, or may even be normal. Further detailed investigation is essential. Childhood ILD should also be suspected in the following circumstances:

- Positive family history of unexplained respiratory disease
- The term baby with progressive respiratory distress from birth
- The baby with bronchiolitis which fails to resolve as expected
- Iron deficiency anemia when all common causes have been excluded; suspect chronic pulmonary hemorrhage.

Childhood ILD may present with acute onset of respiratory failure; examples are acute pulmonary hemorrhage and acute hypersensitivity pneumonitis, when a big antigen load is inhaled.

DIFFERENTIAL DIAGNOSIS

The nonspecific presentation implies that virtually any subacute or chronic pediatric respiratory condition may mimic chILD. The most likely diagnoses will depend on the patterns of disease in the region.

- *The term baby with progressive respiratory distress:* Consider congenital infections, persistence of the fetal circulation, congenital heart disease, meconium and other aspiration syndromes, primary ciliary dyskinesia, pulmonary hypoplastic syndromes, and severe immunodeficiency.
- *The baby with nonresolving bronchiolitis:* Infection with adenovirus or other causes of obliterative bronchiolitis; immunodeficiency including HIV and cystic fibrosis.
- *Pulmonary hemorrhagic syndromes:* Congenital heart disease, coagulopathy.
- *Acute onset of breathlessness* without wheeze is most usually due to acute asthma, but remember the acutely presenting chILDs.

APPROACH TO DIAGNOSIS

These children require a detailed evaluation. The tempo of the approach depends on the degree of illness of the child, and is a matter of judgment. The availability of tests is also a factor; if, for example, *Sp* gene mutation and other testing is not available, it may be justifiable to go on to blind treatment trials. In a child who is stable in low-flow oxygen, it may well be justified to await the results of blood tests, whereas in a rapidly deteriorating child, urgent lung biopsy or empirical treatment (later) may be the correct approach.

If chILD is a possible diagnosis, the next step is HRCT scanning. HRCT should only be performed by an experienced

pediatric radiologist with due care to minimize radiation exposure and maximize image quality. Indications for HRCT are as follows:

- To confirm the presence of chILD, or conversely, reveal an unexpected and different pathology.
- Occasionally, a specific diagnosis can be made (e.g., Langerhans cell histiocytosis, hypersensitivity pneumonitis) or a specific pattern identified (e.g., the cobblestone appearance of pulmonary alveolar proteinosis) but usually the pattern is either suggestive but not necessarily diagnostic (e.g., NEHI) or more usually, non-specific.
- If the child does come to a diagnostic lung biopsy, then the HRCT is used to guide the optimal site of the biopsy.

The next step is to score the severity of the disease (**Table 1**). In an older child, lung function testing may reveal a restrictive pattern of spirometry, reduced lung volumes, and usually reduced carbon monoxide transfer (DLCO). If DLCO is elevated, alveolar hemorrhage should be suspected. The most widely used severity score involves measuring the child's saturations overnight, and on exercise, and also performing an echocardiogram. This last test is not merely to document whether pulmonary hypertension is present, but also to exclude cardiac mimics of chILD, such as any condition causing left atrial hypertension. The choice of blood tests depends on the clinical context; options are listed in **Table 2**. It would clearly be out of context to look for surfactant protein gene mutations in a boy with a history and HRCT classical for hypersensitivity pneumonitis, or look for positive precipitins in a term baby ventilated from birth; good clinical judgment is mandatory.

At this point it is important to reach a decision as to whether bronchoscopy or lung biopsy is indicated. As with all tests, the key question is, what action may result as consequence? So in a baby who is stable and thriving in a small amount of oxygen, with HRCT strongly suggestive of NEHI, it is likely no treatment will be offered irrespective of the results of invasive tests, and so these should not be performed. If invasive testing is being considered, then this should be planned to minimize the number of general anesthetics for the child. Indications for bronchoscopy are:

- Suspected opportunistic infection in a child known to have or with suspected immunodeficiency.
- Confirm pulmonary hemorrhage (hemosiderin laden macrophages) or pulmonary alveolar proteinosis (milky bronchoalveolar lavage [BAL] fluid).

However, for the most part the findings are nondiagnostic, and for most chILD, bronchoscopy is legitimately performed at the time of lung biopsy, but not as a separate procedure.

The ultimate diagnostic procedure is lung biopsy, usually video-assisted thoracoscopic surgery (VATS) or via a mini-thoracotomy. Transbronchial biopsy is not recommended in the context of chILD; the samples are usually too small, unless a very specific pattern such as pulmonary alveolar microlithiasis is present, and there is a definite risk of hemorrhage and pneumothorax. It is essential that there is discussion with the surgeon about the site of biopsy, and also that the tissue is handled correctly after the biopsy, so that electron microscopy and all necessary stains can be performed. It is often wise to get more than one opinion on pathology in these rare conditions.

Table 1 Illness severity score used in childhood interstitial lung disease (chILD)

Score	Symptoms	Hypoxemia < 90% sleep or exercise	Hypoxemia < 90% rest	Pulmonary hypertension
1	No	No	No	No
2	Yes	No	No	No
3	Yes	Yes	No	No
4	Yes	Yes	Yes	No
5	Yes	Yes	Yes	Yes

Table 2 Blood tests to be considered in the work-up of interstitial lung disease (ILD) in children. Not all should be performed in all cases

Test	Disease	Comment
<i>Sp-B, Sp-C, ABCA3, TTF-1</i> genes	Surfactant protein deficiency	Indicated in most children with ILD, unless there are extrapulmonary features or another obvious diagnosis
Angiotensin converting enzyme	Sarcoidosis	Especially if extrapulmonary features
Antineutrophil cytoplasmic antibodies	Wegener granuloma, other vasculitides	Especially if upper airway disease, renal disease, pulmonary hemorrhage
Avian, <i>Micropolyspora faeni</i> precipitins	Allergic alveolitis	CT scan may be suggestive of this diagnosis
Viral and mycoplasma serology	Obliterative bronchiolitis	Not a true ILD, but may be confused on CT
Immune work-up including HIV	Lymphoproliferative syndromes, including follicular bronchiolitis	Also perform if ILD in fact proves to be an opportunistic infection
Autoantibody studies	Systemic lupus, rheumatoid diseases, scleroderma, and other collagen vascular disease	Especially if extrapulmonary features and renal disease
GM-CSF studies (serum autoantibody, receptor genetic studies)	Some of the variants of pulmonary alveolar proteinosis	Adult type with response to GM-CSF has been described in children

Abbreviations: CT, computed tomography; HIV, human immunodeficiency virus; *Sp*, surfactant protein; *TTF*, thyroid transcription factor; GM-CSF, granulocyte-macrophage colony-stimulating factor.

MANAGEMENT

General Considerations

There are no randomized controlled trials of treatment in chILD. If the child is hypoxic, then oxygen should be given; this is probably the only noncontroversial statement to make. All immunizations including influenza should be given unless contraindicated, and the child protected from environmental tobacco smoke as well as other pollutants. Nutrition needs to be optimized; a number of chILD patients have swallowing and feeding issues, for which early referral is essential.

Specific Therapy

Childhood ILD for whom No Treatment is Available

One of the reasons for pursuing a specific diagnosis is that there are conditions in which steroids are ineffective (e.g., NEHI and PIG) or actually harmful (opportunistic infections).

Treatments for Childhood ILD
